The nature of the deposition processes involved determines the limited height of surface-micromachined features (Hal Jerman, from EG&G's IC Sensors, called them *2.5D features*[90]). Specifically, low-pressure CVD (LPCVD) polycrystalline silicon (polysilicon) films generally are only a few micrometers high (low z), in contrast with wet bulk micromachining where only the wafer thickness limits the feature height. A low z may be a drawback for some mechanical sensors. For example, it would be difficult to fashion a large inertial mass for an accelerometer from thin polysilicon plates (a commercial surface-micromachined accelerometer, the ADLX05, has an inertial mass of only 0.3 μg). Not only do many parameters in the LPCVD polysilicon process need to be controlled very precisely, but subsequent high-temperature annealing (e.g., at temperatures of about 580°C) also is needed to transform the deposited amorphous silicon into polysilicon—the main structural material in surface micromachining. Even with the best possible process control, polysilicon has some material disadvantages over single-crystal Si. For example, it generates a somewhat smaller yield strength (values between 2 and 10 times smaller have been reported)[91,92] and has a lower piezoresistivity.[93] Moreover, because a single polysilicon grain diameter may constitute a significant fraction of the thickness of a mechanical member, the effective Young's modulus may exhibit variability from sensor to sensor.[94] An important

positive attribute of polysilicon is that its material properties, although somewhat inferior to single crystal, are far superior compared with those of metal films, and, most of all, because they are isotropic, design is rendered dramatically simpler than with single-crystal material. Dimensional uncertainties may be of greater concern than material issues. Although absolute dimensional tolerances obtained with lithography techniques can be submicrometer, relative tolerances are poor, perhaps 1% on the length of a 100-μm-long feature. The situation becomes critical with yet smaller feature sizes (see Figures 6.3 and 6.4). Although the relatively coarse dimensional control in the microdomain is not specific to surface micromachining, there is no crystallography to rely on for improved dimensional control, as in the case of wet bulk micromachining. Moreover, because the mechanical members in surface micromachining tend to be smaller, more postfabrication adjustment of the features is required to achieve reproducible characteristics. Finally, the wet process for releasing structural elements from a substrate tends to cause sticking of suspended structures to the substrate, or *stiction*, introducing another disadvantage associated with surface micromachining.

Some of the problems associated with surface micromachining mentioned above have been resolved by process modifications and/or alternative designs, and the technique has rapidly gained commercial interest, mainly because it is the most IC-compatible micromachining process developed to date. Moreover, in the past 10–15 years, processes such as silicon on insulator (SOI) (1),[95] hinged polysilicon (2),[96] Keller's molded milliscale polysilicon (3),[97] thick (10 μm and beyond) polysilicon (4),[98] LIGA and LIGA-like processes (5), and porous polysilicon (6) have further enriched the surface micromachining arsenal. Some preliminary remarks on each of these surface micromachining extensions follow.

1. Silicon crystalline features, anywhere between fractions of a micrometer to 100 μm high, can be readily obtained by surface micromachining of the epi silicon or fusion-bonded silicon layer of SOI wafers.[99] Structural elements made from these single-crystalline Si layers result in more reproducible and reliable sensors. SOI or epi-micromachining combines the best features of surface micromachining (i.e., IC compatibility and freedom in *x,y* shapes) with the best features of bulk micromachining (superior single-crystal Si properties). Moreover, SOI surface micromachining frequently involves fewer process steps and offers better control over the thickness of crucial building blocks. Given the poor reproducibility of mechanical properties and generally poor electronic characteristics of polysilicon films, SOI machining may surpass the polysilicon technology for fabricating high performance devices.
2. The fabrication of polysilicon planar structures for subsequent vertical assembly by mechanical rotation around micromachined hinges, introduced by Pister et al.[96] in 1991, dramatically increases the plethora of designs feasible with polysilicon. Today, erecting these polysilicon structures with the probes of an electrical probe station, or occasionally assembly by chance in an HF etch or DI water rinse,[100] represents a too-complicated or unreliable postrelease assembly method for commercial acceptance, and alternative self-assembly means are an urgent need.
3. While at the University of California, Berkeley, Keller, [97] now CEO of MEMS Precision Instruments (http://www.memspi.com), introduced a combination of surface micromachining and LIGA-like molding processes in the HEXSIL (HEXagonal honeycomb polySILicon) process, a technology enabling the fabrication of tall 3D microstructures without postrelease assembly. Using CVD processes, generally only thin films (≈2–5 μm) can be deposited on flat surfaces. If, however, these surfaces are the opposing faces of deep narrow trenches, the growing films will merge to form solid beams. Releasing of such polysilicon structures and the incorporation of electroplating steps expand the surface micromachining bandwidth in terms of choice of materials and accessible feature heights. In this fashion, high-aspect-ratio structures normally associated with LIGA can now also be made of CVD polysilicon.

4. Applying classical LPCVD to obtain polysilicon deposition is a slow process. For example, a layer of 10 µm typically requires a deposition time of 10 h. Consequently, most micromachined structures are based on layer thicknesses in the 2–5-µm range. Based on dichlorosilane (SiH_2Cl_2) chemistry, Lange et al.[98] developed a CVD process in a vertical epitaxy batch reactor with deposition rates as high as 0.55 µm/min at 1000°C. The process yields acceptable deposition times for thicknesses in the 10-µm range. The highly columnar polysilicon films are deposited on sacrificial SiO_2 layers and exhibit low internal tensile stress, making them suitable for surface micromachining.
5. Thick layers of polyimide and other new UV resists have also received a lot of attention as important new extensions of surface micromachining. Because of their transparency to exposing UV light, they can be transformed into tall surface structures with LIGA-like high-aspect ratios. They may also be electroplated and micromolded in any plastic of choice.
6. In Chapter 4 we discussed the transformation of single-crystal Si into a porous material with porosity and pore sizes determined by the current density, type, and concentration of the dopant, as well as the hydrofluoric acid concentration. A transition from pore formation to electropolishing is reached by increasing the current density and/or by decreasing the hydrofluoric acid concentration.[101,102] Porous silicon can also be formed under similar conditions from LPCVD polysilicon.[103]

In this section, we first review the main surface micromachining process steps and clarify the extensions of the surface micromachining technique listed above. Next we compare surface micromachining with bulk micromachining. In the surface micromachining examples at the end of this section, we first look at a lateral resonator. Resonators have found an important industrial application in accelerometers and gyros introduced by Analog Devices. The second example involves Texas Instruments' (TI's) Digital Micromirror Device™ (DMD), a chip now found in many projectors.

Historical Note

The first example of a surface micromachine for an electromechanical application consisted of an underetched metal cantilever beam for a resonant gate transistor made by Nathanson in 1967.[104] By 1970, a first suggestion for a magnetically actuated metallic micromotor emerged.[105] Because of fatigue problems, metals are not typically used as mechanical components. The surface micromachining method as we know it today was first demonstrated by Howe and Muller in the early 1980s and relied on polysilicon as the structural material.[106] These pioneers, and the late Guckel,[107] an early contributor to the field, produced free-standing LPCVD polysilicon structures by removing the oxide layers on which the polysilicon features were formed. Howe's first device consisted of a resonator designed to measure the change of mass on adsorption of chemicals from the surrounding air. However, this gas sensor does not necessarily represent a good application of a surface-micromachined electrostatic structure because humidity and dust foul the thin air gap of such a microstructure in a minimal amount of time. Later, mechanical structures, especially hermetically sealed mechanical devices, provided proof that the IC revolution could be extended to electromechanical systems.[104] In these structures, the height (z-direction) typically is limited to less than 10 µm, ergo the name *surface micromachining*.

Gabriel et al.[108] in 1989 made the first survey of possible applications of polysilicon surface micromachining. Microscale movable mechanical pin joints, springs, gears, cranks, sliders, sealed cavities, and many other mechanical and optical components have been demonstrated in the laboratory.[109,110] For awhile, in the early 1990s, it seemed that every MEMS group in the United States was trying to make surface-micromachined micromotors of the type shown in Figure 7.65.

Micromotors may lack practical use as of yet, but, just as the ion-sensitive field effect transistor (ISFET) galvanized the chemical sensor community in trying out new chemical sensing approaches, micromotors energized the micromachining research community to fervently explore miniaturization of a wide variety of mechanical sensors and actuators. Micromotors

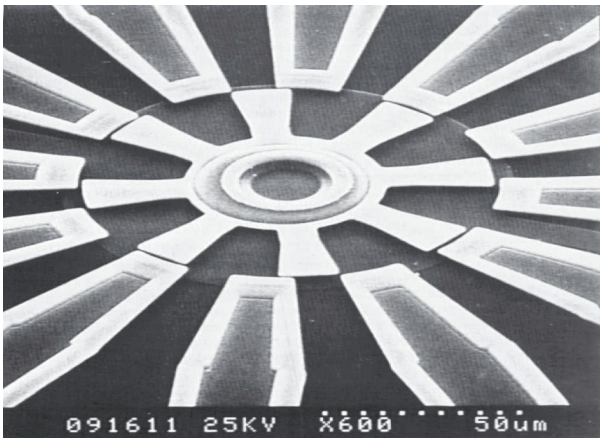

FIGURE 7.65 Surface micromachined motor. (M. Mehregany, 1990. PhD dissertation, MIT.)

also brought about the christening of the micromachining field into MEMS. In 1991, Analog Devices (Norwood, MA) announced the first commercial product based on surface micromachining, namely, the ADXL-50, a 50-g accelerometer for activating air-bag deployment.[111] The ADXL-50 chip is shown in Figure 7.66a. The SEM inset in this figure depicts the polysilicon micromachined mechanical structure. By 2001, Analog Devices was making 2 million surface-micromachined accelerometers a month (at $4 per device in volume). A second commercial success for surface micromachining was based on Texas Instruments' Digital Mirror Device™ (DMD). This surface-micromachined movable aluminum mirror is a digital light switch that precisely controls a light source for projection displays and hard copy applications.[112] A schematic of the tilting mirrors in a DMD chip is shown in Figure 7.66b. The commercial acceptance of this second application confirmed the staying power of surface micromachining.

Surface micromachining is also an established manufacturing process at Cronos (Research Triangle Park, NC; now a JDS Uniphase Company) and Robert Bosch (Stuttgart, Germany).

Surface Micromachining Processes

Basic Process Sequence—Overview

A first simple surface micromachining process sequence for the creation of a freestanding polysilicon anchor was illustrated in Figure 7.1. We will now detail typical surface micromachining fabrication steps using the DARPA-sponsored multiuser MEMS process (MUMPs®). The baseline process of the MUMPs program is a three-layer polysilicon (Poly 0, Poly 1, and Poly 2) surface micromachining process ("polysurf") known as *PolyMUMPs*. The process includes eight lithography levels and seven physical layers. A physical layer represents a layer of material deposited during the fabrication process and is usually represented in mixed-case letters. A lithographic level is used to pattern a physical layer and is always represented in CAPITAL letters. The physical layers illustrated in Figure 7.67 are two mechanical and one electrical layer of polysilicon,

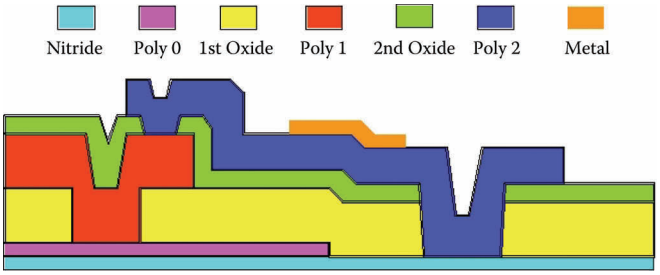

FIGURE 7.67 The seven physical: two mechanical (Poly 1 and Poly 2) and one electrical layer (Poly 0) of polysilicon, two sacrificial oxide layers, one metal conduction and one electrical isolation nitride layer.

two sacrificial oxide layers, one metal conduction, and one electrical isolation nitride layer (also buffer or isolation layer). A sacrificial oxide layer of fast etching silicon dioxide is used to define the separation between mechanical layers and between mechanical layer and the substrate. The nitride layer is used for electrical isolation between substrate and electrical surface layers. The Poly 0 layer is the electrical polylayer used as a ground plane or for electrode formation below the first mechanical layer (Poly 1). The first sacrificial oxide layer will establish a gap between Poly 1 and substrate/nitride after release etching. The second sacrificial oxide layer will make for the gap between a second mechanical layer (Poly 2) and the first mechanical polysilicon (Poly 1) after release. For sacrificial oxide one often uses phosphosilicate glass (PSG), a phosphorous-containing silicon dioxide layer generated by CVD and used for its fast etching properties. A metal layer provides electrical connection to the package.

The eight lithography levels are:

1. POLY ZERO: Defines the polysilicon zero features (Poly 0)
2. ANCHOR 1: Opens points of contact between first polysilicon and substrate (nitride or Poly 0)
3. DIMPLE: Generates "bumps" in undersurface of Poly 1 to minimize stiction
4. POLY 1: Defines first polysilicon features
5. POLY 1-POLY 2-VIA: Opens points of contact between first and second polysilicon
6. ANCHOR 2: Opens points of contact between second polysilicon and substrate/nitride
7. POLY 2: Defines second polysilicon features
8. METAL: Defines location of metal features

Remarks:

- Dimples are small, shallow features on the underside of the lower polysilicon layer to minimize the area of contact between the polysilicon and the substrate.
- A lithography level may or may not correspond with a physical layer: e.g., Poly 1 = POLY 1, but second oxide is patterned by both ANCHOR 2 and POLY 1-POLY 2-VIA.
- Release is the last step of the process where the sacrificial layers are removed by submersion into HF.
- Stiction is the sticking effect between polysilicon and the substrate that occurs during the removal of the sacrificial oxide. Many attempts to limit stiction, including dimples, special release chemicals, and processes, are tried, some successfully (see below).

Since its inception in December 1992, the multiuser MEMS process (MUMPs) quickly became a well-established, commercial program that provides customers with cost-effective access to surface micromachining for prototyping activities. It caused many researchers to focus on design and testing of new MEMS concepts rather than building yet another clean room. MUMPs was approaching its 40th run in December 2000. Another source for surface micromachining prototyping is at Sandia, with the ultraplanar multilevel MEMS technology (SUMMiT), e.g., SUMMiT-IV and SUMMiT-V (http://www.mems.sandia.gov/tech-info/summit-v.html) introduced in 1998 – (four and five polysilicon level processes). SUMMiT is reviewed further below.

Process Steps for Making a Polysilicon Micromotor

The following is a description of the PolyMUMPs process applied to the fabrication of a surface-micromachined electrostatic micromotor. A blanket n^+ diffusion of the silicon substrate (e.g., with $POCl_3$), defining a ground plane, often outlines the very first step in surface micromachining (Step I in Figure 7.68), followed by a passivation step of the substrate, for example, with 0.15-μm-thick LPCVD low stress nitride (sometimes on top of a 0.5-μm

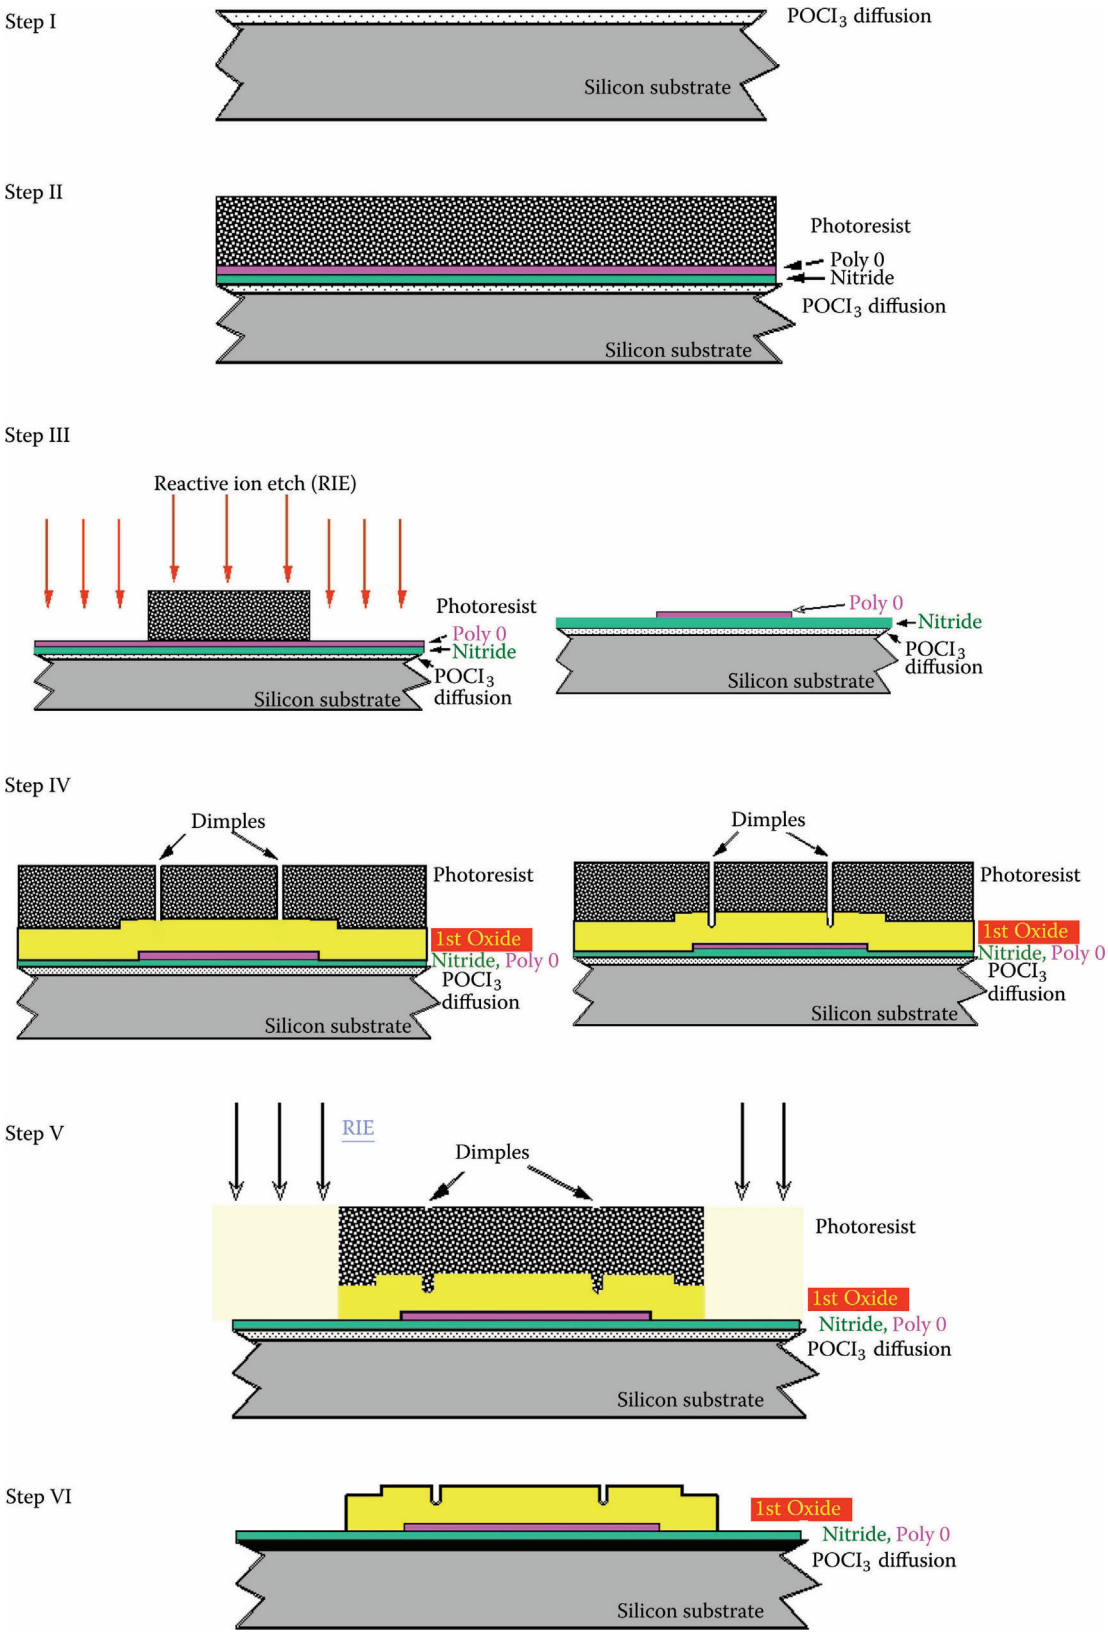

FIGURE 7.68 The PolyMUMPs process applied to the fabrication of a surface-micromachined micromotor.

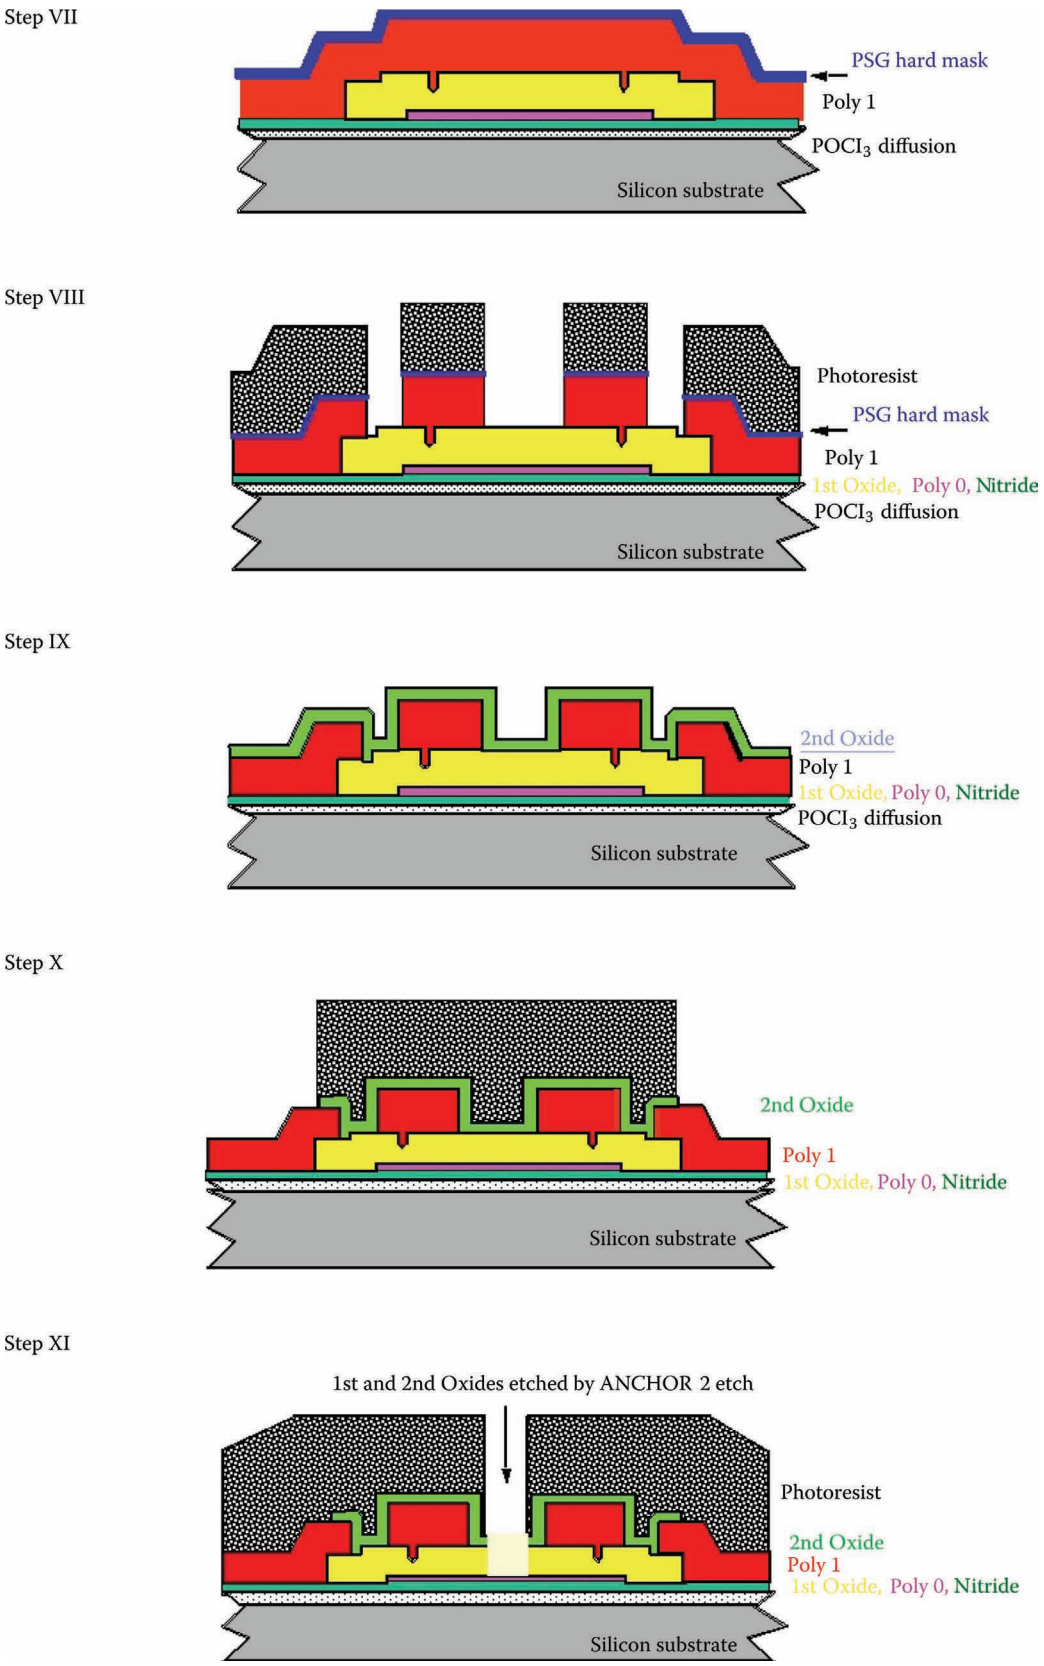

FIGURE 7.68 (*Continued*)

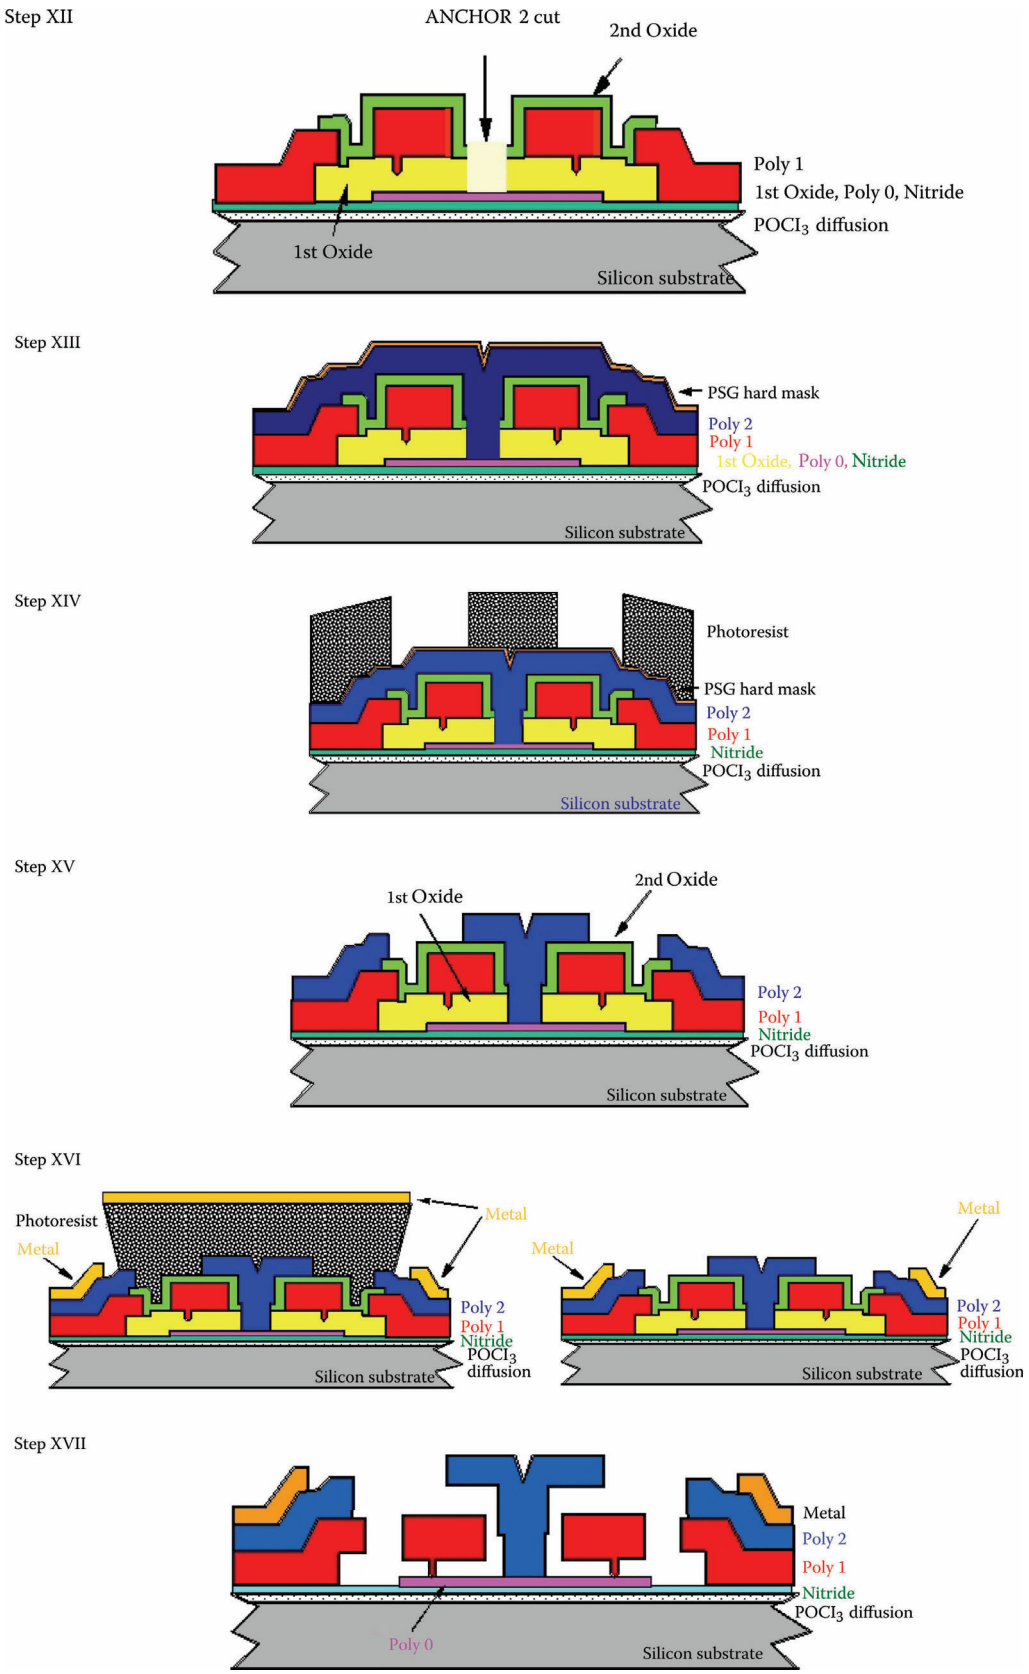

FIGURE 7.68 (*Continued*)

thermal oxide). This is followed by a blanket deposition of polysilicon (Poly 0), and the wafer is spin-coated with a photoresist for patterning (Step II). The photoresist is exposed using the first mask level (POLY 0), and the image is developed. The unwanted polysilicon is removed by RIE etching, transferring the POLY 0 pattern onto the wafer, and the photoresist is stripped in a solvent (Step III).

Step IV involves the deposition of the first sacrificial oxide (PSG) layer (2.0 μm thick) on the wafer by low temperature CVD. The wafer is coated with photoresist, and a second mask level (DIMPLE) is exposed and developed. The dimples are etched into the first oxide by a combination of RIE and buffered oxide etch (BOE) etching. In Step V, the dimple photoresist is stripped, and a new layer of photoresist is applied for the third mask level (ANCHOR 1). The first oxide is patterned and then processed with RIE to remove the oxide from the anchor area. The photoresist is stripped in a solvent bath (Step VI). The wafer is now ready for Poly 1 processing. The ANCHOR 1 level defines where Poly 1 will be attached to the substrate, and the thickness of the first oxide defines how far above the substrate (either nitride or Poly 0) Poly 1 will sit after release. After the wafer is cleaned, the first polysilicon layer (Poly 1) is deposited using LPCVD. An additional thin PSG layer is deposited on top of the Poly 1, and the wafer is annealed at high temperature to reduce the residual stress and dope the Poly 1 (Step VII). We will come back to this stress reduction matter and doping of a polysilicon layer sandwiched between two PSG further below. The wafer is now again coated with photoresist, and the fourth mask (POLY 1) is patterned. The wafer is RIE etched, stopping on the first oxide, using both the photoresist and thin PSG (top) layer as masks for the Poly 1 layer (Step VII). In Step IX, the second sacrificial oxide layer (0.75 μm) is deposited by low temperature CVD, conformally coating the topography on the wafer and defining the separation of the first polylayer from the second polysilicon. The wafer is coated with photoresist, and the fifth mask (POLY 1-POLY 2-VIA) is patterned and RIE etched. This defines the contact regions between Poly 1 and Poly 2 (Step X). The photoresist is stripped, and the wafer is recoated. The sixth mask (ANCHOR 2) is patterned, and both first oxide and second oxide are etched in one step (Step XI). This defines the region where Poly 2 will contact the substrate (either nitride or Poly 0). The photoresist is stripped, and the wafer is ready for the Poly 2 deposition (Step XII). The second polysilicon layer is deposited followed by a thin PSG layer. The structure is annealed to reduce the Poly 2 stress and to dope the Poly 2. Because the CVD film is conformal, all the holes will be filled, to varying degrees, with Poly 2 (Step XIII). The wafer is coated with photoresist, and the seventh mask (POLY 2) is patterned. Both the photoresist and thin PSG (hard mask) will mask the RIE etch (Step XIV). After the Poly 2 layer is etched and the wafer is stripped, the basic mechanical structure is complete (Step XV). A lift-off template is used to deposit the metal layer on the wafer. Photoresist is patterned using the eighth (and ninth) masks (METAL), and the metal is deposited, adhering to the Poly 2, where exposed, and breaking continuity as it goes over the photoresist step (lift-off profile), and the photoresist and remnant metal are removed by rinsing in solvent. The structure is now completed and ready for releasing (Step XVI). A 2.5-min soak in straight 49% HF removes all the sacrificial oxide layers and releases the moveable mechanical parts. The rotor is now free to spin about the center pin, and the stator poles are fixed and electrically active (Step XVII). The chips are rinsed in DI water, followed by soaking in isopropyl alcohol and baking in a convection oven.

Process Steps Details

Pattern Transfer to Buffer/Isolation Layer Suppose the buffer/isolation passivation layer itself needs to be patterned, perhaps to make a metal contact pad to the underlying Si substrate. Then, the appropriate fabrication step is a pattern transfer to the thin isolation film as shown in Figure 7.69. In this case, the isolation layer is a 1-μm-thick thermal SiO_2 film, and we illustrate a wet pattern transfer with a 1-μm resist layer. Typically, an isotropic etch such as buffered HF, also called a *buffered oxide etch* [e.g., BHF or BOE (5:1), which is five parts NH_4F and one part concentrated HF], is used (unbuffered HF attacks the photoresist). This solution etches SiO_2 at a rate of 100 nm/min, and the creation of the opening to the underlying substrate takes about 10 min. The etch progress may be monitored optically (color

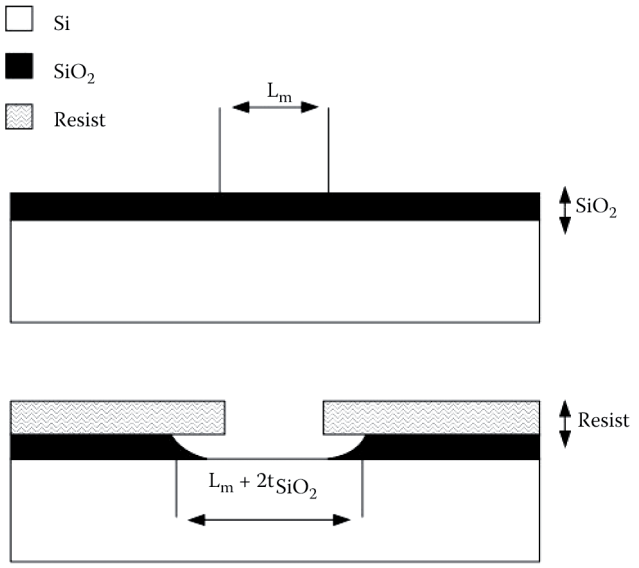

FIGURE 7.69 Wet etch pattern transfer to a thin thermal SiO_2 film for the fabrication of a contact pad to the Si substrate.

change) or by observing the hydrophobic/hydrophilic behavior[113] of the etched layer. With a resist opening, L_m, the undercut typically measures the same thickness as the oxide thickness, t_{SiO2}. In other words, the contact pad will have a size of $L_m + 2t_{SiO2}$. The undercut worsens with loss of photoresist adhesion during etching. Using an adhesion promoter such as HMDS (hexamethyldisilazane) proves useful in such cases. A new bake after 5 min of etching is a good procedure to maintain the resist integrity. After the isotropic etch, the resist is stripped in a piranha etch bath. This strong oxidizer grows about 3 nm of oxide back in the cleared window. To remove the oxide resulting from the piranha, a dip in diluted BHF suffices. After cleaning and drying, the substrate is ready for contact metal and base material deposition. Applying a dry etch (e.g., CF_4-H_2 plasma) to open up the window in the oxide would eliminate undercutting of the resist but requires a longer setup time. With an LPCVD low-stress nitride or a nitride on top of a thermal SiO_2, an often-used combination for etching the buffer/isolation layer is a dry etch (e.g., SF_6 plasma) followed by 5:1 BHF.[114]

Deposition of Structural Material For the best step coverage of a structural material over underlying topography, chemical vapor deposition (CVD) is preferred. If a physical deposition method must be used, sputtering is preferred over evaporation (line-of-sight deposition technique), which leads to the poorest step coverage. In the latter case, edge taper could be introduced advantageously.

The most widely used structural material in surface micromachining is polysilicon (poly-Si or simply "poly"). Polysilicon is deposited by low pressure (25–150 Pa) chemical vapor deposition (LPCVD) in a furnace (a polychamber) at about 600°C. The undoped material is usually deposited from pure silane, which thermally decomposes according to Reaction 7.2. Typical process conditions may consist of a temperature of 605°C, a pressure of 550 mTorr (73 Pa), and a silane flow rate of 125 sccm. Under those conditions, a normal deposition rate is 100 Å/min. To deposit a 1-μm film will take about 90 min. Sometimes the silane is diluted by 70–80% nitrogen. The silicon is deposited at temperatures ranging from 570–580°C for fine-grained polysilicon to 620–650°C for coarse-grained polysilicon. The characteristics of these two types of polysilicon materials were compared above (see Table 7.20). Furnace annealing of the polysilicon film at 1050°C in nitrogen for 1 h is commonly used to reduce stress stemming from thermal expansion coefficient mismatch and nucleation and growth of the polysilicon film. Low-temperature deposition of silicon at 320°C in PECVD and at ~350°C in sputter deposition is also possible, although this results in amorphous films.

To make parts of the microstructure conductive, dopants can be introduced in the polysilicon film by adding dopant gases to the silane gas stream, by drive-in from a solid dopant source, or by ion implantation. When doping from the gas phase, the dopant can be readily controlled in the range of 10^{19}–$10^{21}/cm^3$. Polysilicon deposition rates, in the case of gas-phase doping (in situ doping), may be significantly impacted. For example, decreases in polysilicon deposition rate by as much as a factor of 25 have been reported in phosphine and arsine doping. The effect is associated with the poisoning of reaction sites by phosphine and arsine.[115] The lower deposition rate of in situ phosphine doping can be mitigated by reducing the ratio of phosphine to silane flow by one third.[116] With the latter flow regime, deposition at 585°C (for a 2-μm-thick film), followed by 900°C rapid thermal annealing for 7 min, results in a polysilicon with low residual stress, negligible

stress gradient, and low resistivity.[116,117] In situ boron doping, in contrast to arsine and phosphine doping, accelerates the polysilicon deposition rate through an enhancement of silane adsorption induced by the boron presence.[118] Film thickness uniformity for doped films typically is less than 1%, and sheet resistance uniformity is less than 2%. Alternatively, polysilicon may be doped from PSG films sandwiching the undoped polysilicon film as we alluded to when discussing Steps VII and XIII in Figure 7.68. By annealing such a PSG sandwich at 1050°C in N_2 for 1 h, the polysilicon is symmetrically doped by diffusion of dopant from the top and the bottom layers of PSG. Symmetric doping results in a polysilicon film with a moderate compressive stress. The resulting uniform grain texture avoids gradients in the residual stress, which would cause bending moments, warping microstructures on release. Finally, ion implantation of undoped polysilicon, followed by high-temperature dopant drive-in, also leads to conductive polysilicon. This polysilicon has a moderate tensile stress, with a strain gradient that causes cantilevers to deflect toward the substrate.[119] The polysilicon is now ready for patterning by RIE in, e.g., CF_4-O_2 plasma.

Although the mechanical properties are less understood than for single-crystal Si, microstructures based on polysilicon as a mechanical member have been commercialized swiftly.[111,119]

Surface micromachining of thin single-crystalline Si layers in epitaxial layers or fusion-bonded and etched back Si, as well as surface micromachining involving resists such as polyimides, is also very common and is discussed separately below. Other structural materials used in surface micromachining include aluminum, SiO_2, silicon nitride, silicon oxynitride, diamond, SiC, sputtered silicon, GaAs, tungsten, α-Si:H, Ni, W, Al, etc. More information on the material properties of these materials in thin film form is provided in the section on Surface Micromachining Modifications and in Volume III, Chapter 5 (Selected Materials and Processes for MEMS and NEMS).

Base Layer (also Spacer or Sacrificial Layer) Deposition A thin LPCVD phosphosilicate glass (PSG) layer (e.g., 2 μm thick) is a preferred base, spacer, or sacrificial layer material. Adding phosphorous to SiO_2 to produce PSG enhances the etch rate in HF.[120,121] Other advantages to using doped SiO_2 include its utility as a solid-state diffusion dopant source to make subsequent polysilicon layers electrically conductive and helping to control window taper (planarization). As deposited phosphosilicate displays a nonuniform etch rate in HF and must be densified, typically carried out in a furnace at 950°C for 30 min to 1 h in a wet oxygen ambient. The etch rate in BHF can be used as the measure of the densification quality. The base window etching stops at the buffer isolation layer, often a Si_3N_4/SiO_2 layer that also forms the permanent passivation of the device. Windows in the base layer are used to make anchors onto the buffer/isolation layer for mechanical structures.

The edges of the etched windows in the base may need to be tapered to minimize coverage problems with subsequent structural layers, especially if these layers are deposited with a line-of-sight deposition technique. An edge taper is introduced through an optimization of the plasma etch conditions (see Chapter 3), through the introduction of a gradient of the etch rate, or by reflow of the etched spacer. Viscous flow at higher temperature smoothes the edge taper. The ability of PSG to undergo viscous deformation at a given temperature primarily is a function of the phosphorous content in the glass; reflow profiles get progressively smoother the higher the phosphorous concentration—reflecting the corresponding enhancement in viscous flow.[122] Doped oxides used as diffusion sources contain 5–15 wt% of the dopant. Doped oxides for passivation or interlevel insulation contain 2–8 wt% phosphorus to prevent the diffusion of ionic impurities to the device. PSG used for the reflow process contains 6–8 wt% phosphorus and reflows at temperatures between 950 and 1100°C. Oxides with lower phosphorus concentrations will not soften and flow, but higher phosphorus concentrations can give rise to deleterious effects because phosphorus can react with atmospheric moisture to form phosphoric acid, which can consequently corrode the aluminum metallization. Addition of boron to PSG further reduces the reflow temperature without exacerbating this corrosion problem [undoped SiO_2 is often used above

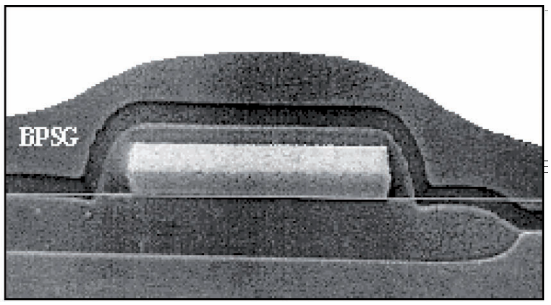

FIGURE 7.70 Edge taper reflow of BPSG layer.

and below PSG or borophosphosilicate glass (BPSG) to prevent corrosion of Al]. BPSG typically contains 4–6 wt% P and 1–4 wt% B and reflows at 800°C. In Figure 7.70 we depict the reflow of a BPSG spacer after patterning in a dry etch; the SEM shows the BPSG oxide layer after an 800°C reflow step, showing smooth topography over the step.

Ion implantation of PSG creates a rapidly etching, damaged PSG layer.[123–125] The steady-state taper is a function of the etch rate in PSG etchants (e.g., BHF).

Selective Etching of Spacer Layer

Selective Etching To create movable micromachines, the microstructures must be freed from the spacer layers. The challenge in freeing microstructures by undercutting is evident from Figure 7.71. After patterning the polysilicon by RIE in, e.g., SF_6 plasma, it is immersed in an HF solution to remove the underlying sacrificial layer, releasing the structure from the substrate. The release step is the source of several technological woes. Commonly, a layer of sacrificial phosphosilicate glass, between 1 and 2000 μm long and 0.1–5 μm thick, is etched in concentrated, dilute, or buffered HF (BHF = BOE). The spacer etch rate, R_s, should be faster than the attack on the microstructural element, R_m, and that of the insulator layer, R_i. For this type of complete undercutting, only wet etchants can be used. Etching narrow gaps and undercutting wide areas with BHF can take hours. The removal rate is this slow because the sacrificial layer is only a few micrometers thick, and the reaction becomes quickly diffusion limited. As a consequence, the depth of sacrificial layer dissolved under the structure will increase slowly with the etching time as $d_{\text{release}} \propto \sqrt{t_{\text{etch}}}$ Simply said, releasing a structure twice as wide will take four times more time. However, if the etching lasts too long, the chemical may start attacking the device structural material, too. Detailed studies on the etching mechanism of oxide spacer layers were undertaken by Monk et al.[126,127] They found that the etching reaction shifts from kinetic controlled to diffusion controlled as the etch channel becomes longer. This affects mainly large-area structures because diffusion limitations were observed only after approximately 200 μm of channel etching or 15 min in concentrated HF. Eaton and Smith[128] developed a release etch model that is an extension of the work done by Monk et al.[126,127] and Liu et al.[129] To shorten the etch time, extra apertures in the microstructures are sometimes provided for additional access to the spacer layer (see Figure 7.72).

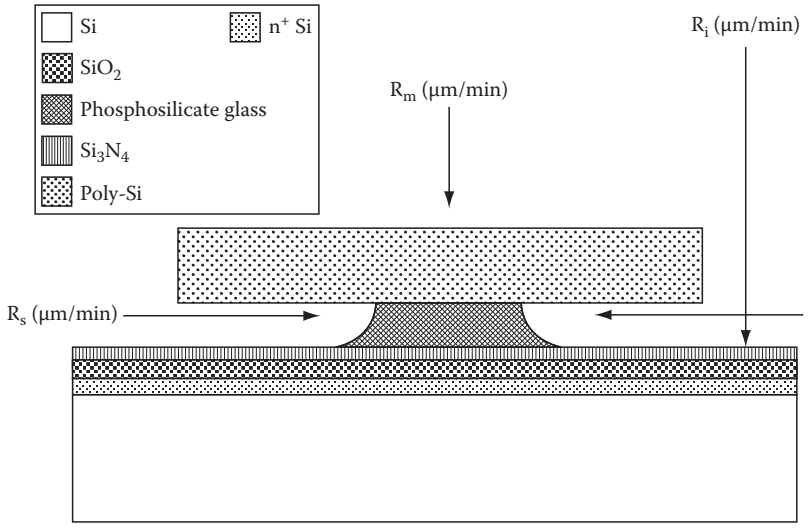

FIGURE 7.71 Selective etching of spacer layer.

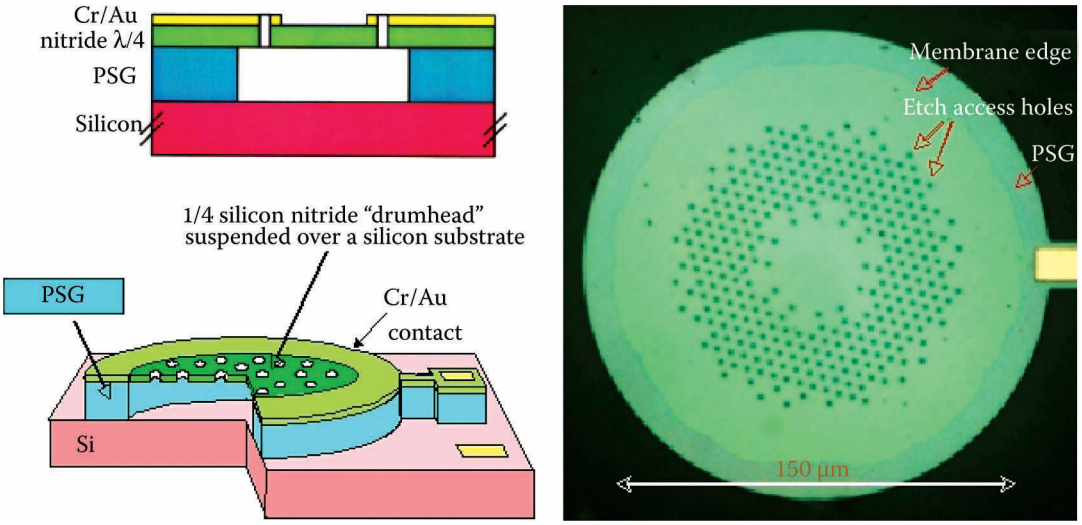

FIGURE 7.72 Analog optical modulator. The 1/4 silicon nitride "drumhead" suspended over a silicon substrate is equipped with access holes to etch the BSG faster. (Goossen, K., J. Walker, and S. Arney. 1994. Silicon modulator based on mechanically-active antireflection layer with 1 Mbit/sec capability. *IEEE Photonics Tech Lett* 6:1119.[130])

These access holes in the structural layer are typically spaced by roughly 30 μm, allowing for the HF to etch all the oxide beneath in less than 5 min.

The etch rate of PSG, the most common spacer material, increases monotonically with dopant concentration, and thicker sacrificial layers etch faster than thinner layers.[126]

The selectivity ratios for spacer layer, microstructure, and buffer layer are not infinite,[131] and in some instances even silicon substrate attack by BHF is observed under polysilicon/spacer regions.[132,133] It also has been shown that during an HF release step the mechanical properties of polysilicon, including residual stress, Young's modulus, and fracture strain, are affected.[134] Heavily phosphorous-doped polysilicon is especially prone to attack by BHF. In general, the Young's modulus and fracture strain of a thin polysilicon film decrease with increasing exposure time to HF and increasing HF concentration. Silicon nitride deposited by LPCVD etches much more slowly in HF than oxide films, making it a more desirable isolation film. When depositing this film with a silicon-rich composition, the etch rate is even slower (15 nm/min).[114] Eaton et al.[135] compared oxide and nitride etching in a 1:1 HF/H_2O and in a 1:1 HF/HCl solution and concluded that the HCl-based etch yielded both faster oxide etch rates (617 vs. 330 nm/min) and slower nitride etch rates (2 vs. 3.6 nm/min), providing a much greater selectivity of the oxide to silicon nitride (310 vs. 91!). The same authors also studied the optimum composition of a sacrificial oxide for the fastest possible etching in their most selective 1:1 HF/HCl etch. The faster sacrificial layer etch limited the damage to nitride structural elements. Their results are summarized in Table 7.21. A densified CVD SiO_2 was used as a control, and a 5%/5% borophosphosilicate glass (BPSG) was found to etch the fastest.

Using low-pressure vapor HF, Watanabe et al.[136] found high etch ratios of PSG and BPSG to thermal oxides of more than 2000, with the BPSG etching slightly faster than the PSG. We will see further that low-pressure vapor HF also leads to less stiction of structural elements to the substrate. In Table 7.22 we present etch rate and etch ratios for R_i and R_s in BHF (7:1) for a few selected materials.

Etching is followed by rinsing and drying. The problems with wet release continue during this drying and

TABLE 7.21 Etch Rate in 1:1 HF/HCl of a Variety of Sacrificial Oxides

Thin Oxide	Lateral Etch Rate (Å/min)
CVD SiO_2 (densified at 1,050 °C for 30 min)	6,170
Ion implanted and densified CVD SiO_2 (P, 8 10^{15}/cm^2, 50 keV)	8,330
Phosphosilicate (PSG)	11,330
5%/5% borophosphosilicate (BPSG)	41,670

Table 7.22 Etching of Spacer Layer and Buffer Layer in BHF (7:1)

	Material		
Property	LPCVD Si_3N_4	LP CVD SiO_2	LP CVD 7% PSG
Etch rate	7–12 Å/min	700 Å/min	~10,000 Å/min
Selectivity ratio	R_i = 1	R_s = 60–100	R_s ~800–1,200 Å/min

rinsing step. The meniscus created by the receding liquid/air interface tends to pull the structure against the substrate. This intimate contact gives rise to surface forces like Van der Walls force, which will irremediably pin one's structure to the substrate when the drying is complete, effectively destroying the device. This phenomenon is referred to as stiction (see Stiction below). Extended rinsing causes a native oxide to form on the surface of the polysilicon structure. Such a passivation layer often is desirable and can be formed more easily by a short dip in 30% H_2O_2.

Etchant-Spacer-Microstructure Combinations A wide variety of etchant, spacer, and structural material combinations has been used; a limited listing is presented in Table 7.23. One interesting case concerns polysilicon as the sacrificial layer. This was used, for example, in the fabrication of a vibration sensor at Nissan Motor Co.[137] In this case, polysilicon is etched in KOH from underneath a nitride/polysilicon/nitride sandwich cantilever. Also, a solution of HNO_3 and BHF can be used to etch polysilicon, but it proves difficult to control. Using aqueous solutions of NR_4OH, where R is an alkyl group, provides a better etching solution for polysilicon, with greater selectivity with respect to silicon dioxide and phosphosilicate glass. The relatively slow etch rate enables better process control,[138] and the etchant does not contain alkali ions, making it more CMOS compatible. With tetramethyl ammonium hydroxide (TMAH), the etch rate of CVD polysilicon, deposited at 600°C from SiH_4, follows the rates of the (100) face of single-crystal silicon and is dopant dependent. The selectivity of Si/SiO_2 and Si/PSG, at temperatures less than 45°C, is measured to be about 1000. Hence a layer of 500 Å of PSG can be used as the etch mask for 10,000 Å of polysilicon. In addition, porous Si has been used as a sacrificial layer in micromachining. The high surface area of this material makes for rapid etching in KOH.[139]

In Texas Instruments' Digital Micro Device (DMD) (Figure 7.66b) the structural layer is aluminum and the sacrificial layer is a polymer. The polymer is removed with oxygen plasma, and prolonged release time will only slightly affect the metal.

Figure 7.73 illustrates a fabrication sequence for a polyimide corrugated structure. The sacrificial Al in Step 4 may be etched away by a mixture of phosphoric acidic, acetic acid, and nitric acid (see Table 7.23).

Stiction

Stiction during Release The use of sacrificial layers enables the creation of very intricate movable polysilicon surface structures. An important limitation of such polysilicon shapes is that large-area structures tend to deflect through stress gradients or surface tension induced by trapped liquids and attach to the substrate/isolation layer during the final rinsing

Table 7.23 Etchants—Spacer and Microstructural Layer

Etchant	Buffer/Isolation	Spacer	Microstructure
Buffered HF (5:1,NH_4F/conc. HF)	LPCVD Si_3N_4/thermal SiO_2	PSG	Polysilicon[133]

and drying step, a stiction phenomenon that may be related to hydrogen bonding, residual contamination, and the Casimir force (see also Volume I, Chapter 3). In Volume III, Chapter 7 on scaling laws, we will come to appreciate that surface forces become dominant in the microdomain, and not only stiction but also friction are of great concern to the micromachinist. One of the principal causes of malfunctioning in MEMS is stiction, namely, the collapse of movable elements into nearby surfaces, resulting in their permanent adhesion. This can occur during fabrication, especially as a result of capillary forces, or during operation (in-use stiction, see below).

The sacrificial layer removal with a buffered oxide etch (BOE) followed by a long, thorough rinse in deionized water and drying under an infrared lamp typically represent the last steps in the surface micromachining sequence. As the wafer dries, the surface tension of the rinse water pulls the delicate microstructure to the substrate where a combination of forces—van der Waals forces, hydrogen bonding, and Casimir forces—keeps it firmly attached (see Figure 7.74).[119] Once the structure is attached to the substrate by stiction, the mechanical force needed to dislodge it usually is large enough to damage the micromechanical structure.[125,141] The same phenomena are thought to be involved in room temperature wafer bonding (Volume III, Chapter 7). Van der Waals forces and hydrogen bonding are covered in Volume III, Chapter 3 on nanochemistry: bottom-up manufacturing. Casimir forces are quantum mechanical in nature (see Volume I, Chapter 3) and inversely proportional to the fourth power of the distance between the plates. One can quickly establish that two mirrors of 1 cm^2 separated by a distance of 1 μm have an attractive Casimir force of 130 nN (see Volume III, Chapter 8). Although this force appears small, at distances less than 1 μm the Casimir force becomes the dominant force between two neutral objects. At separations of 10 nm, the Casimir effect produces the equivalent of 1 atm! Obviously this is a force to reckon with in MEMS and NEMS devices (see Volume III, Chapter 8 on actuators). We will not further dwell on the mechanics of the stiction process here, but the reader should refer to the theoretical and experimental analysis of the mechanical stability and adhesion of microstructures under capillary forces by Mastrangelo et al.[149,150]

Strategies that are used to overcome stiction have tackled it at the design and fabrication level. An important fabrication idea has been to reduce the contact surface by introducing dimples under the structure. Creating stand-off bumps on the underside of a polysilicon plate[114,151] or adding meniscus-shaping microstructures to the perimeter of the microstructure are mechanical means to help reduce sticking[152] (see Figure 7.75).

Fedder et al.[153] used another mechanical approach to avoid stiction by temporarily stiffening the microstructures with polysilicon links. The very stiff polysilicon structures are not affected by liquid surface tension forces, and the links are severed afterward with a high current pulse once the potentially

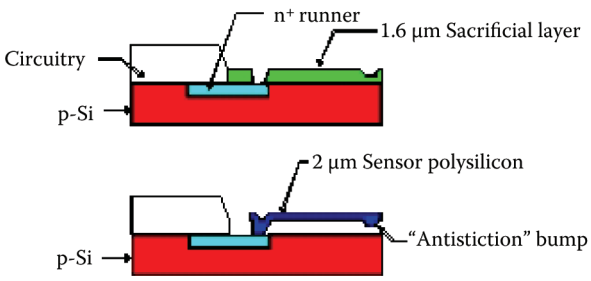

FIGURE 7.75 Stand-off bump or antistiction bump.

destructive processing is complete. Yet another mechanical approach to avoid stiction involves the use of sacrificial supporting polymer columns. A portion of the sacrificial layer is substituted by polymer spacer material, spun on after partial etch of the oxide glass. After completion of the oxide etch, the polymer spacer prevents stiction during evaporative drying. Finally, an isotropic oxygen plasma etches the polymer to release the structure.[154]

Ideally, to ensure high yields, contact between structural elements and the substrate should be avoided during processing. In a liquid environment, however, this may become impossible because of the large surface tension effects. Consequently, most solutions to the stiction problem involve reducing the surface tension of the final rinse solution by physicochemical means. Lober et al.,[131] for example, tried HF vapor, and Guckel et al.[155,156] used freeze-drying of water/methanol mixtures. Freezing and sublimating the rinse fluid in a low-pressure environment gives improved results by circumventing the liquid phase. Takeshima et al.[157] used t-butyl alcohol freeze-drying. Because the freezing point of this alcohol lies at 25.6°C, it is possible to perform freeze-drying without special cooling equipment. Supercritical drying results in increased microstructure yields.[158] With this technique, the rinse fluid is displaced with a liquid that can be driven into a supercritical phase under high pressure. This supercritical phase does not exhibit surface tension, which allows for the drying of released microstructures without sticking. Typically, CO_2 at 35°C and 1100 psi are used (see also Chapter 1).

Kozlowski et al.[159] substituted HF in successive exchange steps by the monomer divinylbenzene to fabricate very thin (500 nm) micromachined polysilicon bridges and cantilevers. The monomer was polymerized under UV light at room temperature and was removed in oxygen plasma. Analog Devices applied a proprietary technique involving only standard IC process technology in the fabrication of a microaccelerometer to eliminate yield losses due to stiction.[118]

Coating the structure with a nonsticking layer [e.g., fluorocarbon, hydrophobic self-assembled mono-layer (SAM)] has also proved successful, and this method, albeit more complex, has the added advantage to provide long-lasting protection (see below under "In-Use Stiction").

The two most popular methods today to avoid stiction are etching a polymer sacrificial layer in an O_2 plasma and using xenon difluoride (XeF_2) to etch sacrificial silicon (see also Chapter 3). Xenon difluoride has been used successfully to release very compliant or nanosized oxide structures where silicon was used as the sacrificial material. The process does not use plasma, making the chamber rather simple, and several manufacturers like XactiX (http://www.xactix.com) (in cooperation with STS) in the United States and PentaVacuum in Singapore offer tools to exploit the technology.

In-Use Stiction Stiction remains a fundamental reliability issue because of contact with adjacent surfaces after release. Stiction-free passivation that can survive the packaging temperature cycle is not known at present.[94] Attempted solutions are summarized below.

Adhesive or stiction energy may be minimized in a variety of ways: for example, by forming bumps on surfaces (see above) or roughening of opposite surface plates.[160] Also, self-assembled monolayer (SAM) coatings have been shown to reduce surface adhesion and to be effective at friction reduction in bearings at the same time.[161] Making the silicon surface very hydrophobic or coating it with diamond-like carbon are other potential solutions for preventing postrelease stiction of polysilicon microstructures. Man et al.[162] eliminate postrelease adhesion in microstructures by using a thin conformal fluorocarbon film. The film eliminates the adhesion of polysilicon beams up to 230 μm long even after direct immersion in water. The film withstands temperatures as high as 400°C, and wear tests show that the film

remains effective after 10^8 contact cycles. Along the same line, ammonium fluoride-treated Si surfaces are thought to be superior to the HF-treated surfaces because of a more complete hydrogen termination, which leads to a cleaner hydrophobic surface.[163] Gogoi et al.[164] introduced electromagnetic pulses for postprocessing release of stuck microstructures.

Wong et al.[165] at the Georgia Institute of Technology are mimicking one of nature's best nonstick surfaces—lotus plant leaves—to help create more reliable MEMS structures unaffected by water and even claim improved biocompatible surfaces able to prevent cells from adhering to implanted medical devices. As we discuss in Volume I, Chapter 6, the lotus plant's ability to repel water and dirt results from an unusual combination of a superhydrophobic (water-repelling) surface and a combination of micrometer-scale hills and valleys and nanometer-scale waxy bumps that create rough surfaces that do not give water or dirt a chance to adhere. With its superhydrophobicity and surface roughness, a lotus surface coating can prevent stiction.

Control of Film Stress

After reviewing typical surface micromachining process sequences, we are ready to investigate some of the mechanical properties of the fabricated mechanical members. Consider a straight lateral resonator as shown in Figure 7.76a. Electrostatic force is applied by a drive comb to a suspended shuttle. Its motion

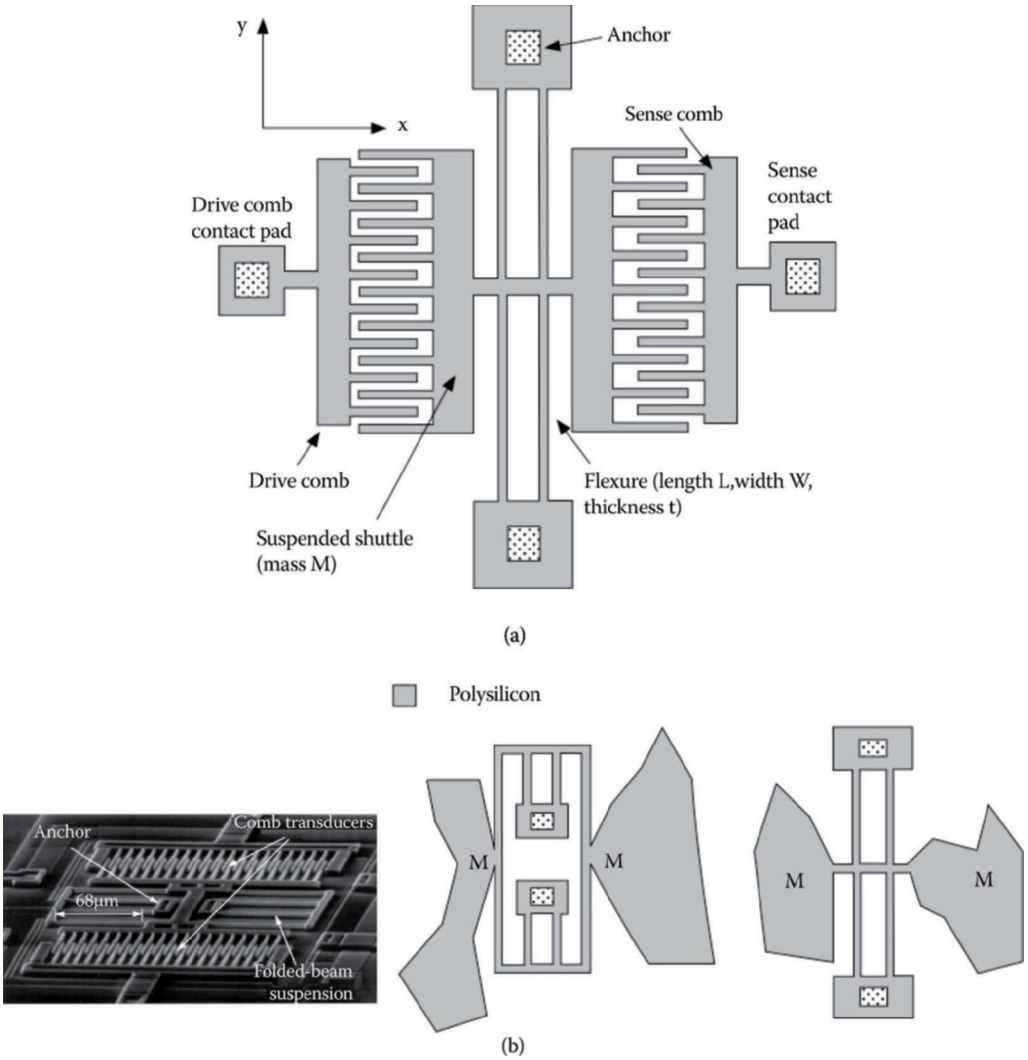

FIGURE 7.76 (a) Layout of a lateral resonator with straight flexures. (b) Folded flexures (left) to release stress are compared with straight flexures (right). *M* is shuttle mass. Scanning electron microscope picture represents a folded beam lateral resonator. (Nguyen, C. T. C., and R. T. Howe. 1993. *Electron devices meeting, 1993. IEDM '93. Technical Digest, International.* Washington DC: IEEE.[166])

is detected capacitively by a sense comb. For many applications, a tight control over the resonant frequency, f_0, is required. An analytical approximation for f_0 of this type of resonator can be deduced from Rayleigh's method:

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{2EtW^3}{mL^3} + \frac{24\sigma_r tW}{5\,mL}} \qquad (7.29)$$

where

E = the Young's modulus of polysilicon
L, W, and t = the length, width, and thickness of the flexures, respectively
m = the mass of the suspended shuttle (of the order of 10^{-9} kg or less)

For typical values (L = 150 μm and W = t = 2 μm) and a small tensile residual stress, the resonant frequency f_0 is between 10 and 100 kHz.[94] For typical values of L/W, the stress term in Equation 7.29 dominates the bending term. Any residual stress, σ_r, obviously will affect the resonant frequency. Consequently, stress and stress gradients represent critical stages for microstructural design.

Ignoring the stress term the resonant frequency in Equation 7.29 scales as the square root of the ratio of the stiffness and mass (Figure 7.77) (see also scaling in Volume III, Chapter 7). Thus, frequency scales as L^{-1}, and hence micro- and nanoresonators can lead to very high frequencies.

One of the many challenges of any surface-micromachining process is to control the intrinsic stresses in the deposited films. Several techniques can be used to control film stress. Some we detailed before, but we list them again for completeness sake:

- Large-grained polysilicon films, deposited around 625°C, have a columnar structure and are always compressive. Compressive stress can cause buckling in constrained structures. Annealing at high temperatures, between 900 and 1150°C, in nitrogen significantly reduces the compressive stress in as-deposited polysilicon[167,168] and can eliminate stress gradients. No significant structural changes occur when annealing a columnar polysilicon film. The annealing process is not without danger in cases where active electronics are integrated on the same chip. Rapid thermal annealing might provide a solution (see "IC Compatibility" below).
- Undoped polysilicon films are in an amorphous state when deposited at 580°C or less. The stress and the structure of this low-temperature material depend on temperature and partial pressure of the silane. A low-temperature anneal leads to a fine-grained polysilicon with low tensile stress and very smooth surface texture.[155] Tensile rather than compressive films are a necessity if lateral dimensions of clamped structures are not to be restricted by compressive buckling.
- Phosphorous,[169–171] boron,[170,172,173] arsenic,[170] and carbon[174] doping have all been shown to affect the state of residual stress in polysilicon films. In the case of single-crystal Si, to compensate for strain induced by dopants, one can implant with atoms with the opposite atomic radius versus Si. Similar approaches would most likely be effective for polysilicon as well.
- Tang et al.[114,175] developed a technique that sandwiches a polysilicon structural layer between a top and bottom layer of PSG and lets the high-temperature anneal drive in the phosphorous symmetrically, producing low-stress polysilicon with a negligible stress gradient.
- Another stress reduction method is to vary the materials composition, something readily done in CVD processes. An example of this method is the Si enrichment of Si_3N_4, which reduces the tensile stress.[176,177]
- During plasma-assisted film deposition processes, stress can be influenced dramatically. In a physical deposition process such as sputtering, stress control involves varying gas pressure and substrate bias. In plasma-enhanced

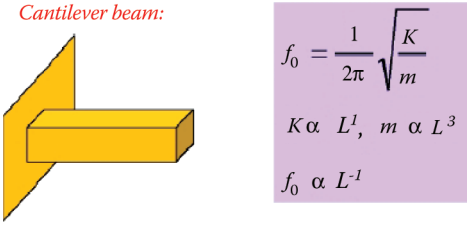

FIGURE 7.77 Scaling of the resonant frequency of simple cantilever beam.

chemical vapor deposition (PECVD), the RF power, through increased ion bombardment, influences stress. In this way, the stress in a thin film starts out tensile, decreases as the power increases, and finally becomes compressive with further RF power increase. PECVD equipment manufacturers are also working to build stress control capabilities into new equipment by controlling plasma frequency (see above). In CVD, stress control involves all types of temperature treatment programs.

- A clever mechanical design might facilitate structural stress relief.[178] By folding the flexures in the lateral resonator in Figure 7.76b and by the overall structural symmetry, the relaxation of residual polysilicon stress is possible without structural distortion. By folding the flexures, the resonant frequency, f_0, becomes independent of σ_r (see Equation 7.29). The springs in the resonator structure provide freedom of travel along the direction of the comb-finger motions (x) while restraining the structure from moving sideways (y), thus preventing the comb fingers from shorting out the drive electrodes. In this design, the spring constant along the y-direction must be higher than along the x-direction, i.e., $k_y >> k_x$. The suspension should allow for the relief of the built-in stress of the polysilicon film and the axial stress induced by large vibrational amplitudes. The folded-beam suspensions meet both criteria. They enable large deflections in the x-direction (perpendicular to the length of the beams) while providing stiffness in the y-direction (along the length of the beams). Furthermore, the only anchor points (see Figure 7.76b) for the whole structure reside near the center, thus allowing the parallel beams to expand or contract in the y-direction, relieving most of the built-in and induced stress.[114] Tang also modeled and built spiral and serpentine springs supporting torsional resonant plates. An advantage of the torsional resonant structures is that they are anchored only at the center, enabling radial relaxation of the built-in stress in the polysilicon film.[114] For some applications, the design approach with folded flexures is an attractive way to eliminate residual stress. However, a penalty for using flexures is increased susceptibility to out-of-plane warpage from residual stress gradients through the thickness of the polysilicon microstructure.[94]
- Corrugated structural members, introduced in the MEMS field by Jerman for bulk micromachined sensors,[179] also reduce stress effectively. In the case of a single-crystal Si membrane, stress may be reduced by a factor of 1,000–10,000.[180] One of the applications of such corrugated structures is the decoupling of a mechanical sensor from its encapsulation by reducing the influence of temperature changes and packaging stress.[180,181] Thermal stress alone can be reduced by a factor of 120.[182] Besides stress release, corrugated structures enable much larger deflections than do similar planar structures. This type of structural stress release was studied in some detail for single-crystal Si,[183] polyimide,[148] and LPCVD silicon nitride membranes,[184] but the quantitative influence of corrugated polysilicon structures still requires further investigation. A schematic view of the fabrication process of a polyimide corrugated diaphragm was shown in Figure 7.73.

Dimensional Uncertainties

The often-expressed concerns about run-to-run variability in material properties of polysilicon or other surface-micromachined materials are somewhat misplaced, Howe points out.[114] He contrasts the relatively large dimensional uncertainties inherent to any lithography technique with polysilicon quality factors of up to 100,000 and long-term (>3 years) resonator frequency variation of less than 0.02 Hz. We follow his calculations here to prove the relative importance of the dimensional uncertainties. The shuttle mass M of a resonator as shown in Figure 7.76 is proportional to the thickness (t) of the polysilicon film, and neglecting the residual stress term, Equation 7.29 reduces to:

$$f_0 \propto \left(\frac{W}{L}\right)^{\frac{3}{2}} \tag{7.30}$$

In case the residual stress term dominates in Equation 7.29, the resonant frequency is expressed as:

$$f_0 \propto \left(\frac{W}{L}\right)^{\frac{1}{2}} \tag{7.31}$$

The width-to-length ratio is affected by systematic and random variations in the masking and etching of the microstructural polysilicon. For 2-µm-thick structural polysilicon, patterned by a wafer stepper and etched in a reactive-ion etcher, a reasonable estimate for the variation in linear dimension of etched features, Δ is about 0.2 µm (10% relative tolerance).

From Equation 7.30 the variation Δ in lateral dimensions will result in an uncertainty δf_0 in the lateral frequency of:

$$\frac{\delta f_0}{f_0} \approx \frac{3}{2}\left(\frac{\Delta}{W}\right) \tag{7.32}$$

for a case where the residual stress can be ignored. With a nominal flexure width of W = 2 µm, the resulting uncertainty in resonant frequency is 15%. For the stress-dominated case, Equation 7.31 indicates that the uncertainty is now given as:

$$\frac{\delta f_0}{f_0} \propto \frac{1}{2}\left(\frac{\Delta}{W}\right) \tag{7.33}$$

The same 2-µm-wide flexure would now lead to a 5% uncertainty in resonant frequency. Interestingly, the stress-free case exhibits the most significant variation in the resonant frequency. In either case, resonant frequencies must be set by some postfabrication frequency trimming or other adjustment.

In Chapter 6 we draw further attention to the increasing loss of relative manufacturing tolerance with decreasing structure size (see Figure 6.3).

Sealing Processes in Surface Micromachining

Sealing cavities to hermetically enclose sensor structures is a significant attribute of surface micromachining. Sealing cavities in surface micromachines often embodies an integral part of the overall fabrication process and presents a desirable chip level, batch-packaging technique. The resulting surface packages (microshells) are much smaller than typical bulk micromachined ones. A sealed cavity made with epi-micromachining is shown in Figure 7.82 further below, and more details on packaging using surface micromachining techniques are provided in Volume III, Chapter 4.

IC Compatibility

Putting detection and signal conditioning circuits right next to the sensing element enhances the performance of the sensing system, especially when dealing with high impedance sensors. A key benefit of surface micromachining, besides small device size and single-sided wafer processing, is its compatibility with CMOS processing. IC compatibility implies simplicity and economy of manufacturing. In the examples at the end of this chapter, we will discuss, for example, how Analog Devices used a mature 4-µm BiCMOS process to integrate electronics with a surface-micromachined accelerometer.

To develop an appreciation of integration issues involved in combining a CMOS line with surface micromachining, we highlight Yun's[185] comparison of CMOS circuitry and surface micromachining processes in Table 7.24A. Surface micromachining processes are similar to IC processes in several aspects. Both processes use similar materials, lithography, and etching techniques. CMOS processes involve at least 10 lithography steps where lateral small feature size plays an important role. Some processing steps, such as gate and contact patterning, are critical to the functionality and performance of the CMOS circuits. Furthermore, each processing step is strongly correlated with other steps. Change in any one of the processing steps will lead to modifications in a number of other steps in the process. In contrast, surface micromachining appears relatively simple. It usually consists of two to six masks, and the feature sizes are much larger. The critical processing steps, such as structural polysilicon, often are self-aligned, which eliminates lithographic alignment. The CMOS process is mature, generic, and fine-tuned, whereas surface micromachining strongly depends on the application and still needs maturing.

Table 7.24B presents the critical temperatures associated with the LPCVD deposition of a

Table 7.24 Surface Micromachining and CMOS

A. Comparison of CMOS and Surface Micromachining

	CMOS	Surface Micromachining
Common features	Silicon-based processes Same materials Same etching principles	
Process flow	Standard	Application specific
Vertical dimension	~1 μm	~1–5 μm
Lateral dimension	<1 μm	2–10 μm
Complexity (number of masks)	>10	2–6

B. Critical Process Temperatures for Microstructures

	Temperature (°C)	Material
LP CVD deposition	450	Low-temperature oxide (LTO)/PSG
LP CVD deposition	610	Low-stress polysilicon
LP CVD deposition	650	Doped polysilicon
LP CVD deposition	800	Nitride
Annealing	950 1,050	PSG densification Polysilicon stress annealing

variety of frequently used materials in surface micromachining. Polysilicon is used for structural layers, and thermal SiO_2, LPCVD SiO_2, and PSG are used as sacrificial layers; silicon nitride is used for passivation. The highest temperature process in Table 7.24B is 1050°C and is associated with the annealing step to release stress in the polysilicon layers. Doped polysilicon films deposited by LPCVD under conventional IC conditions usually are in a state of compression that can cause mechanically constrained structures such as bridges and diaphragms to buckle. The annealing step above at about 1000°C promotes crystallite growth and reduces the strain. If a polysilicon microstructure is built after the CMOS active electronics have been implemented (a so-called *post-CMOS procedure*), temperatures greater than 950°C must be avoided because junction migration will take place at those temperatures. This is especially true with devices incorporating shallow junctions where migration might be a problem at temperatures as low as 800°C. The degradation of the aluminum metallization presents a bigger problem. Aluminum typically is used as the interconnect material in the conventional CMOS process. At temperatures of 400–450°C, the aluminum metallization will start suffering. Anneal temperatures (densification of the PSG and stress anneal of the polysilicon) only account for some of the concerns; in general, several compatibility issues must be considered: 1) deposition and anneal temperatures, 2) passivation during micromachining etching steps, and 3) surface topography.

Yun[185] compared three possible approaches to build integrated microdynamic systems: pre-, mixed, and post-CMOS microstructural processes. He concluded that building up the microstructures after implementation of the active electronics offers the best results.

To avoid problems with microstructure topography, which commonly includes step heights of 2–3 μm, the CMOS module is fabricated before the microstructure module in a post-CMOS process. Although this solves topography problems, it introduces constraints on the CMOS. In a post-CMOS process, the electronic circuitry is passivated to protect it from the subsequent micromachining processes. The standard IC processing may be performed at a regular IC foundry, whereas the surface micromachining occurs as an add-on in a specialized sensor fabrication facility. LPCVD silicon nitride (deposited at 800°C; see Table 7.24B) is stable in HF solutions

and is the preferred passivation layer for the IC during the long-release etching step. PECVD nitride can be deposited at around 320°C, but it displays relatively poor step coverage, whereas pinholes in the film allow HF to diffuse through and react with the oxide underneath. LPCVD nitride is conformably deposited. Although it shows fewer pinholes, circuitry needs to be able to survive the 800°C deposition temperature.

Aluminum metallization must be replaced by another interconnect scheme to increase the post-CMOS temperature ceiling higher than 450°C. Tungsten, which is refractory, shows low resistivity, and has a thermal expansion coefficient matching that of silicon, is an obvious choice. One problem with tungsten metallization is that tungsten reacts with silicon at about 600°C to form WSi_2, implying the need for a diffusion barrier. The process sequence for the tungsten metallization developed at the University of California, Berkeley is shown in Figure 7.78. A diffusion barrier consisting of $TiSi_2$ and TiN is used. The TiN film forms during a 30-s sintering step to 600°C in N_2. Rapid thermal annealing with its reduced time at high temperatures (10 s to 2 min) and high ramp rates (~150°C/s) allows very precise process control and a dramatic reduction of thermal

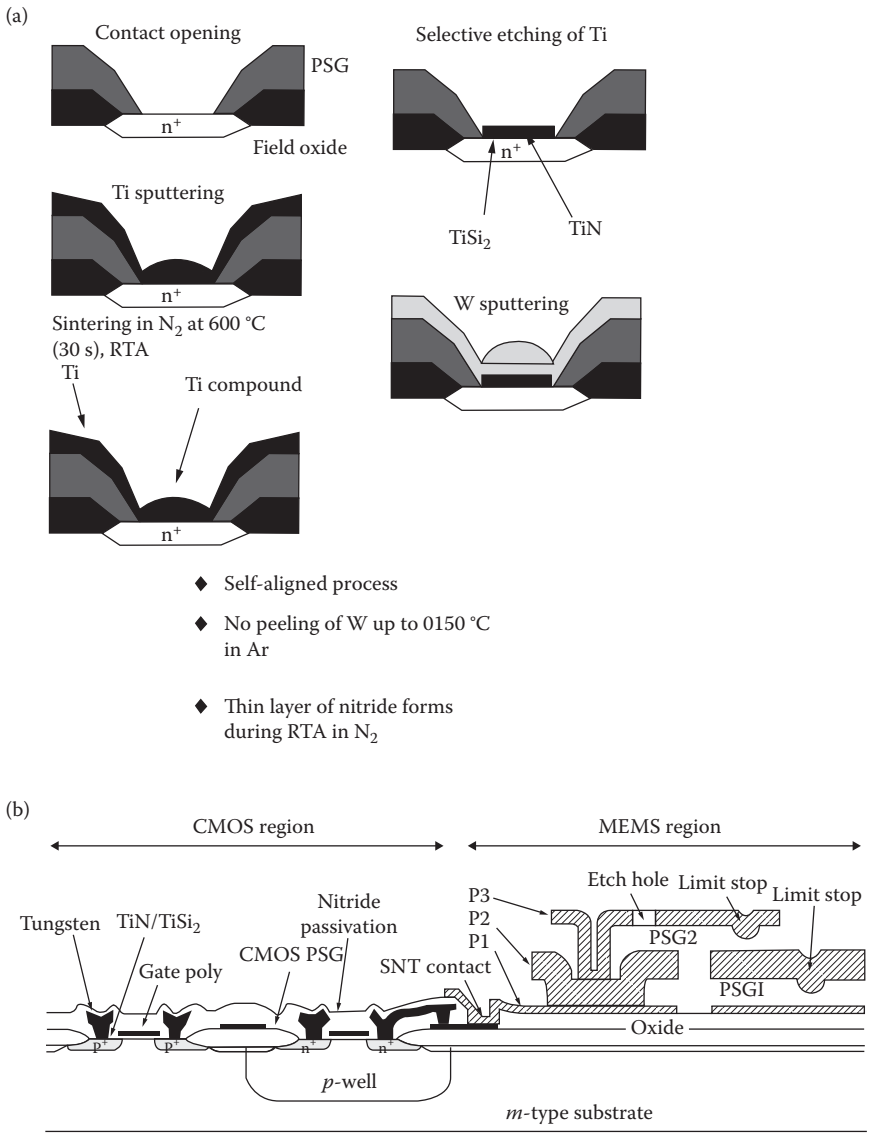

FIGURE 7.78 (a) Tungsten metallization process in a modified CMOS process. (Adapted from Yun, W. 1992. *A surface micromachined accelerometer with integrated CMOS detection circuitry.* PhD thesis. University of California, Berkeley. With permission.[185]) (b) CMOS electronics combined with postprocessed MEMS device.

budgets, reducing duress for the active on-chip electronics. Titanium silicide is formed at the interface of titanium and silicon, whereas titanium nitride forms simultaneously at the exposed surface of the titanium film. The $TiSi_2$/TiN forms a good diffusion barrier against the formation of WSi_2 and at the same time provides an adhesion and contact layer for the W metallization.

To avoid the junction migration in a post-CMOS process, rapid thermal annealing is used for both the PSG densification and polysilicon stress anneal: 950°C for 30 s for the PSG densification and 1000°C for 60 s for the stress anneal of the polysilicon. Alternatively, fine-grained polysilicon can be used because it yields a controlled tensile strain with low-temperature annealing.[186]

Despite some advantages, the post-CMOS process with tungsten metallization is not the preferred implementation. Hillock formation in the W lines during annealing and high contact resistance remains problematic.[116] The heavily doped structural and sacrificial layers may also affect the finely tuned CMOS fabrication sequence. Most importantly, the use of tungsten for circuit interconnects is not consistent with mainstream IC technologies, where aluminum interconnects predominate. Given that IC manufacturers have already invested enormous resources into the development of multilevel aluminum interconnect technologies, and further given the inferior resistivity of tungsten versus aluminum, the described tungsten-based post-CMOS process, although useful as a demonstration tool, is not likely to be adapted in industry.[187] A post-CMOS process for high-aspect-ratio integrated single-crystal silicon microstructures was described in Example 3.3.

The mixed CMOS/micromachining approach implements a processing sequence that puts the processes in a sequence to minimize performance degradation for both electronic and mechanical components. According to Yun, this requires significant modifications to the CMOS fabrication sequence. Nevertheless, Analog Devices relied on such an interleaved process sequence to build the first commercially available integrated microaccelerometer (see Example 7.1). The modifications required on a standard BiCMOS line are minimal: to facilitate integration of the IC and to surface micromachine the thickness of deposited microstructural films, the line is limited to 1–4 μm. Relatively deep junctions permit thermal processing for the sensor polysilicon anneal, and interconnections to the sensor are made only via n^+ underpasses. Therefore, no metallization is present in the sensor area. This industrial solution remains truer to the traditional IC process experience than the post-CMOS procedure. Howe[116] recently detailed another example of such a mixed process In Howe's scenario, the micromachining sequence is inserted after the completion of the electronic structures but before contact etching or aluminum metallization. By limiting the polysilicon annealing to 7 min at 900°C, only minor dopant redistribution is expected. Contact and metallization lithography and etching are more complex now because of the severe topography of the polysilicon microstructural elements. These processes, however, have their own associated limitations: mixed processes often require longer, more expensive development periods for new product lines.

The pre-CMOS approach is to fabricate microstructural elements before any CMOS process steps. At first glance, this seems like an attractive approach because no major modifications would be needed for process integration. However, because of the vertical dimensions of microstructures, step coverage is a problem for the interconnection between the sensor and the circuitry (the latest approach introduced by Howe faces the same dilemma). Passivation of the microstructure during the CMOS process can also become problematic. Furthermore, the heavily doped structural layers can affect the fine-tuned CMOS fabrication sequences, such as gate oxidation. Consequently, this approach is only used for special applications.[185] Precircuit processes may place limitations on foundry-based fabrication schemes because circuit foundries may be sensitive to contamination from MEMS foundries.

A unique pre-CMOS process (micromechanics first) that overcomes the planarity issues of building the MEMS before the CMOS has been developed at Sandia National Labs (http://mems.sandia.gov/tech-info/summit-v.html).[188] The SUMMiT-V™ fabrication process is a batch fabrication process using conventional IC processing tools. Using this

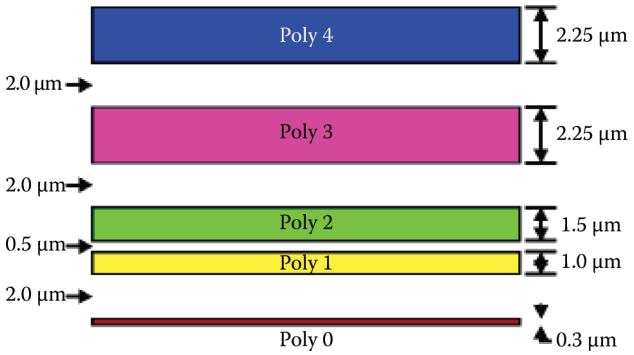

FIGURE 7.79 Sandia's Ultraplanar Multilevel MEMS Technology (SUMMiT-V™) (http://mems.sandia.gov/tech-info/summit-v.html).

technology, high-volume, low-cost production can be achieved. Topography issues are mitigated using chemical-mechanical polishing (CMP) to achieve planarization (see Chapter 1 on lithography), and stress is maintained at low levels using a proprietary process. The process uses 14 individual masks, approximately the same quantity as in many CMOS IC processes (Figure 7.79).

In this approach, micromechanical devices are fabricated in a trench etched in a Si epilayer. After the mechanical components are complete, the trench is filled with oxide, planarized using CMP, and sealed with a nitride membrane. The flat wafer with the embedded micromechanical devices is then processed by means of conventional CMOS processing. Additional steps are added at the end of the CMOS process to expose and release the embedded micromechanical devices and to hook them up with the CMOS. A cross-section of a structure made with this technology is shown in Figure 7.80.

The SPIE "Smart Structures and Materials 1996" meeting in San Diego, CA, had two complete sessions dedicated to the crucial issue of integrating electronics with polysilicon surface micromachining.[189] Research aimed at achieving truly modular merged circuits + microstructures technology is still ongoing.

Surface Micromachining Modifications

Silicon on Insulator—SOI Surface Micromachining

Introduction SOI is an exciting new approach to both IC chip making and MEMS. In SOI, bulk silicon wafers are replaced with wafers that have three layers: a thin surface layer of silicon (from a few hundred angstroms to several micrometers thick), an underlying layer of insulating material, and a support or "handle" silicon wafer. The insulating layer, usually made of silicon dioxide, is called the *buried oxide* or *BOX* and is typically a few thousand angstroms thick. As we will see below, this thin buried oxide layer, sandwiched between two layers of Si, can be achieved in several different ways.

When transistors are built within the thin top silicon layer, they switch signals faster (up to 10 GHz), run at lower voltages, and are much less vulnerable to signal noise from background cosmic ray particles. Furthermore, on an SOI wafer each transistor is isolated from its neighbor by a complete layer of silicon dioxide, which makes them immune to "latch-up" problems, and they can be spaced closer together than transistors built on bulk silicon wafers. Thus, building circuits on SOI allows for more compact

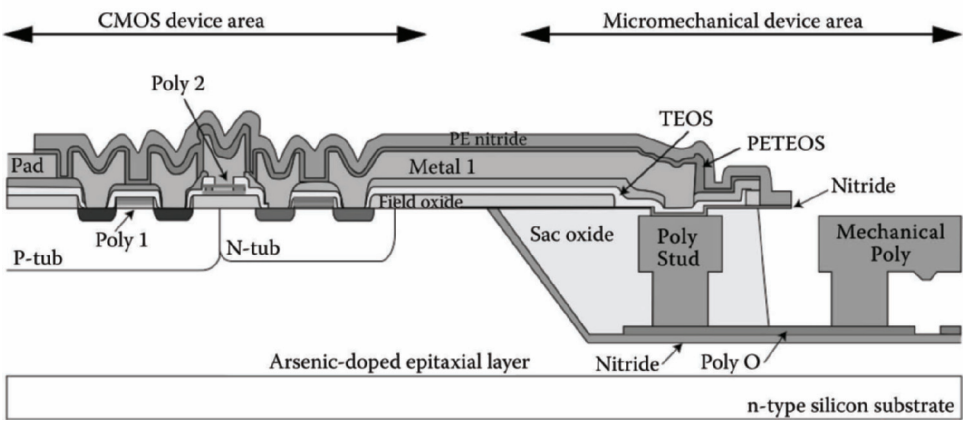

FIGURE 7.80 Schematic cross-section of the embedded micromechanics approach to Sandia's CMOS/MEMS integration.

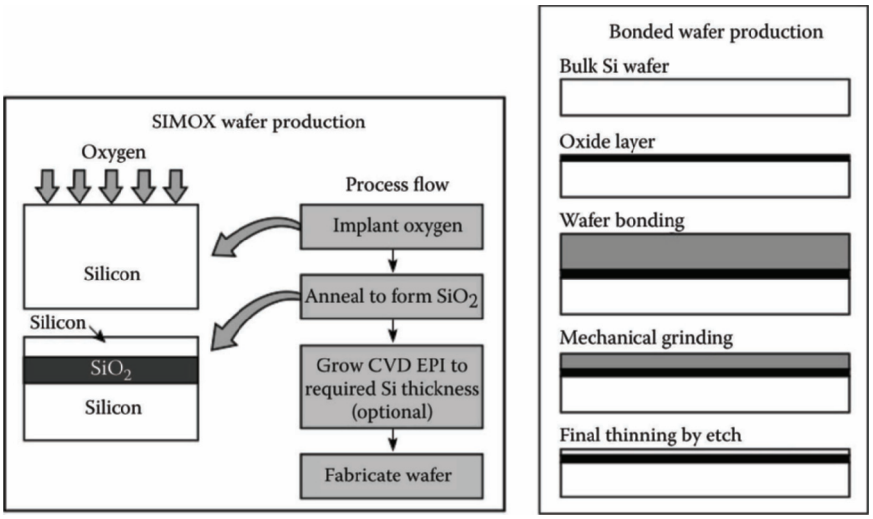

FIGURE 7.81 How SOI wafers are made.

chip designs, resulting in smaller IC devices (with higher production yield) and more chips per wafer (increasing fabrication productivity).

In MEMS, silicon crystalline features, anywhere between fractions of a micrometer to 100 μm high, can be readily obtained by surface micromachining of the epi silicon or fusion-bonded silicon layer of SOI wafers.[99] Structural elements made from these single-crystalline Si layers result in more reproducible and reliable sensors than those made from polysilicon. SOI or epi-micromachining combines the best features of surface micromachining (i.e., IC compatibility and freedom in *x*,*y* shapes) with the best features of bulk micromachining (superior single-crystal Si properties). Moreover, SOI surface micromachining frequently involves fewer process steps and offers better control over the thickness of crucial building blocks. Given the poor reproducibility of mechanical properties and generally poor electronic characteristics of polysilicon films, SOI machining may surpass the polysilicon technology for fabricating high-performance devices.

SOI Surface Micromachining Below, we present a short review of the three most popular methods for producing SOI wafers, introduce some uses of SOI in MEMS, and compare SOI versus polysilicon surface micromachining.

SOI Wafer Fabrication Techniques Three major techniques currently are applied to produce SOI wafers (Figure 7.81) (see also under "Epitaxy" above): SIMOX (Separated by IMplanted OXygen), the Si fusion bonded (SFB) wafer technique, and zone-melt recrystallized (ZMR) polysilicon. With SIMOX, standard Si wafers are implanted with oxygen ions and then annealed at high temperatures (1300°C). The oxygen and silicon combine to form a silicon oxide layer beneath the silicon surface. The oxide layer's thickness and depth are controlled by varying the energy and dose of the implant and the anneal temperature. In some cases, a CVD process deposits additional epitaxial silicon on the top silicon layer. Attempts have also been made to implant nitrogen in Si to create abrupt etch stops [in the SIMON process (Separation by IMplantation Of Nitrogen]. At high-enough energies, the implanted nitrogen is buried 0.5–1 μm deep. At a high-enough dose, the etching in that region stops. It is not necessary to implant a stoichiometric amount of nitrogen; a dose lower by a factor of two to three suffices. After implantation, it is necessary to anneal the wafer because the implantation destroys the crystal structure at the surface of the wafer.

The Si fusion bonded wafer process starts with an oxide layer (typically about 1 μm) grown on a standard Si wafer. That wafer is then bonded to another wafer, with the oxide sandwiched between. For the bonding, no mechanical pressure or other forces are applied. The sandwich is annealed at 1100°C for 2 h in a nitrogen ambient, which creates a strong bond between the two wafers. One of the wafers is then

ground to a thickness of a few micrometers using mechanical and CMP.

A third process for making SOI structures is to recrystallize polysilicon (e.g., with a laser, an electron beam, or a narrow strip heater), which has been deposited on an oxidized silicon wafer. This process is called *zone melting recrystallization* (ZMR) and is used primarily for local recrystallization but has not yet been explored much for use in micromachining applications.

The crystalline perfection of conventional silicon wafers in SFB and ZMR is completely maintained in the SOI layer because the wafers do not suffer from implant-induced defects. By using plasma etching, wafers with a top Si layer thickness of as little as 1000–3000 Å with total thickness variations of less than 200 Å can be made.[190] SOI top Si layers of 2 µm thick are more standard.[191] A tremendous amount of effort is spent in the IC industry on controlling the SOI thin Si layer thickness, which benefits any narrow tolerance IC and micromachine.

Etched-back fusion-bonded Si wafers and SIMOX are used extensively to build both ICs and micromachines, and both are commercially available. In 1989 TI introduced its commercial 64K static random access memory (SRAM) based on SOI, and AMD's 90 nm is also based on SOI technology (introduced in late 2004). One vendor is SOITEC (http://www.soitec.com/en/products).

SOI Use in MEMS

Overview Kanda[192] reviews different types of SOI wafers in terms of their micromachining and IC applications. Working with SOI wafers, he points out, offers several advantages over bulk Si wafers: fewer process steps are needed for feature isolation; parasitic capacitance is reduced; and power consumption is lowered. In the IC industry, SOI wafers are principally used for high-speed CMOS ICs (<10 GHz), smart power ICs (voltages up to 100 V), 3D ICs, and radiation-hardened devices.[193]

An important use of silicon on insulator wafers is in the production of high-temperature sensors. Compared with p-n junction isolation, which is limited to about 125°C, much higher temperature (up to 300°C) devices are possible based on the dielectric insulation of SOI. A wide variety of SOI surface-micromachined structures have been explored, including pressure sensors, accelerometers, torsional micromirrors, light sources, and optical choppers.[95,99] Often in those micromachining applications, SOI wafers are used to produce an etch stop. The silicon fusion bonded (SFB) method offers the more versatile MEMS approach because of the associated potential for thicker single-crystal layers and the option of incorporating buried cavities, facilitating micromachine packaging. Sensors manufactured by means of SFB now are commercially available.[194] The SIMOX approach is less labor intensive and holds better membrane thickness control. An important expansion of the SOI technique is selective epitaxy. The latter enables a wide range of new mechanical structures and enables novel etch-stop methods,[195] as well as electrical and/or thermal separation and independent optimization of active sensor and readout electronics.[196] In most cases, SOI machining involves dry anisotropic etching to etch a pattern into the Si layer on top of the insulator. These structures then are released by etching the sacrificial buried SiO_2 insulator layer, which displays a thickness with very high reproducibility (400 ± 5 nm) and uniformity (<±5 nm), especially in the case of SIMOX. Etched free cantilevers and membranes consist of single-crystalline silicon with thicknesses ranging from micrometers and submicrometers (SIMOX) up to hundreds of micrometers (SFB).

The increasing use of SOI technology for the fabrication of MEMS devices has brought with it its own set of unique problems that must be overcome for applications where CD control is important. For example, the etching of deep trenches in SOI wafers necessitates a fast etch process, followed by a slow etch process as soon as the buried dioxide layer is reached.[197] The main problem in plasma processing of SOI is the notching at the oxide interface, which results from the deflection of the incident ions by charging up the insulating oxide surface. The notch width increases with time, and it is here that etch uniformity begins to play an important role because overetching times to clear the wafer can become significant. For example, a 400-µm-deep etch with +5% uniformity requires a >10% overetch to ensure that all features etch to the required depth. Thus, some areas of the wafer will be subject to a 40-µm

overetch, and precise control of the profile during overetching becomes essential.

Creating Buried Cavities in Silicon by Silicon Fusion Bonded Micromachining Silicon fusion bonding enables the formation of thick single-crystal layers with cavities built in. An example is shown in Figure 7.82.[99] The device pictured involves two 4-in. <100> wafers: a handle wafer and a wafer used for the SOI surface. The p-type (3–7 Ωcm) handle wafer is thermally oxidized at 1100°C to obtain a 1-µm-thick oxide. Thermal oxidation enables thicker oxides than the ones formed in SIMOX by ion implantation and avoids the potential implantation damage in the working material. To make a buried cavity, the oxide is patterned and etched. To produce yet deeper cavities, the Si handle wafer may be etched as well (as in Figure 7.82). In the case shown, the top wafer consists of the same p-type substrate material as the handle wafer with a 2–30-µm-thick n-type epitaxial layer. The epitaxial layer determines the thickness of the final mechanical/structural element. The epitaxial layer is fusion bonded to the cavity side of the handle wafer (2 h at 1100°C). The top wafer is then partially thinned by grinding and polishing (Figure 7.82a). An insulator is deposited and patterned on the back side of the handle wafer to etch access holes to the insulator. After the insulator at the bottom of the etch hole is removed by a buffered oxide etch (BOE), aluminum is sputtered and sintered to make contact to the n-type epilayer for the electrochemical etch back of the remaining p-type material (Figure 7.82b). The final single-crystal silicon thickness is uniform to within ±0.05 µm (standard deviation) and does not require a costly, high-accuracy polish step.

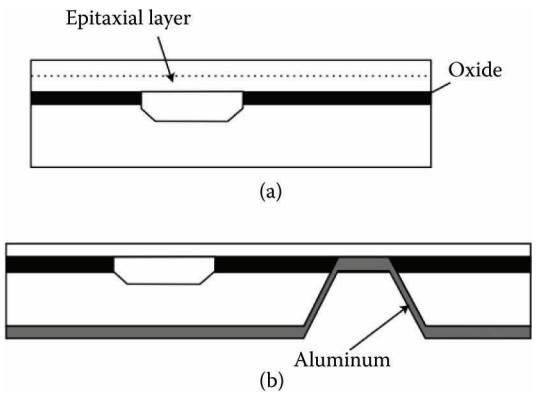

FIGURE 7.82 (a) Wafer sandwich after grind-and-polish step. (b) Wafer after electrochemical etch-back in KOH, buried oxide removal, and aluminum deposition. [From Noworolski, J. M., E. Klaassen, J. Logan, K. Petersen, and N. Maluf. 1995. *Eighth international conference on solid-state sensors and actuators (Transducers '95).* Stockholm, Sweden: IEEE. With permission.[99]]

Draper Laboratory is using SOI processes in the development of inertial sensors, gyros, and accelerometers as an alternative to devices fabricated by the dissolved wafer process (see Example 4.1). The main advantage is that the former consists of an all-Si process rather than a Si/Pyrex sandwich; an all Si device will exhibit less thermal stress.[198]

Fabricating Pressure Sensors in SIMOX Surface Micromachining Both capacitive and piezoresistive pressure sensors were microfabricated from SIMOX wafers.[95] Figure 7.83 illustrates the process sequence by Diem et al.[95] for fabricating an absolute capacitive pressure sensor. The 0.2-µm silicon surface layer of the SIMOX wafer is thickened with doped epi-silicon to 4 µm. An access hole is RIE etched in the Si layer, and vacuum cavity and electrode gap are obtained by etching the SiO_2 buried layer. Because the buried thick oxide layer exhibits a very high reproducibility and homogeneity over the whole wafer (0.4 µm ± 5 nm), the resulting vacuum cavity and electrode gap after etching also are very well controlled. The small gap results in relatively high capacitance values between the free membrane and bulk substrate (20 pf/mm^2). Diaphragm diameter, controlled by the SiO_2 etching, is up to several hundred micrometers (±2 µm). The etching hole is hermetically sealed under vacuum by plasma CVD deposition of nonstressed dielectric layer plugs.

With the above scheme, Diem et al. realized an absolute pressure sensor with a size of less than 1.5 mm^2. The temperature dependence of a capacitive sensor is mainly a result of the temperature coefficient of the offset capacitance. Therefore, temperature compensation is needed for high accuracy sensors. A drastic reduction of the temperature dependence is obtained by a differential measurement, especially if the reference capacitor resembles the sensing capacitor. A reference capacitor is designed with the membrane blocked by several plugs for pressure

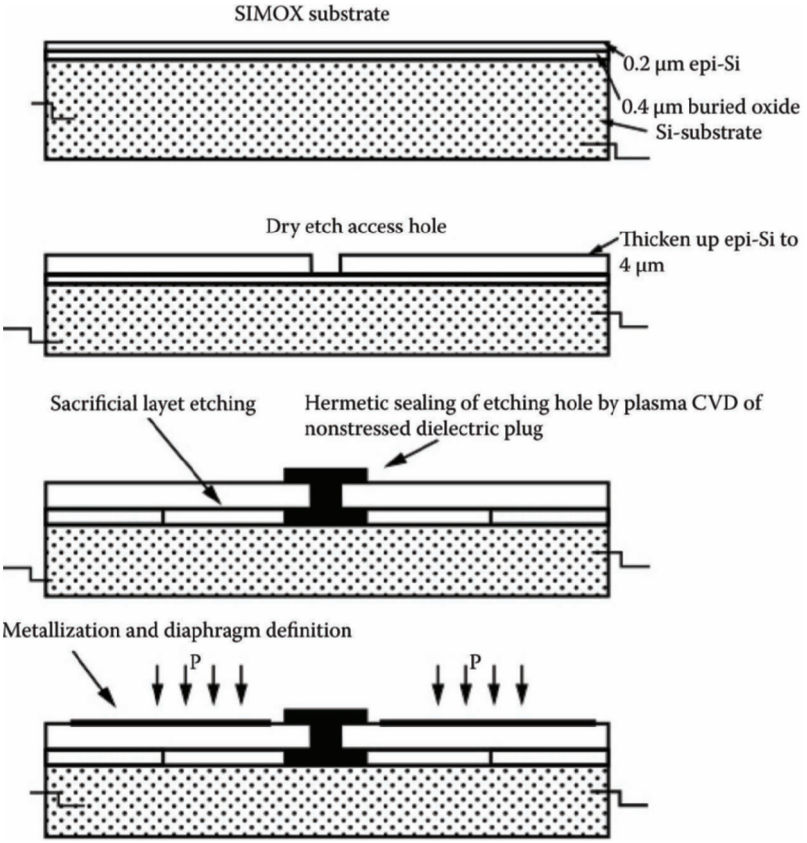

FIGURE 7.83 Process sequence of a SIMOX absolute capacitive pressure sensor by Diem et al. [From Diem, B., M. T. Delaye, F. Michel, S. Renard, and G. Delapierre. 1993. *Seventh international conference on solid-state sensors and actuators (Transducers '93).* Yokohama, Japan: IEEE. With permission.[95]]

insensitivity. The localization and the number of plugs are modeled by finite element analysis (FEA; ANSYS software was used) to get a deformation lower than 1% of the active sensor's deformation. Even without temperature calibration, the high output of the differential signal results in an overall output error better than ±2% over the whole temperature range (–40°C to +125°C) compared with 10% for nondifferential measurements. The temperature coefficient of the sensitivity is about 100 ppm/°C, which agrees with the theoretical variation of the Young's modulus of silicon. A piezoresistive sensor can be achieved by implanting strain gauges in the membrane. Although SIMOX wafers are more expensive than regular wafers, they come with several process steps embedded, and they make packaging easier.

Selective Epitaxy Surface Micromachining In the discussion on epitaxy, we drew attention to the potential of selective epitaxy for creating novel microstructures. The example in Figure 7.50 illustrates the selective deposition of epi-silicon on a Si substrate through a SiO_2 window. The same figure also demonstrates the simultaneous deposition of polysilicon on SiO_2 and crystalline epi-silicon on silicon, creating the basis for a structure featuring an epi-silicon anchor with polysilicon side arms.

Neudeck et al.[199,200] at Purdue and Gennissen et al.[195,196] in Twente proved that selective epitaxy can also be applied for automatic etch stop on buried oxide islands. Figure 7.84a demonstrates how epitaxial lateral overgrowth (ELO) can bury oxide islands. After removal of the native oxides from the seed windows, epi is grown for 20 min at 950°C and at 60 Torr using a $Si_2H_2Cl_2$-HCl-H_2 gas system. The epi growth front moves parallel to the wafer surface while growing in the lateral direction, leaving a smooth planar surface. During epi growth, the HCl prevents polynucleation on the nonsilicon areas. The epi quality is strongly dependent on the orientation of the seed holes

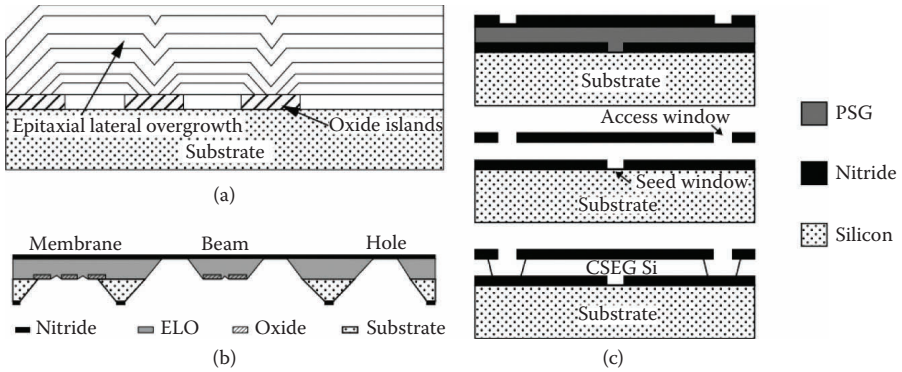

FIGURE 7.84 Micromachining with epi-silicon. (a) Lateral overgrowth process of epi-silicon (ELO, epitaxial lateral overgrowth) out of <100>-oriented holes in an oxide mask. (b) KOH etch stop on buried oxide islands or front side nitride. (c) Principle of confined selective epitaxial growth. (From Bartek, M., P. T. J. Gennissen, P. J. French, and R. F. Wolffenbuttel. 1995. *Eighth international conference on solid-state sensors and actuators (Transducers '95).* Stockholm, Sweden: IEEE. With permission.[196])

in the oxide. Seed holes oriented in the <100> direction lead to the best epi material and surface quality. Selective epi's other big problem for fabrication remains sidewall defects.[201] The buried oxide islands stop the KOH etch of the substrate, enabling formation of beams and membranes as shown in Figure 7.84b. This technique might form the basis of many high-performance microstructures. The Purdue and Twente groups also work on confined selective epitaxial growth (CSEG), a process pioneered by Neudeck et al.[200] In this process a micromachined cavity is formed above a silicon substrate with a seed contact window to the silicon substrate and access windows for epi-silicon (Figure 7.84c).[196] Low-stress, silicon-rich nitride layers act as structural layers to confine epitaxial growth; PSG is used as sacrificial material. This confined selective epitaxial growth technique allows electrical and/or thermal isolation separation, as well as independent optimization of active sensor and readout electronic areas.

SOI versus Polysilicon Surface Micromachining

The power of polysilicon surface micromachining mainly lays in its CMOS compatibility. When deposited on an insulator, both polysilicon and single crystal layers enable higher operating temperatures (>200°C) than bulk micromachined sensors featuring p-n junction isolation only (130°C max).[202] An additional benefit for SOI-based micromachining is IC compatibility combined with single-crystal Si performance excellence. The maximum gauge factor (see Volume I, Equation 4.93) of a polysilicon piezoresistor is about 30, roughly 15 times larger than that of a metal strain gauge but only one third that of an indiffused resistor in single-crystal Si.[203] Higher piezoresistivity and fracture stress would seem to favor SOI for sensor manufacture. However, there is an important counterargument: the piezoresistivity and fracture stress in polysilicon are isotropic, a major design simplification. Moreover, by laser recrystallization, the gauge factor of polysilicon might increase to greater than 50,[204] and by appropriate boron doping the temperature coefficient of resistance (TCR) can reach 0 versus a TCR of, e.g., 1.7×10^{-3} K^{-1} for single-crystal p-type silicon. Neither technical nor cost issues will be the deciding factor in determining which technology will become dominant in the next few years. Micromachining is very much a hostage to trends in the IC industry; promising technologies such as GaAs and micromachining do not necessarily take off, in no small part because of the invested capital in some limited sets of standard silicon technologies. On this basis, SOI surface micromachining is the favored candidate; SOI extends silicon's technological relevance and experiences, increasing investment from the IC industry and thus benefiting SOI micromachining.[192]

Based on the above, we believe that SOI micromachining not only introduces an improved method of making many simple micromachines, but it also will probably become the favored

approach of the IC industry. A summary of SOI advantages is listed below:

- IC industry use in all type of applications such as MOS, bipolar digital, bipolar linear, power devices, BiCMOS, CCDs, and heterojunction bipolar[205]
- Batch packaging through embedded cavities
- CMOS compatibility
- Substrate industrially available at increasingly lower costs (about $200 today)
- Excellent mechanical properties of the single-crystalline surface layer
- Freedom of shapes in the *x*-*y* dimensions and continually improving dry etching techniques, resulting in larger aspect ratios and higher features
- Freedom to choose a very well-controlled range of thicknesses of epi surface layers
- SiO_2 buried layer as sacrificial and insulating layer and excellent etch stop
- Dramatic reduction of process steps as the SOI wafer comes with several "embedded" process steps
- High-temperature operation

A tutorial on SOI can be found at http://www.freescale.com/webapp/sps/site/overview.jsp?code=TM_SOI.

Hinged Polysilicon

One way to achieve high vertical structures with surface micromachining is to build large, flat structures horizontally and then rotate them on a hinge to an upright position. Pister et al.[194–203] developed the polysilicon hinges shown in Figure 7.85A; on these hinges, long structural polysilicon features (1 mm and beyond) can be rotated out of the plane of a substrate. To make these hinged structures, a 2-µm-thick PSG oxide layer (PSG-1) is deposited on the Si substrate as the sacrificial material, followed by the deposition of the first polysilicon layer (2-µm-thick Poly 1). Photolithography and dry etching to form the desired structural elements, including hinge pins to rotate them, pattern the polysilicon structural layer. Following the deposition and patterning of Poly 1, another layer of sacrificial material (PSG-2) of 0.5-µm thickness is deposited (Figure 7.85Aa). Contacts are made through both PSG layers to the Si substrate, and a second layer of polysilicon is deposited and patterned (Poly 2), forming a staple to hold

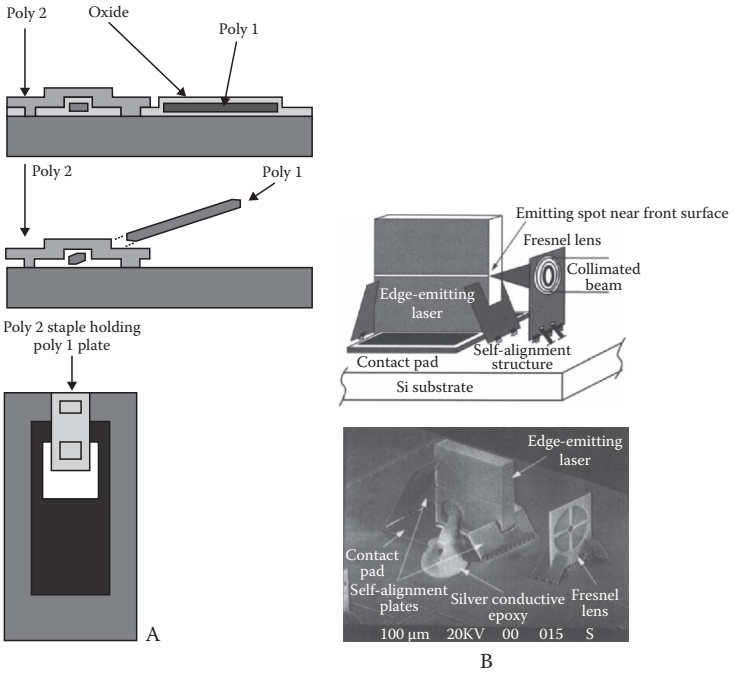

FIGURE 7.85 Microfabricated hinges. (A) Cross-section, side view, and top view of a single-hinged plate before and after the sacrificial etch. SEM of a hinge (MCNC). (B) Schematic (top) and SEM micrograph of the self-aligned hybrid integration of an edge-emitting laser with a micro-Fresnel lens. (From Lin, L. Y., S. S. Lee, M. C. Wu, and K. S. J. Pister. 1995. *Proceedings: IEEE micro electro mechanical systems (MEMS '95)*. Amsterdam, the Netherlands: IEEE. With permission.[206])

the first polysilicon layer hinge to the surface (Figure 7.85Ab). The first and second layers of poly are separated everywhere by PSG-2 for the first polysilicon layer to freely rotate off the wafer surface when the PSG is removed in a sacrificial etch. After the sacrificial etch, the structures are rotated in their respective positions (Figure 7.85Ac). This is accomplished in an electrical probe station by skillfully manipulating the movable parts with the probe needles. Once the components are in position, high friction in the hinges tends to keep them in the same position. To obtain more precise and stable control of position, additional hinges and supports are incorporated. To provide electrical contact to the vertical polysilicon structures, one can rely on the mechanical contact in the hinges, or polysilicon beams (cables) can be attached from the vertical structure to the substrate.

Pister's research team made a wide variety of hinged microstructures, including hot wire anemometers, a box dynamometer to measure forces exerted by embryonic tissue, a parallel-plate gripper,[207] a microwindmill,[208] a microoptical bench (MOB) for free-space integrated optics,[206] and a standard CMOS single piezoresistive sensor to quantify the single heart cell contractile forces of a rat.[209] One example from this group's efforts is illustrated in Figure 7.85B, showing an SEM photograph of an edge-emitting laser diode shining light onto a collimating micro-Fresnel lens.[206] The micro-Fresnel lens in the SEM photo is surface micromachined in the plane and erected on a polysilicon hinge. The lens has a diameter of 280 μm. Alignment plates at the front and the back sides of the laser are used for height adjustment of the laser spot so that the emitting spot falls exactly onto the optical axis of the micro-Fresnel lens. After assembly, the laser is electrically contacted by silver epoxy. Although this hardly outlines standard IC manufacturing practices, excellent collimating ability for the Fresnel lenses has been achieved. The eventual goal of this work is a microoptical bench (MOB), in which microlenses, mirrors, gratings, and other optical components are prealigned in the mask layout stage using computer-aided design. Additional fine adjustment would be achieved by on-chip microactuators and micropositioners such as rotational and translational stages. Erecting these polysilicon structures with the probes of an electrical probe station and, occasionally, assembly by chance in the HF etch or deionized water rinse represent too complicated or too unreliable postrelease assembly methods for commercial acceptance. At the University of Illinois (Urbana), the Micro Actuator, Sensors, and Systems Group headed by Dr. Chang Liu uses magnetic actuation to position a large array of hinged microstructures in parallel. A magnetic material, Permalloy, is electroplated and integrated into the hinged microstructures. The result may be improved manufacturability and stability of these delicate structures.

Friction in polysilicon joints is high because friction is proportional to the surface area (s^2) and becomes dominant over inertial forces (s^3) in the microdomain (see Volume III, Chapter 7). Such joints are not suitable for microrobotic applications. Although attempts have been made to incorporate polysilicon hinges in such applications,[210] plastically deformable hinges make more sense for microrobot machinery involving rotation of rigid components. Noting that the external skeleton of insects incorporates hard cuticles connected by elastic hinges, Suzuki et al.[146] fabricated rigid polysilicon plates (E = 140 GPa) connected by elastic polyimide hinges (E = 3 GPa) as shown in Figure 7.86. Holes in the polysilicon plates shorten the PSG etch time compared with plates without holes. The plates without holes remain attached to the substrate, whereas the ones with holes are completely freed. Using electrostatic actuators, the structure shown in Figure 7.85 can be made to flap like the wing of a butterfly. By

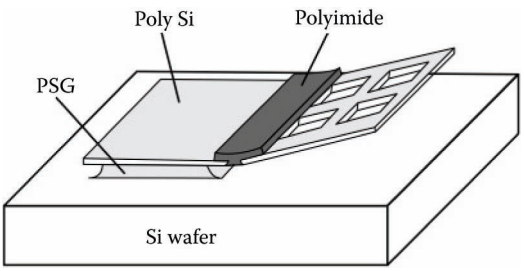

FIGURE 7.86 Flexible polyimide hinge and polysilicon plate (butterfly wing). (From Kim, Y. W., and M. G. Allen. 1991. *Sixth international conference on solid-state sensors and actuators (Transducers '91).* San Francisco: IEEE. With permission.[143])

applying an AC voltage of 10 kHz, resonant vibration of such a flapping wing was observed.[144]

Hoffman et al.[211] demonstrated aluminum plastically deformable hinges on oxide movable thin plates. Oxide plates and Al hinges were etched free from a Si substrate by using XeF_2, a vapor phase etchant exhibiting excellent selectivity of Si over Al and oxide. According to the authors, this process, because of its excellent CMOS compatibility, might open the way to designing and fabricating sophisticated integrated CMOS-based sensors with rapid turnaround time (see also Chapter 3).

Milliscale Molded Polysilicon Structures

The manual assembly of fabricated microparts complicates assembly of tall 3D features in the hinged polysilicon approach we just described, which is similar to building a miniature boat in a bottle. Keller, while at the University of California, Berkeley, came up with an elegant alternative for building tall, high-aspect-ratio microstructures in a process that does not require postrelease assembly steps.[97] The technique involves deep dry etching of trenches in a Si substrate, deposition of sacrificial and structural materials in those trenches, and demolding of the deposited structural materials by etching away the sacrificial materials. CVD processes can typically only deposit thin films (~1–2 μm) on flat surfaces. If, however, these surfaces are the opposing faces of deep narrow trenches, the growing films will merge to form solid beams. In this fashion, high-aspect-ratio structures that would normally be associated with LIGA now also can be made of CVD polysilicon. The procedure is illustrated in Figure 7.87.[97,212] The first step is to etch deep trenches into a silicon wafer. The depth of the trenches equals the height of the desired beams and is limited to about 100 μm with aspect

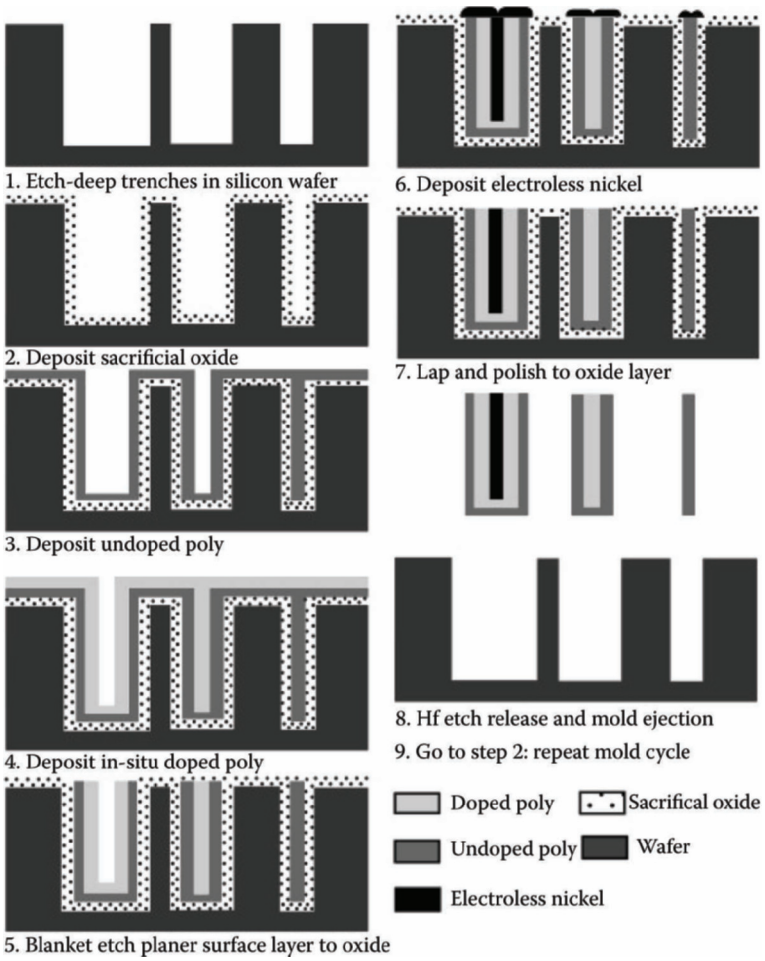

FIGURE 7.87 Schematic illustration of HEXSIL process. The mold wafer may be part of an infinite loop. (Courtesy of Dr. C. Keller, MEMS Precision Instruments.)

ratios of about 10 (e.g., a 10-μm-diameter hole with a depth of 100 μm). For trench etching, Keller uses a Cl_2 plasma etch with the following approximate etching conditions: flow rates of 200 sccm for He and 180 sccm for Cl_2, a working pressure of 425 mTorr, a power setting of 400 W, and an electrode gap of 0.8 cm. The etch rate for Si in this mode equals 1 μm/min. Thermal oxide and CVD oxide act as masks with 1 μm of oxide needed for each 20 μm of etch depth. Before the Cl_2 etch, a short 7-s SF_6 pre-etch removes any remaining native oxide in the mask openings. During the chlorine etch, a white sidewall passivating layer must be controlled to maintain perfect vertical sidewalls. After every 30 min of plasma etching, the wafers are submerged in a silicon isotropic etch long enough to remove the residue.[213] Beyond 100 μm, severe undercutting occurs, and the trench cross-section becomes sufficiently ellipsoidal to prevent molded parts from being pulled out. Advances in dry cryogenic etching are continually improving attainable etch depths, trench profiles, and minimum trench diameter. We can expect continuous improvements in the tolerances of this novel technique. After plasma etching, an additional 1 μm of silicon is removed by an isotropic wet etch to obtain a smoother trench wall surface. Alternatively, to smooth sidewalls and bottom of the trenches, a thermal wet oxide is grown and etched away. The sacrificial oxide in step 2 is made by CVD phosphosilicate glass (PSG) (at 450°C, 140 Å/min), CVD low-temperature oxide (LTO at 450°C), or CVD polysilicon (580°C, 65 Å/min). The latter is completely converted to SiO_2 by wet thermal oxidation at 1100°C. The PSG needs an additional reflowing and densifying anneal at 1000°C in nitrogen for 1 h. This results in an etching rate of the sacrificial layer of ~20 mm/min in 49% HF. The mold shown in Figure 7.87 displays three different trench widths and can be used to build integrated micromachines incorporating doped and undoped polysilicon parts, as well as metal parts. The remaining volume of the narrowest trench after oxide deposition is filled completely with the first deposition of undoped polysilicon (Poly 1) in step 3. The undoped poly will constitute the insulating regions in the micromachine. Undoped CVD polysilicon was formed in this case at 580°C, with a 100-sccm silane flow rate, and a 300-mTorr reactor pressure, resulting in a deposition rate of 0.39 μm/h. The deposited film under these conditions is amorphous or very fine grained. Generally speaking, CVD polysilicon films conform well to the underlying topography on the wafer and show good step coverage. With trenches of an aspect ratio in excess of 10, some thinning of the film on the sidewalls occurs. Because the narrowest trenches are completely filled in by the first deposition, they cannot accept material from later depositions. The trenches of intermediate width are lined with the first material and then completely filled in by the second deposition. In the case illustrated, the second deposition (step 4) consists of in situ doped polysilicon and forms the resistive region in the micromachine under construction. To prevent diffusion of *P* from the doped poly deposited on top of the narrow undoped beams, a blanket etch in step 5 is used to remove the doped surface layer before the anneal of the doped poly. The third deposition, in step 6 of the example case, consists of electroless nickel plating on polysilicon surfaces but not on oxide surfaces and results in the conducting parts of the micromachine. By depositing structural layers in order of increasing conductivity, as done here, regions of different conductivity can be separated by regions of narrow trenches containing only nonconducting material. Lapping and polishing in step 7 with a 1-μm diamond abrasive in oil planarizes the top surface, readying it for HF etch release and mold ejection in step 8. Annealing of the polysilicon is required to relieve the stress before removing the parts from the wafer so they remain straight and flat. In step 8, the sacrificial oxide is dissolved in 49% HF. A surfactant such as Triton X100 is added to the etch solution to facilitate part ejection by reducing surface adhesion between the part and the mold. The parts are removed from the wafer, and the wafer may be returned to step 2 for another mold cycle. An example micromachine, resulting from the described process, is the thermally actuated tweezers shown in Figure 7.88. These HEXSIL tweezers measure 4 mm long, 2 mm wide, and 80 μm tall. The thermal expansion beam to actuate the tweezers consists of the in situ doped polysilicon; the insulating parts are made from the undoped polysilicon material. Nickel-

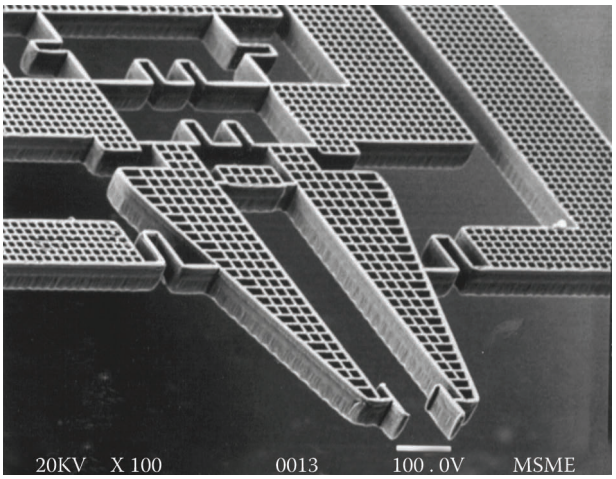

FIGURE 7.88 SEM micrograph of HEXSIL tweezers: 4 mm long, 2 mm wide, and 80 µm tall. Lead wires for current supply are made from nickel-filled polysilicon beams; in situ phosphorus-doped polysilicon provides the resistor part for actuation. The width of the beam is 8 mm: 2 mm polysilicon, 4 mm nickel, and 2 mm polysilicon. (Courtesy of Dr. C. Keller, MEMS Precision Instruments.)

filled polysilicon beams are used for the current supply leads. It is possible to combine the HEXSIL process with classical polysilicon micromachining, as illustrated in Figure 7.89a, where HEXSIL forms a stiffening rib for a membrane filter fashioned by surface micromachining of a surface polysilicon layer. The surface polysilicon is deposited after HEXSIL. A critical need in HEXSIL technology is controlled mold ejection. Keller et al.[213] have experimented with HEXSIL-produced bimorphs, making the structure spring up after release. Keller at MEMS Precision Instruments is exploiting HEXSIL technology commercially (http://www.memspi.com). Keller did his early HEXSIL work at the University of California, Berkeley and later incorporated the Bosch deep RIE process (see Chapter 3) to create tweezers structures similar to the one shown in Figure 7.88, which can now be fabricated in single-crystal silicon (see Figure 7.89b). MEMS Precision Instruments today makes microtweezers with one of three processes: HEXSIL, deep RIE Bosch process, or Sandia's SUMMiT-V process.

Thick Polysilicon

Applying classical LPCVD to obtain polysilicon deposition is a slow process. For example, a layer of 10 µm typically requires a deposition time of 10 h.

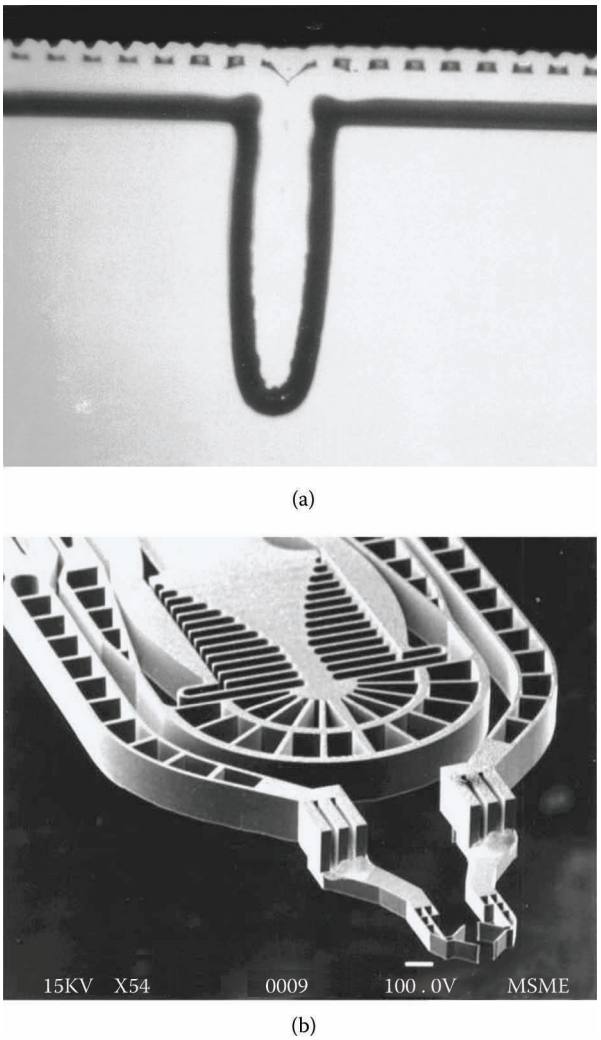

FIGURE 7.89 (a) SEM micrograph of surface-micromachined membrane filter with a stiffening rib (50 mm high). Original magnification 1000×. (b) Single-crystal microtweezers made by the Bosch deep RIE process. (Courtesy of Dr. C. Keller, MEMS Precision Instruments.)

Consequently, most micromachined structures are based on layer thicknesses in the 2–5-µm range. Basing their process on dichlorosilane (SiH_2Cl_2) chemistry, Lange et al.[98] developed a CVD process in a vertical epitaxy batch reactor with deposition rates as high as 0.55 µm/min at 1000°C. The process yields acceptable deposition times for thicknesses in the 10-µm range (20 min). The highly columnar polysilicon films are deposited on sacrificial SiO_2 layers and exhibit low internal tensile stress, making them suitable for surface micromachining. The surface roughness comprises about 3% of the thickness, which might preclude some applications.

Kahn et al.[214] made mechanical property test structures from thick undoped and in situ B-doped

polysilicon films. The elastic modulus of the B-doped polysilicon films was determined as 150 ± 30 GPa. The residual stress of as-deposited undoped thick polysilicon was determined as 200 ± 10 MPa.

This "thick epi-polysilicon surface micromachining" has been used to fabricate accelerometers with a seismic mass thickness well beyond what regular micromachining can achieve (http://www.sensorscan.com/sensoren/sensoren/accelerometer_1.htm).

Resists as Structural Elements and Molds in Surface Micromachining

Introduction Deep UV photoresists were covered in Chapter 1. In this section, we briefly reiterate some of the material covered there in the context of surface micromachining. Deep UV photoresists enable the molding of high-aspect-ratio microstructures in a wide variety of moldable materials, or they are used directly as structural elements in the case of permanent photoresists.

UV Depth Lithography

Polyimide Surface Structures Because of their transparency to exposing UV light, polyimide surface structures can be made very high and exhibit LIGA-like high-aspect ratios. By using multiple coats of spun-on polyimide, thick suspended plates are possible. Moreover, composite polyimide plates can be made, depositing and patterning a metal film between polyimide coats. Polyimide surface microstructures are typically released from the substrate by selectively etching an aluminum sacrificial layer, although Cu and PSG (e.g., in the polyimide flapping wing in Figure 7.86) have been used as well (see also Table 7.23).

Polyimides, because they are easily deformed, usually do not qualify as mechanical members but have been used, for example, in plastically deformable hinges (see Figure 7.86).[144,211] An early result in polyimide surface micromachining was obtained at SRI International, where polyimide pillars (spacers) about 100 µm in height were used to separate a Si wafer, which was equipped with a field emitter array, from the display glass plate of a field emission flat panel display.[215] The concept of a field emission display is illustrated in Figure 7.90a. The flat panel display and an SEM picture of the pillars are shown in Figure 7.90b. The field-emitter tip arrays are positioned between these supporting polyimide posts. The Probimide 348 FC formulation of Ciba-Geigy was used. This viscous precursor formulation (48% by weight of a polyamic ester, a surfactant for wetting, and a sensitizer) with a 3500 cs viscosity was applied to the Si substrate and formed into a film of a 125-µm thickness by spinning. A 30- to 40-min prebake at about 100°C removed the organic solvents from the precursor. The mask with the pillar pattern was then aligned to the wafer coated with the precursor and subjected to about 20 min of UV radiation. After driving off moisture by another baking operation, the coating, still warm, was spray developed (QZ 3301 from Ciba-Geigy), revealing the desired spacer matrix. By baking the polyimide at 100°C in a high vacuum (10^{-9} Torr), the pillars shrunk to about 100 µm, whereas the polyimide became more dense and exhibited greater structural integrity.

Frazier et al.[216] obtained a height-to-width aspect ratio of about 7 with polyimide structures. Ultraviolet was used to produce structures with heights in the range of 30–50 µm. At greater heights, the verticality of the sidewalls became relatively poor. Spun-on thickness in excess of 60 µm in a single coat was obtained for both Ciba-Geigy and Dupont commercial UV-exposable, negative-tone polyimides. Using a G-line mask aligner, exposure energy of 350 mJ/cm^2 was sufficient to develop a pattern with the Ciba-Geigy QZ 3301 developer. Allen and his team combined polyimide insert molds with electrodeposition to make a wide variety of metal structures.[217]

Other Resists Used for UV Deep Lithography Surface Micromachining Besides polyimides, research on Novolak-type resists also is leading to higher 3D features. Lochel et al.[206] use Novolak, positive tone resists of high viscosity (e.g., AZ 4000 series, Hoechst). They deposit, in multiple-coating process, layers up to 200 µm thick in a specially designed spin coater that incorporates a corotating cover. The subsequent deep UV lithography yields patterns with aspect ratios up to 10, steep edges (more than 88°), and a minimum feature size down to 3 µm. By combining this resist technology with sacrificial

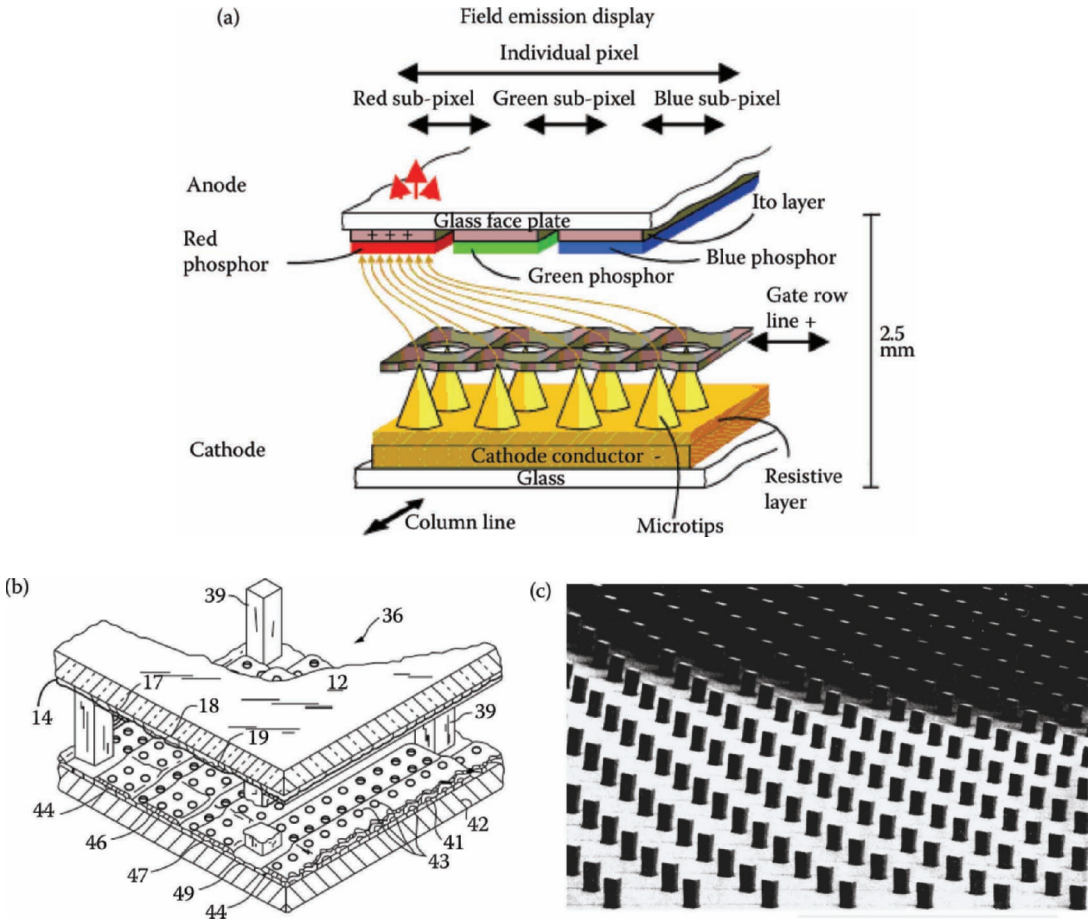

FIGURE 7.90 Polyimide structural elements. (a) Principle of a field emission display. (b) Micro-machined flat panel display. Number 39 represents one of the spacer pillars in the matrix of polyimide pillars (100 mm high). The spacer array separates the emitter plate from the front display plate. (c) SEM of the spacer matrix. (Courtesy of Dr. I. Brodie.) The height of the pillars is similar to what can be accomplished with LIGA. Because only a simple UV exposure was used, this polyimide is referred to as poor man's LIGA process, or pseudo-LIGA. (From I. Brodie et al., US Patent 4,923,421, 1990; and Brodie, I., H. R. Gurnick, C. E. Holland, and H. A. Moessner. 1990. *Method for providing polyimide spacers in a field emission panel display.*[215])

layers and electroplating, a wide variety of 3D microstructures result.

Along the same line, researchers at IBM experimented with Epon SU-8 (Shell Chemical), an epoxy-based, onium-sensitized, UV transparent negative photoresist used to produce high-aspect-ratio (>10:1) features and straight sidewalled images in thick film (>200 μm) using standard lithography.[218,219] SU-8 imaged films were used as stencils to plate Permalloy for magnetic motors.[218]

Patterns generated with these thick resist technologies should be compared with LIGA-generated patterns, not only in terms of aspect ratio but also in terms of sidewall roughness and sidewall run-out. Such a comparison will determine which surface machining technique to use for the job.

Porous Polysilicon

In Chapter 4, we discussed the transformation of single-crystal Si into a porous material with porosity and pore sizes determined by the current density, type, and concentration of the dopant, and the hydrofluoric acid concentration. A transition from pore formation to electropolishing is reached by increasing the current density and/or by decreasing the hydrofluoric acid concentration.[101,102] Porous silicon can also be formed under similar conditions from LPCVD polysilicon.[103] In this case, pores roughly follow the grain boundaries of the polysilicon. Figure 7.91 illustrates the masking and process sequence to prepare a wafer to make thin layers of porous Si between two insulating layers of low

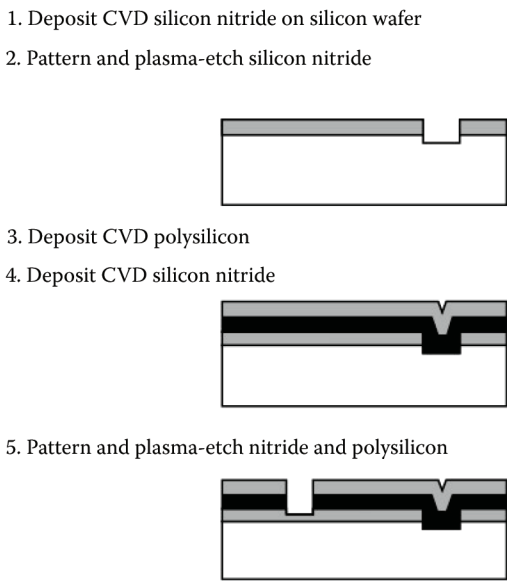

FIGURE 7.91 Masking and process sequence preparing a wafer for laterally grown porous polysilicon. (From Field, L. 1987. EECS/ERL Res. summary. University of California, Berkeley. With permission.[220])

stress silicon nitride.[220] The wafer, after the process steps outlined in Figure 7.91, is put in a Teflon test fixture, protecting the back from HF attack. An electrical contact is established on the back of the wafer, and a potential is applied with respect to a platinum-wire counter electrode immersed in the same HF solution. Electrolytes consisting of 5–49 wt% HF and current densities from 0.1–50 A cm^{-2} are used. The advance of a pore-etching front, growing parallel to the wafer surface, may be monitored using a line-width measurement tool. The highest observed rate of porous-silicon formation is 15 µm min^{-1} (in 25 wt% HF). In the electropolishing regime, at the highest currents, the etch rate is diffusion limited, but the reaction is controlled by surface reaction kinetics in the porous Si growth regime.

By changing the conditions from pore formation to electropolishing and back to porous Si, an enclosed chamber may be formed with porous polysilicon walls (plugs) and "floor and ceiling" silicon nitride layers. Sealing of the cavities by clogging the microporous polysilicon was attempted by room temperature oxidation in air and in an H_2O_2 solution. Leakage through the porous plug persisted after those room temperature oxidation treatments, but with a Ag deposition from a 400-mM $AgNO_3$ solution and subsequent atmospheric tarnishing (48 h, Ag_2S) the chambers appeared to be sealed, as determined from the lack of penetration by methanol. This technology might open up possibilities for filling cavities with liquids and gases under low-temperature conditions. The chamber provided with a porous plug might also make a suitable on-chip electrochemical reference electrode with an electrolyte reservoir.

Hydrofluoric acid can penetrate thin layers of polysilicon either at foreign particle inclusion sites or at other critical film defects, such as grain boundaries (see above). This way, the HF can etch underlying oxide layers, creating, for example, circular regions of freestanding polysilicon, so-called *blisters*. The polysilicon permeability associated with blistering of polysilicon films has been applied successfully by Judy et al.[221,222] to produce thin-shelled hollow beam electrostatic resonators from thin polysilicon films deposited onto PSG. The possible advantage of using these hollowed structures is to obtain a higher resonator quality factor *Q*. The devices were made in such a way that the 0.3-µm-thick undoped polysilicon completely encased a PSG core. After annealing, the structures were placed in HF, which penetrated the polysilicon shell and dissolved away the PSG, eliminating the need for etch windows. It was not possible to discern the pathways through the polysilicon using TEM.

Lebouitz et al.[223] applied permeable polysilicon etch-access windows to increase the speed of creating microshells for packaging surface-micromachined components. After etching the PSG through the many permeable Si windows, the shell is sealed with 0.8 µm of low-stress LPCVD nitride.

Porous Si can be used very effectively as a sacrificial layer both in polysilicon surface micromachining and in SOI micromachining (see Table 7.23).[139] The high surface area of the porous Si results in rapid etching in KOH at room temperature. The porous layer can be formed directly under a deposited layer or under the epilayer in SOI surface micromachining.

Silicon is not the only material that can be converted into a porous sponge-like material. Most semiconductor materials can be modified this way, and in Volume III, Chapter 5 on selected MEMS and NEMS materials we discuss micromachining of

high-aspect-ratio structures in porous anodic aluminum oxide. The latter enables a class of MEMS applications such as high-temperature gas microsensors, vacuum microelectronics, RF-MEMS, nozzles, filters, membranes, and so on.[224]

Comparison of Bulk Micromachining with Surface Micromachining

Surface and bulk micromachining have many processes in common. Both techniques rely heavily on photolithography; oxidation; diffusion and ion implantation; LPCVD and PECVD for oxide, nitride, and oxynitride; plasma etching; use of polysilicon; and metallizations with sputtered, evaporated, and plated Al, Au, Ti, Pt, Cr, and Ni. Where the techniques differ is in the use of anisotropic etchants, anodic and fusion bonding, (100) versus (110) starting material, p^+ etch stops, double-sided processing and electrochemical etching in bulk micromachining, and the use of dry etching in patterning and isotropic etchants in release steps for surface micromachines. Combinations of substrate and surface micromachining also frequently appear. The use of polysilicon avoids many challenging processing difficulties associated with bulk micromachining and offers new degrees of freedom for the design of integrated sensors and actuators. Design freedom includes many more possible shapes in the *x,y* plane and the ease of integration of several sensors on one die (e.g., a two-axis accelerometer). The technology combined with sacrificial layers also allows the nearly indispensable further advantage of in situ assembly of the tiny mechanical structures because the structures are preassembled as a consequence of the fabrication sequence. Another advantage focuses on thermal and electrical isolation of polysilicon elements. Polycrystalline piezoresistors can be deposited and patterned on membranes of other materials, for example, on a SiO_2 dielectric. This configuration is particularly useful for high-temperature applications. The p-n junctions act as the only electrical insulation in the single-crystal sensors, resulting in high leakage currents at high temperatures, whereas current leakage for the polysilicon/SiO_2 structure virtually does not exist. The limits of surface micromachining are striking. CVD silicon usually caps at layers no thicker than 1–2 μm because of residual stress in the films and the slow deposition process (thick polysilicon needs further investigation).* A combination of a large variety of layers may produce complicated structures, but each layer is still limited in thickness. Also, the wet chemistry needed to remove the interleaved layers may require many hours of etching (except when using the porous Si option discussed above), and even then stiction often results.

The structures made from polycrystal silicon exhibit inferior electronic and slightly inferior mechanical properties compared with single-crystal silicon. For example, polysilicon has a lower piezoresistive coefficient (resulting in a gauge factor of 30 vs. 90 for single-crystal Si), and it has a somewhat lower mechanical fracture strength. Polysilicon also warps because of the difference of thermal expansion coefficient between polysilicon and single-crystal silicon. Its mechanical properties strongly depend on processing procedures and parameters.

Table 7.25 introduces a comparison of surface micromachining with wet bulk micromachining. The status depicted reflects the mid-1990s and only includes polysilicon surface micromachining. As discussed, SOI micromachining, thick polysilicon, hinged polysilicon, polyimide, and millimeter-molded polysilicon structures have dramatically expanded the application bandwidth of surface micromachining. In Chapter 10 on replication techniques-LIGA, we will see how x-ray lithography further expands the *z*-direction for new surface-micromachined devices with unprecedented aspect ratios and extremely low surface roughness. In Table 7.26 we compare physical properties of single-crystal silicon with those of polysilicon.

Although polysilicon can be an excellent mechanical material, it remains a poor electronic material. Reproducible mechanical characteristics are difficult and complex to consistently realize. Fortunately, SOI surface micromachining and other newly emerging surface micromachining techniques can alleviate many of the problems.[229]

* As a direct consequence, the inertial mass in a surface-micromachined accelerometer, such as the ADXL05 from Analog Devices, is only 0.3 μg, and the corresponding noise, dominated by Brownian noise, is 500 μg/√Hz. By contrast, the mass for a bulk-micromachined accelerometer can easily be made 100 μg.

Table 7.25 Comparison of Bulk Micromachining with Surface Micromachining

Bulk Micromachining	Surface Micromachining
Large features with substantial mass and thickness	Small features with low thickness and mass
Uses both sides of the wafer	Multiple deposition and etching required to build up structures
Vertical dimensions: one or more wafer thicknesses	Vertical dimensions are limited to the thickness of the deposited layers (~2 μm) leading to compliant suspended structures with the tendency to stick to the support
Generally involves laminating Si wafer to Si or glass	Surface micromachined device has its built-in support and is more cost effective
Piezoresistive or capacitive sensing	Capacitive and resonant sensing mechanisms
Wafers may be fragile near the end of the production	Cleanliness critical near end of process
Sawing, packaging, testing is difficult	Sawing, packaging, testing is difficult
Some mature products and producers	No mature products or producers
Not very compatible with IC technology	Natural but complicated integration with circuitry; integration is often required due to the tiny capacitive signals

Table 7.26 Comparison of Materials Properties of Si Single Crystal with Crystalline Polysilicon

Material Property	Single-Crystal Si (SCS)	Polysilicon
Thermal conductivity (W/cm°K)	1.57	Strong function of the grain structure of the film; 0.30–0.35 (for fine grains and double that for larger grains)
Thermal expansion (10^{-6}/°K)	2.33	2–2.8
Specific heat (cal/g°K)	0.169	0.169
Piezoresistive coefficients	n-Si (π_{11} = –102.2) p-Si (π_{44} = +138.1) e.g., gauge factor of 90	e.g., gauge factor of 30 (>50 with laser recrystallization)
Refractive index		4.1 at 600 nm
Mobility ($cm^2/V/s$)	Holes: 600 Electrons: 1500	Maximum for electrons: 30
Density (cm^{-3})	2.32	2.32
Fracture strength (GPa)	6	0.8–2.84 (Undoped polysilicon)
Dielectric constant	11.9	Sharp maxima of 4.2 and 3.4 eV at 295 and 365 nm, respectively
Residual stress	None	Depends on structure as deposited films are compressive
Temperature resistivity coefficient ($°C^{-1}$)TCR	0.0017 (p-type)	0.0012 nonlinear, + or – through selective doping, increases with decreasing doping level can be made 0!
Poisson ratio	0.262 max for (111)	0.23
Young's modulus (10^{11} N/m^2)	1.90 (111)	1.61
Resistivity at room temperature (ohm.cm)	Depends on doping	Strong function of the grain structure of the film. Plateaus at 4 10^{-4} above 1 10^{21} cm^{-3} P (always higher than for SCS)

Examples

Example 7.9: Analog Devices Accelerometer

Both Robert Bosch GmbH (Stuttgart, Germany) and Analog Devices (Norwood, MA) offer surface-micromachined accelerometers based on lateral resonators. We will only review the Analog Devices ADXL accelerometer product family here. The ADXL-50 constituted the first commercially available surface-micromachined MEMS structures. Today, surface-micromachined accelerometers are incorporated in Ford and General Motors cars, among others, as well as inside joysticks for computer games, robots, watches, and shoes.

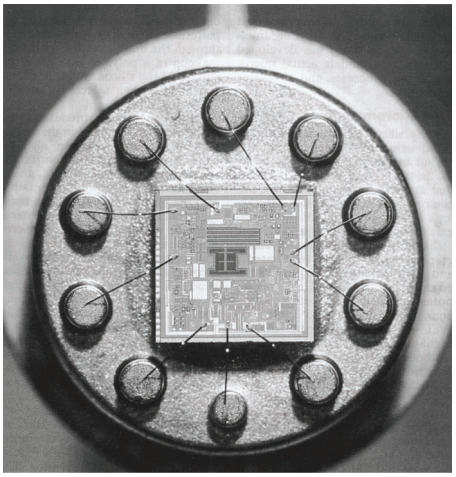

FIGURE 7.92 Analog Devices' ADXL-50 accelerometer with a surface-micromachined capacitive sensor (center), on-chip excitation, self-test, and signal-conditioning circuitry. (From Core, T. A., W. K. Tsang, and S. J. Sherman. 1993. Fabrication technology for an integrated surface-micromachined sensor. *Solid State Technol* 36:39–47. With permission.[119])

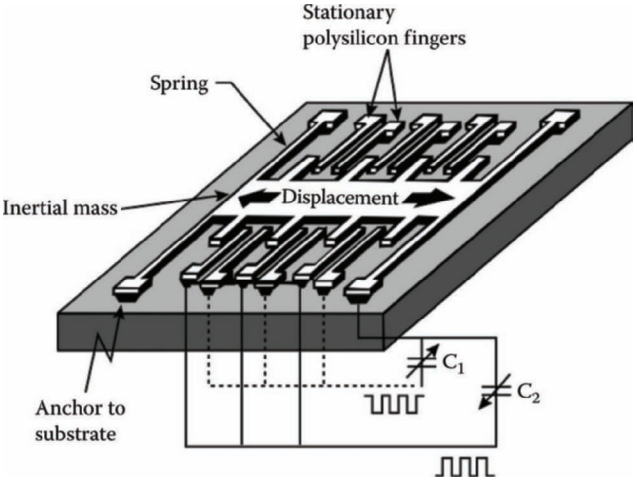

FIGURE 7.93 Illustration of the basic mechanical structure of Analog Devices' ADXL family of surface-micromachined accelerometers. A comb-like plate suspended from springs forms the inertial mass. Displacements of the mass are measured capacitively with respect to two sets of stationary finger-like electrodes. (Based on Maluf, N. 2000. *An introduction to microelectromechanical systems engineering.* Boston: Artech House.[3])

To facilitate integration of their surface-micromachined accelerometers with on-board electronics, Analog Devices opted for a mature 4-μm BiCMOS process.[119] BiCMOS is a manufacturing process for semiconductor devices that combines bipolar and CMOS to give the best balance between available output current and power consumption. Figure 7.92 presents a photograph of the finished accelerometer with on-chip excitation, self-test, and signal conditioning circuitry.

The suspended comb-like H-shaped structure in the center of the die is the sensitive element, and its primary axis of sensitivity lies in the plane of the die (*x-y* plane). In bulk micromachining, the sense axis is more often orthogonal to the plane of the die (*z*-axis). The polysilicon-sensing element of the ADLAX-50 only occupies 5% of the total die area and consists of three sets of 2-μm-thick polysilicon finger-like electrodes (Figure 7.93).

Two sets are anchored to the substrate, and a third set is suspended about 1 μm above the surface by means of two folded polysilicon beams acting as suspension springs. The fingers of the movable shuttle mass are interlaced with the fingers of the two fixed sets. The whole chip measures 500 × 625 μm and operates as an automotive airbag deployment sensor. The measurement accuracy is 5% over the ±50-g range. Deceleration in the axis of sensitivity exerts a force on the central mass that, in turn, displaces the interleaved capacitor plates, causing a fractional change in capacitance. The overall capacitance is small, typically on the order of 100 fF, and for the ADXL-05 (rated at ±5 g), with an inertial mass of 0.3 μg only, the capacitance change is as small as 100 aF.[197] These small capacitance changes necessitate on-chip integrated electronics to reduce the impact of parasitic sources. In operation, the ADXL family has a force-balance electronic control loop to prevent the mass from macroscopic movements, greatly improving output linearity because the center element never moves by more than a few nanometers. Applying a large-amplitude, low-frequency voltage, below the natural frequency of the sensor, allows one to compensate for accelerometer plate movement by external acceleration. At the same time, the sensing excitation frequency (1 MHz) is much higher than the resonant frequency, so that it does not produce an actuation force on the capacitor plates. As long as sense and actuation signals do not interfere, sense and actuation plates may be the same. Straight flexures were used for the layout of the lateral resonator shuttle mass (see also Figure 7.76a).

In the sensor design, n^+ underpasses connect the sensor area to the electronic circuitry, replacing the usual heat sensitive aluminum connect lines. Most of the sensor processing is

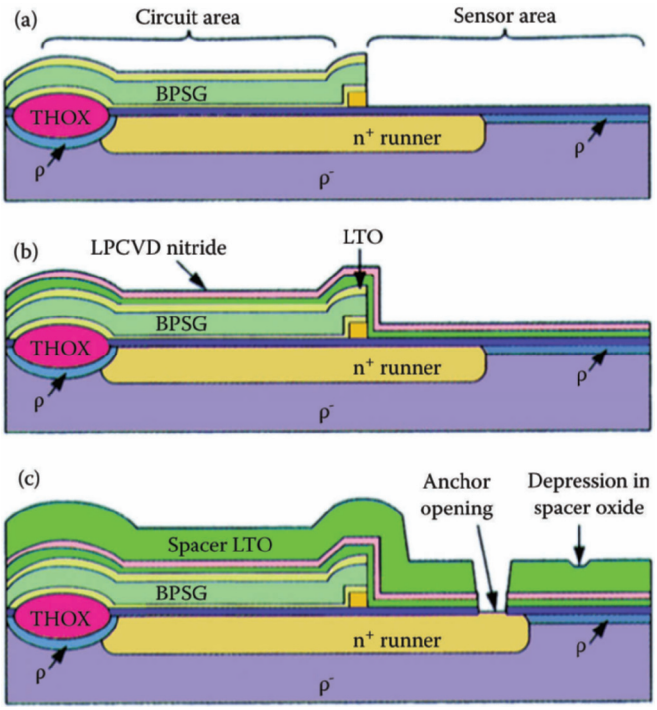

FIGURE 7.94 Preparation of IC chip for polysilicon. (a) Sensor area post-BPSG planarization and moat mask. (b) Blanket deposition of thin oxide and thin nitride layer. (c) Bumps and anchors made in LTO spacer layer. (From Core, T. A., W. K. Tsang, and S. J. Sherman. 1993. Fabrication technology for an integrated surface-micromachined sensor. *Solid State Technol* 36:39–47. With permission.[119])

inserted into the BiCMOS process right after the borophosphosilicate glass (BPSG) planarization. After planarization, a designated sensor region or moat is cleared in the center of the die (Figure 7.94a). A thin oxide is then deposited to passivate the n+ underpass connects, followed by a thin, low-pressure, vapor-deposited nitride to act as an etch stop (buffer layer) for the final polysilicon release etch (Figure 7.94b). The spacer or sacrificial oxide used is a 1.6-μm densified low-temperature oxide (LTO) deposited over the whole die (Figure 7.94c). In a first timed etch, small depressions that will form bumps or dimples on the underside of the polysilicon sensor are created in the LTO layer. These will limit stiction in case the sensor comes in contact with the substrate. A subsequent etch cuts anchors into the spacer layer to provide regions of electrical and mechanical contact (Figure 7.94c). The 2-μm-thick sensor polysilicon is then deposited, implanted, annealed, and patterned (Figure 7.95a). The relatively deep junctions of the BiCMOS process permit the polysilicon thermal anneal and brief dielectric densifications without resulting in degradation of the electronic functions. Next is the IC metallization, which starts with the removal of the sacrificial spacer oxide from the circuit area along with the LPCVD nitride and LTO layer. A low-temperature oxide is deposited on the polysilicon sensor part, and contact openings appear in the IC part of the die where platinum is deposited to form a platinum silicide (Figure 7.95b). The trimmable thin-film material, TiW barrier metal, and Al/Cu interconnect metal are sputtered on and patterned in the IC area. The circuit area is then passivated in two separate deposition steps. First, plasma oxide is deposited and patterned (Figure 7.95c), followed by a plasma nitride (Figure 7.96a) to form a seal with the earlier deposited LPCVD nitride. The nitride acts as an HF barrier in the subsequent long etch release. The plasma oxide left on the sensor acts as an etch stop for the removal of the plasma nitride. Subsequently, the sensor area is prepared for the final release etch.

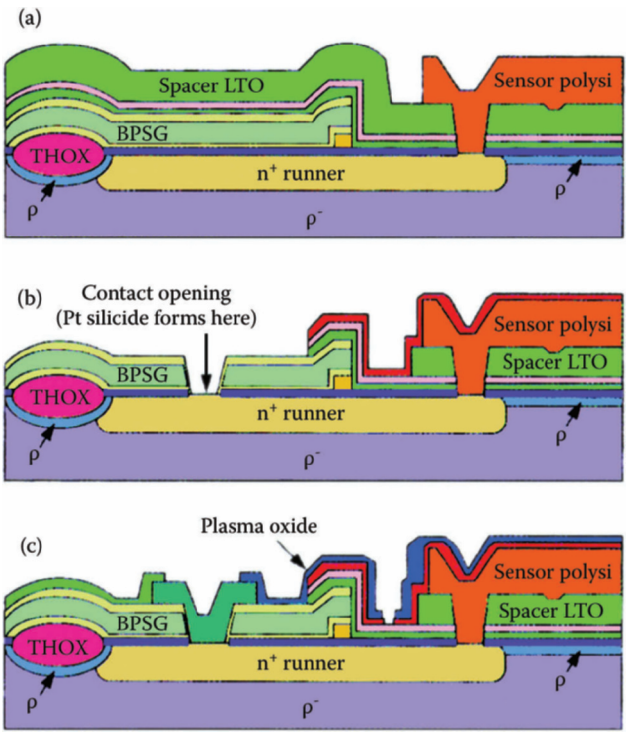

FIGURE 7.95 Polysilicon deposition and IC metallization. (a) Cross-sectional view after polysilicon deposition, implant, anneal, and patterning. (b) Sensor area after removal of dielectrics from circuit area, contact mask, and Pt silicide. (c) Metallization scheme and plasma oxide passivation and patterning. (From Core, T. A., W. K. Tsang, and S. J. Sherman. 1993. Fabrication technology for an integrated surface-micromachined sensor. *Solid State Technol* 36:39–47. With permission.[119])

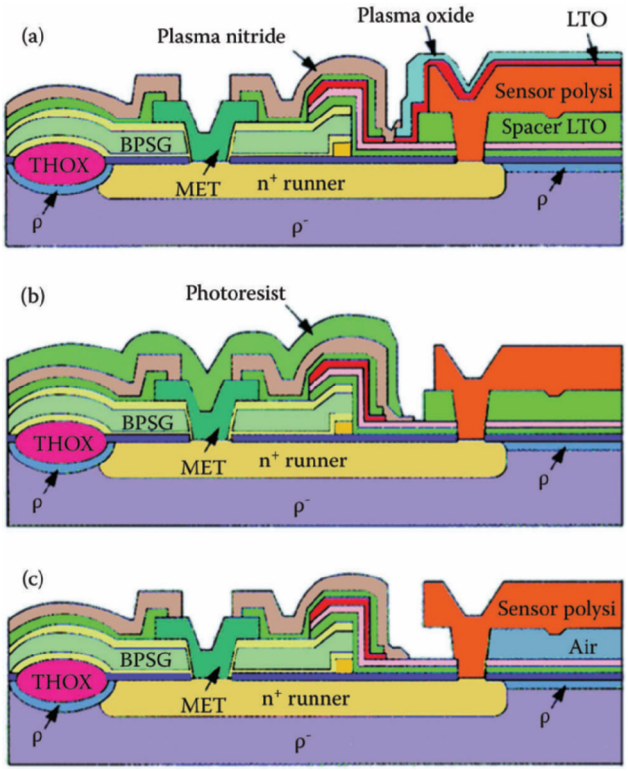

FIGURE 7.96 Prerelease preparation and release. (a) Postplasma nitride passivation and patterning. (b) Photoresist protection of the IC. (c) Freestanding, released polysilicon beam. (From Core, T. A., W. K. Tsang, and S. J. Sherman. 1993. Fabrication technology for an integrated surface-micromachined sensor. *Solid State Technol* 36:39–47. With permission.[119])

The undensified dielectrics are removed from the sensor, and the final protective resist mask is applied. The photoresist protects the circuit area from the long-term buffered oxide etch (Figure 7.96b). The final device cross-section is shown in Figure 7.96c.

Example 7.10: TI Micromirrors

In 1987 the first digital micromirror device (DMD™) was developed at TI by Dr. Larry Hornbeck [US Patent 4,615,595 (October 7, 1986)]. A typical DMD consists of a 2D array of optical switching elements (pixels) on a silicon substrate, as shown in Figure 7.97.

Two pixels are schematically illustrated in Figure 7.98 together with the underlying Si chip and circuitry. Each pixel is made up of a reflective aluminum micromirror supported from a central post. The central mirror post at the back of the mirror is mounted on a lower aluminum metal platform—the yoke. The yoke is suspended

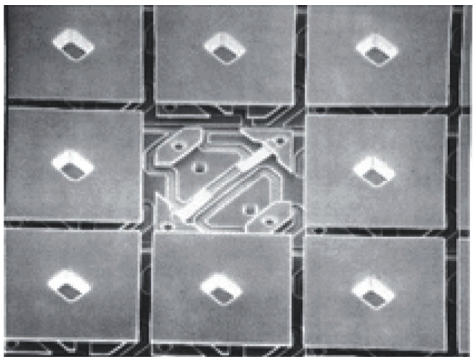

FIGURE 7.97 Texas Instruments DMD pixel array. One pixel has been removed to show the silicon chip below the reflective aluminum mirrors.

above the silicon substrate by thin compliant L-shaped hinges (made from a proprietary Al alloy) anchored to the underlying substrate by two stationary posts. The different components of an individual micromirror are illustrated in Figure 7.99. Two bias electrodes tilt the mirror either +10° or –10° by applying 24 V between one electrode or the other and the yoke. Off-axis illumination of the Al mirror reflects into the projection lens only when the micromirror is in its +10° state, producing a bright appearance or ON state. In the flat position and in the –10° state the pixel appears dark. In the fully deflected position, the yoke touches a landing

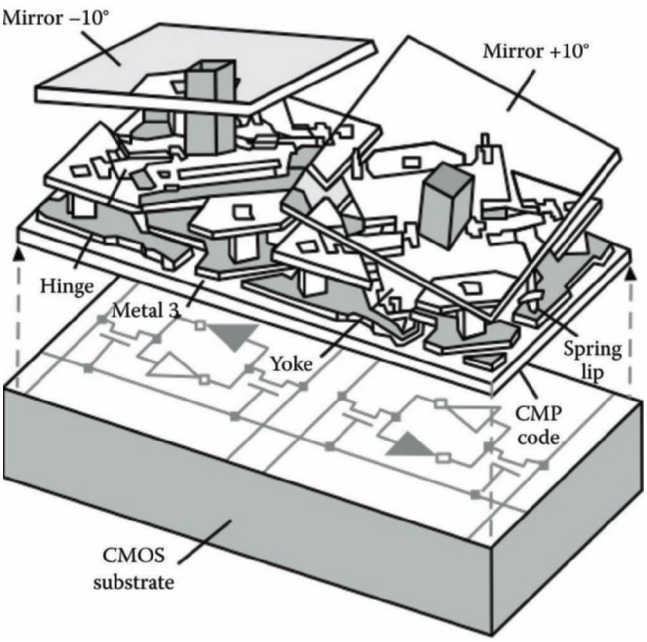

FIGURE 7.98 Schematic of two pixels in a Texas Instruments of a DMD. The mirrors are made transparent for clarity of the drawing. The +10° mirror is in the ON position, and the –10° is in the OFF position.

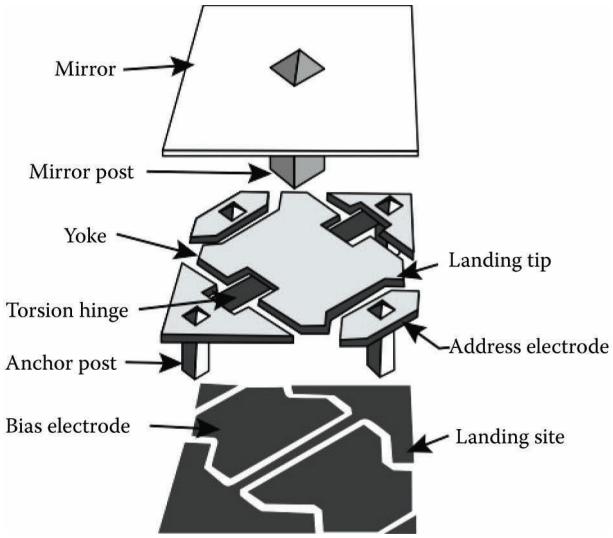

FIGURE 7.99 Illustration of the various components of a single DMD pixel. The basic structure consists of a bottom aluminum layer containing two electrodes, a middle aluminum layer containing a yoke suspended by two torsional hinges, and a top reflective aluminum mirror. An applied electrostatic voltage on a bias electrode deflects the yoke and the mirror toward that electrode. A pixel measures approximately 17 μm on a side. (Adapted from Maluf, N. 2000. *An introduction to microelectromechanical systems engineering.* Boston: Artech House.[3])

site with its landing tips, and because the landing site is biased at the same voltage, electrical shorting is prevented. Once the applied voltage is removed, the springy aluminum alloy hinges restore the micromirror to its initial position. A standard DMD microchip contains more than 442,000 switchable mirrors on a surface 5/8 in. wide. Mirrors are switched according to memory impulses stored in static-random-access memory (SRAM) cells beneath the tiny array, with mirrors tilting plus or minus 10° to reflect light into or away from an imaging lens. The mirrors can be independently cycled at 100,000 flips/s. Grays can be achieved by multiple mirrors or by flipping the mirror quickly between black and white states. Colors can be generated by having the incident light shine through a rotating disk divided into three colored segments: red, blue, and green. A separate image is generated for each color, timed to appear as the appropriate segment covers the light source. Printing and display technology can now enjoy the advantage of digital fidelity and digital stability.

In Figure 7.99, one single pixel is illustrated with its various components.[197]

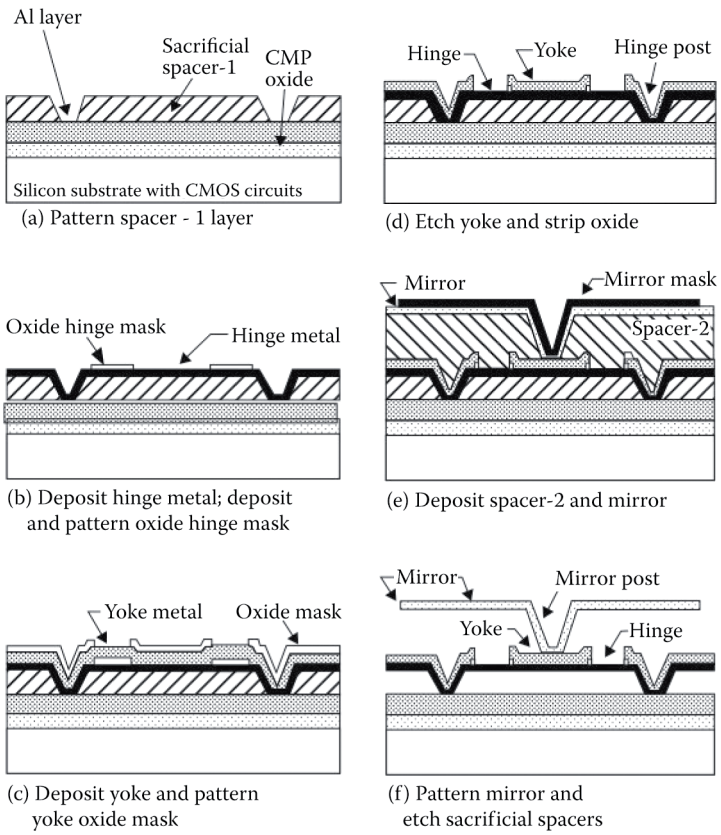

FIGURE 7.100 Fabrication steps of the Texas Instruments DMD. Steps (a) through (f) are explained in the text. (Based on Maluf, N. 2000. *An introduction to microelectromechanical systems engineering.* Boston: Artech House.[3])

The surface micromachining process to fabricate DMDs on wafers incorporating CMOS electronic address and control circuitry is illustrated in Figure 7.100. Because of the underlying active circuitry and the presence of Al metal for connectors and MEMS structures, all micromachining process steps are carried out at temperatures less than 400°C. After completing the CMOS circuitry, a thick oxide is deposited over the whole Si wafer and is chemomechanically polished to provide a flat surface to start building the mirror array. A sputter-deposited Al layer is patterned to provide bias and address electrodes, landing pads, and electrical interconnects to the underlying electronics. Hardened photoresist is used as the sacrificial material (Figure 7.100a). A proprietary Al alloy is sputter deposited to form the hinges for the mirror. It is the nature of this aluminum alloy that secures the mechanical integrity of the mirror actuation. Subsequently, the torsion hinge regions are protected by a patterned thin PECVD-deposited silicon dioxide (Figure 7.100b). In the next step, a thicker coat of another proprietary aluminum alloy is deposited to form the yoke structure; this new coat of Al buries the thin oxide hinge mask. A second PECVD oxide mask is deposited over this second level of Al metal and patterned in the shape of the yoke and anchor posts (Figure 7.100c). In a dry etch step, the exposed aluminum areas are removed down to the organic sacrificial resist except where the oxide hinge mask remains. In those regions, only the thick yoke metal is removed, stopping on the SiO_2 mask and so preserving the underlying hinge structure (Figure 7.100d). Both thin layers of PECVD oxide mask are stripped before a second layer of sacrificial resists is deposited, UV-hardened, and patterned. A third aluminum alloy is sputter deposited and defines the mirror and the central mirror post. Again a thin layer of PECVD silicon dioxide is deposited and patterned to define the mirror (Figure 7.100e). An oxygen plasma etch removes both sacrificial layers and releases the micromirrors (Figure 7.100f). Finally after release a special passivation step deposits a thin antistiction layer to prevent adhesion between the yoke tips and the landing pads. Because the weight of the micromirrors is insignificant, the DMD micromirrors can withstand 1500-G mechanical shocks. Optimization of the hinge metal alloy and fabrication processes have resulted in a mean time between failure of more than 100,000 h. Invented by Larry Hornbeck at TI, DMD is the key component in more than 17 projector brands and brought the first digital cinema to *Star Wars* and *Toy Story II*. A competing technology, the actuated mirror array (AMA; now Daewoo's TMA) invented by Gregory Um, is also a MEMS technology. Unlike DMD, TMA is built with piezo materials, and for high resolution its large array size and consequent cost still pose "sticky issues," but it achieves brightness 15% higher than any other projector. DMDs are also used in place of masks to map the human genome. At the University of Wisconsin, arrays for "gene expression analysis," usually produced with lithographic masks like displays, are being replaced with the same DMD used for projection display to make "virtual masks" containing nearly half a million features.

For his amazing piece of engineering, TI's Larry J. Hornbeck received the first Emmy Award ever bestowed for a projection display technology.

Questions

7.1: What is the mean free path (MFP)? How can you increase the MFP in a vacuum chamber? For metal deposition in an evaporation system, compare the distance between target and evaporation source with the working MFP. Which one has the smaller dimension? 1 atmosphere pressure = … mm Hg = … torr. What are the physical dimensions of impingement rate?

7.2: If we want to deposit a metal film on a substrate by resistance heated evaporation (as opposed to E-beam), what kind of metals are preferred? How is the thickness of a deposited thin film measured during evaporation?

7.3: Why is sputter deposition so much slower than evaporation deposition? Make a detailed comparison of the two deposition methods.

7.4: Develop the principal equation for the material flux to a substrate in a CVD process, and indicate how one moves from a mass transport limited to reaction-rate limited regime.

Explain why, in one case, wafers can be stacked close and vertically, while in the other a horizontal stacking is preferred.

7.5: Describe step coverage in CVD processes. Explain how gas pressure and surface temperature may influence the different coverage profiles.

7.6: Compare sputter deposition with evaporation for a simple metal such as Ag. Compare the two techniques for as many different parameters as you remember. Give examples where you would use one technique over the other.

7.7: CVD: (a) Show different types of step coverage and explain the most important parameters influencing each. (b) Describe the difference between PECVD and LPCVD.

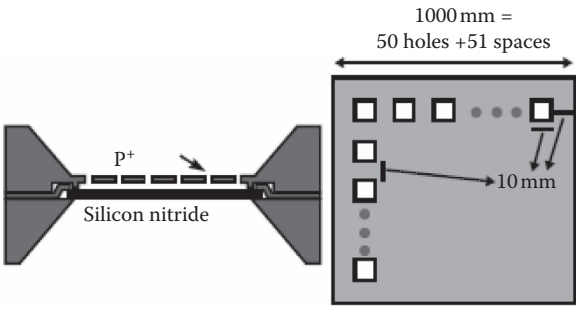
7.8: What are the characteristics of electron beam heated evaporation compared to resistance heated evaporation? Mark correct answers with an X.

( ) It is more complex.
( ) It is very versatile.
( ) It only works under lower temperatures.
( ) Everything a resistance heated evaporator can deposit can also be accommodated by electron beam heated evaporation.
( ) A magnetic field can be used to increase the temperature.
( ) It is not possible to provide a large evaporant surface area in electron beam heated evaporation.
( ) The adhesion between an evaporant and a substrate is accomplished by local reactions (sticking). Titanium and chromium are often used as a "glue" to improve the adhesion between an evaporant and a substrate.
( ) When the partial pressure of an evaporant vapor exceeds its equilibrium vapor pressure, it will condense.
( ) When a system is under equilibrium vapor pressure, the net transfer rate of material from one state to the other state is equal to 1.
( ) The cosine law is the underlying principle that a Kundsen cell can deposit a perfectly uniform coating inside a spherical glass jar.

7.9: Design at least three micromachines enabling the testing of thin film mechanical properties.

7.10: Detail several processes to create vacuum shells in a solid.

7.11: Consider a MEMS-based condenser acoustic transducer as shown in the figure below. The diaphragm is made of silicon nitride, and the back plate is perforated. A stress gauge was used to measure the stress in the silicon nitride and was found to be $1.5 \times 10^8 N/m^2$.



- Thickness of air gap = 5 mm
- Thickness of diaphragm = 5 mm
- Density of $Si_3N_4 = 3 \times 10^3 kg/m^3$

Total of 2500 square holes

(a) Write the differential equation governing the dynamic behavior of the movable diaphragm.
(b) Solve the differential equation under the 3 cases of overdamped, underdamped, and critically damped conditions.
(c) Calculate the mass of the diaphragm, the small signal capacitance, and the air-streaming resistance as per the layout shown if the device is to be operated in air and water.
(d) Calculate the cut-off frequency for the overdamped case in air and in water.

7.12: Discuss the advantages/disadvantages of using surface vs. bulk micromachining.

7.13: Define the following terms in 3–4 lines with examples where applicable:
LPCVD
PECVD
DRIE
Difference between RIE and plasma etching
LIGA process
SCREAM process

Silicon fusion bonding
Dissolved wafer process

7.14: Describe 5 methods you could implement to prevent stiction between surface micromachined components.

7.15: Design a comb drive for the MUMPs process.
(a) Show the mask layouts (top view) of the relevant layers.
(b) Calculate the maximum force, maximum displacement, and resonance frequency that you expect to achieve with this design.

Make sure the following constraints are satisfied:
- The total number of comb fingers should be less than 80.
- The device fits into a $200 \times 200\ \mu m^2$ square area.
- The maximum applied voltage is 30V.
- The device satisfies all design rules for MUMPs processing.

7.16: For pressure sensing diaphragms of the order of 100 µm square, why is it impractical to use capacitance to measure deflection?

7.17: List five methods you could use to release stress in a poly-Si comb resonator and describe the relative merits of each approach.

7.18: Take a look at the Sandia website at http://mems.sandia.gov/scripts/images.asp. Many of the surface micromachined gears have tiny holes in their surfaces. Why are these there?

> Elderly: In physics, mathematics and astronautics it means over thirty; in other disciplines, senile decay is sometimes postponed to the forties. There are of course, glorious exceptions; but as every researcher just out of college knows, scientists of over fifty are good for nothing but board meetings, and should at all costs be kept out of the laboratory.

Introduction

In this chapter we review chemical, photochemical, and electrochemical forming.* In chemical forming, chemical reactions create features by forming new compounds. The energy source at the work piece in this additive process is chemical. The method is extremely broad and covers fabrication with metals, ceramics, and polymers. Reactions are induced by combining different reagents and are often aided by heat and/or catalysts and also may be accompanied by a shape-forming step using, for example, a spraying nozzle, a mold, or a template. Almost all manufacturing processes include one or more chemical forming steps and can be part of lithography- or nonlithography-based schemes. Chemical and thermal forming processes are difficult to distinguish because they are almost always intertwined. Some chemical forming processes involve an exothermic reaction, and such processes we classify as purely chemical (they do not require the application of external heat). This is the case, for example, in reaction injection molding (RIM; see Chapter 10) and for self-assembled monolayers (SAMs; see page 523 below). Other chemical forming processes are endothermic and require a significant increase in temperature for the reaction to initiate such as in the oxidation of Si (see Volume I, Chapter 4) or chemical vapor deposition of polycrystalline Si (CVD; see Chapter 7). The distinction between chemical and thermal forming is somewhat arbitrary, and in this chapter we cover as additional chemical forming methods those low temperature material deposition techniques that are used in chemical and biological sensor manufacture, often arranged in some type of an array configuration. The additional chemical forming methods covered are sol-gel deposition from alkoxide-based precursors, organic film spin coating, polymer dry film lamination, polymer dip coating, polymer spraying, polymer casting, organic film doctor's blade (also called *knife coating*), glow discharge polymerization, low temperature silk screening of organics, Langmuir-Blodgett deposition, and SAMs. Some of the chemical forming processes discussed here involve self-assembly such as in the case of SAMs, in which case one refers to bottom-up manufacturing. Whereas top-down nanofabrication is principally based on lithography and traditional mechanical machining, etching, and grinding, bottom-up manufacturing, which we also call nanochemistry in this book, is based in chemical synthesis, self-assembly, and positional assembly (see Volume III, Chapter 3). Arraying of low temperature materials (often organics) for sensor arrays may be accomplished by lithography, digital mirror deposition (a type of lithography as well), ink-jetting, mechanical microspotting, and

* In Part II on subtractive manufacturing techniques, we did make the same distinction between chemical, photochemical, and electrochemical etching. All three subtractive manufacturing techniques were covered in Chapter 4 on wet chemical etching and wet bulk micromachining-pools as tools.

microcontact printing. Some of the same additive methods discussed in this section will reappear in Chapter 9 on thermal forming where they involve the manufacture of ceramics in which heat application is more essential.

In photochemical forming, photoenergy solidifies a material into a three-dimensional (3D) shape as we illustrate with our description of rapid prototyping and microphotoforming (stereolithography) with, as newest embodiments, parallel stereolithography and two-photon polymerization.

In the case of electrochemical forming, the energy at the work piece is electrochemical. Electrochemical and electroless metal deposition are gaining renewed interest because of their emerging importance in making mold inserts for replication meth-odologies in both microelectromechanical sys-tems (MEMS) and nanoelectromechanical systems (NEMS) (see also Chapter 10). The foundations underlying electrochemical deposition were covered in detail in Volume I, Chapter 7; here we contrast electroless metal deposition with electrodeposition and introduce some additional electrochemical techniques. These new electrodeposition methods sort out into through-mask plating, such as in the fabrication of thin-film read-write heads, the damascene process, and in anodization; instant masking in EFAB (Electrochemical FABrication); and maskless metal deposition methods such as microjet plating, laser-enhanced jet plating, local electrochemical deposition using scanning electrochemical microscopes (SECMs), and techniques to electrodeposit slanted and curved surfaces.

Chemical Forming

Introduction

It should come as no surprise that chemical forming techniques are gaining importance because today bottom-up manufacturing or nanochemistry, a type of chemical forming, constitutes one of the most intensely researched topics. Bottom-up fabrication or nanochemistry constitutes a special class of chemical forming incorporating chemical synthesis of small particles, self-assembly, and positional assembly. In nanochemistry device structures are created via systematic assembly of atoms, molecules, or other basic units of matter. Instead of manipulating Si wafers or other solid substrates, we manipulate small amounts of chemicals, even molecules and atoms. Molecular engineers, manipulating and modifying natural polymers such as DNA and proteins, led the way into nanochemistry and practiced this type of nanotechnology long before electrical and mechanical engineers got involved. Now we are designing and manipulating at the molecular level, whereas before it was either evolution that did it for us (e.g., a virus as a nanomachine) or results happened that we never really understood and so could not optimize (e.g., stained glass window—small metal nanoparticle comparable in size with the wavelength of light).

Although there is some overlap, not all chemical forming techniques involve minute amounts of reacting chemicals, nor do they all entail self-assembly or positional assembly. The chemical forming methods covered in this chapter are sol-gel, organic film spin coating, polymer dry film lamination, polymer dip coating, polymer spraying, polymer casting, organic film doctor's blade (or knife coating), glow discharge polymerization, low temperature silk screening of organics, Langmuir-Blodgett deposition, and self-assembled monolayers (SAMs).

Arraying of organics for sensor arrays may be accomplished by lithography, digital mirror deposition, ink-jetting, mechanical microspotting, and microcontact printing.

Sol-Gel Technique

Introduction

Colloids, we saw in Volume I, Chapter 7, are mixtures in which one material is dispersed in another, with the dispersed material divided into particles ranging in size from 1 nm to 10 μm. They have many properties distinct from those of solutions of ordinary-sized molecules and from mixtures of macroscopic phases such as slurries of visible particles. The dispersed material may either be dissolved (i.e., in the case of solutions of macromolecules), giving a lyophilic colloid, or they may constitute a separate phase, giving a lyophobic colloid. We only deal with lyophobic colloids here,

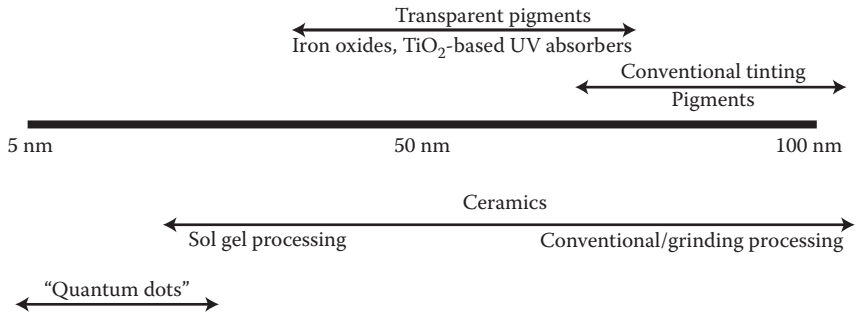

FIGURE 8.1 Nanoparticle products and their manufacture.

which may be further classified according to the types of phases that compose them, as shown in Volume I, Chapter 7. Some important definitions pertaining to the sol-gel field follow and might help in the understanding of the sol-gel process.

- Colloid: A colloid is a suspension in which the dispersed phase is so small (1 nm–10 μm) that gravitational force is negligible, and interactions are dominated by short-range forces, such as van der Waals attraction and surface charges. The suspended particles usually exhibit Brownian motion.
- Sol: A sol is a colloidal suspension of solid particle or clusters in a liquid.
- Gel: Semirigid mass of a lyophilic sol in which all the dispersion medium is penetrated into the sol particles.
- Emulsion: An emulsion is a suspension of liquid droplets in another liquid.
- Aerosol: An aerosol is a collection of very small particles suspended in a gas. The particles can be liquid (mist) or solid (dust or fume). The term *aerosol* is also commonly used for a pressurized container (aerosol can) designed to release a fine spray of a material such as paint.
- Precursors: The starting compound of the sol-gel process.
- Alkoxide: A basic salt derived from an alcohol by the replacement of the hydroxyl hydrogen with a metal. They are formed by the reaction of an alcohol and an alkali metal. For example, silicon tetraethoxide (TEOS), $Si(OC_2H_5)_4$.
- Hydrolysis: Reaction in which a hydroxyl ion is attached to the metal atom [$Si(OR)_4 + H_2O \rightarrow HO–Si(OR)_3 + ROH$, where R is an alkyl].
- Condensation reaction: Reagents combine splitting off water [$HO–Si(OR)_3 + HO–Si(OR)_3 \rightarrow (OR)_3\ SiO\text{-}Si(OR)_3 + H_2O$].

The sol-gel process is a wet-chemical additive technique for the fabrication of materials (typically metal oxides) starting from a chemical solution that reacts to produce colloidal particles (a sol). The Derjaguin, Landau, Verwey, and Overbeek theory (the DLVO theory) was introduced in Volume I, Chapter 7 to describe the stability of these colloids.

Sol-gel processing received increasing attention since the 1990s from both the research community and industry as nanoparticles became more important. Colloids form a most important gateway toward bottom-up nanotechnology: the sol-gel technique constitutes a chemical forming process for making very small particles, e.g., 20–40-nm diameter, a particle size that is virtually impossible to make by conventional mechanical ball milling or grinding* (Figure 8.1).

Sol-Gel Process

The first metal alkoxides were prepared in 1846 by Ebelmen using $SiCl_4$. Ebelmen noticed that on exposure to the atmosphere, these chemicals formed a gel. This process was then used in the 1930s by the Schott glass company in Germany to produce metal oxides (http://www.solgelchemist.com/web1.doc). In a sol-gel process, as illustrated in Figure 8.2, chemical precursors, mainly alkoxides (organic epoxides are an alternative for alkoxides) and metal chlorides, are dissolved in an aqueous or alcohol-based solution. Hydrolysis and condensation reactions nucleate

* High-energy ball milling is required to make particles less than 50 nm (see Volume III, Chapter 3).

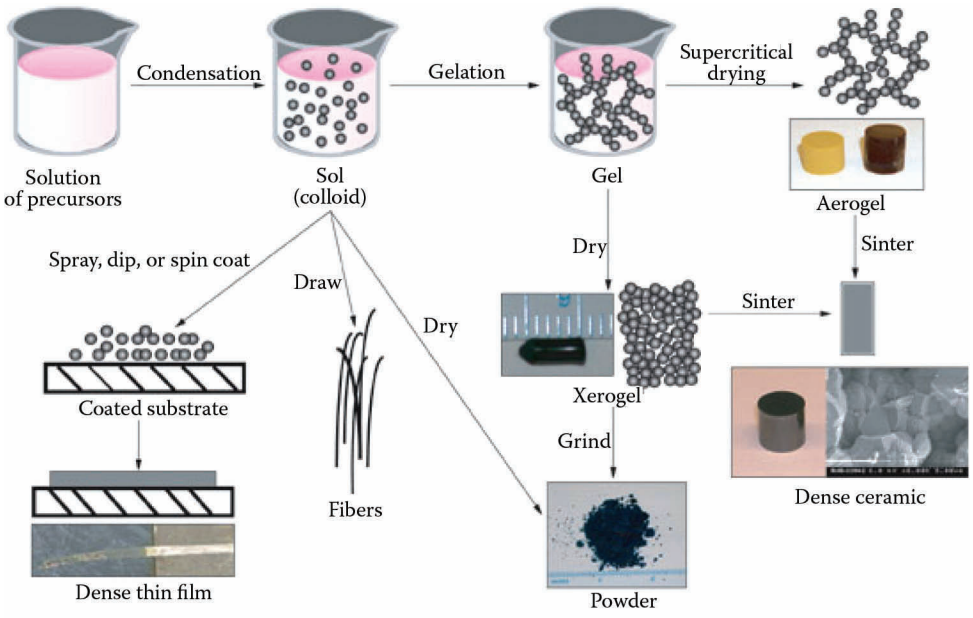

FIGURE 8.2 Sol-gel processes and sol-gel products. In sol-gel chemistry, molecular precursors are converted to nanometer-sized particles, to form a colloidal suspension, or sol. The gel can be processed by various drying methods (shown by the arrows) to develop materials with distinct properties.

and generate many small nucleation seeds (groups of atoms that build the basic crystal structure). The seeds grow by taking more atoms/molecules from the solution to form clusters. The growth pattern is random, with the atoms or molecules coming from every direction, and fractal-like cluster structures result. The clusters are nanosized, forming a colloid. As we saw in Volume I, Chapter 7, the stability of this colloid depends on the electrokinetic potential ζ (also the zeta potential), from which all electrokinetic effects can be derived. When the absolute value of the zeta potential is more than 50 mV, the dispersion is very stable, whereas with a ζ potential close to zero, the coagulation of particles leads to precipitation.

When growth continues, the nanoclusters start to build up a porous network. This is when gelation takes place. The gel point is the point in the phase diagram where the sol abruptly changes from a viscous liquid to a gelatinous, polymerized network and where the dispersion medium is fully penetrated into the sol network (Figure 8.3). Both sol and gel formation are low-temperature processes.

The transformation to a gel can be initiated in several ways, but the most convenient approach is to change the pH of the reaction solution. Formation of a metal oxide involves connecting the metal centers with oxo (M-O-M) or hydroxo (M-OH-M) bridges, therefore generating metal-oxo or metal-hydroxo polymers in solution. The drying process serves to remove the liquid phase from the gel, thus forming a porous material; then a thermal treatment (firing) may be performed to favor further polycondensation and enhance mechanical properties. The method used to remove the solvent from the gel strongly affects the end product's properties. For example, from Figure 8.2 it can be seen that if the solvent in a wet "gel" is removed under a supercritical condition, the gel's original 3D structure is preserved, and a highly porous and extremely low-density material called an *aerogel* is obtained. The supercritical processing condition is realized by exchanging the liquid solvent with CO_2. The latter is then removed at slightly elevated temperatures and under high pressure. This way aerogels can be

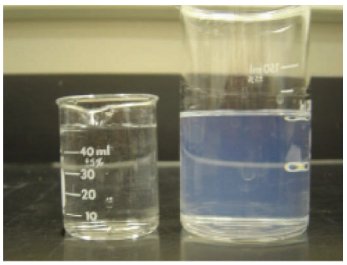

FIGURE 8.3 Gelation: TiO_2 from sol (left) to wet gel (right).

FIGURE 8.4 Aerogel. This photo illustrates the excellent insulating properties of aerogel. The crayons on top of the aerogel are protected from the flame underneath and are not melting.

produced where 99% of the bulk material consists of pores (Figure 8.4). A Lawrence Livermore group created an aerogel weighing only 1.0 mg/cm^3, which is listed in the *Guinness Book of World Records 2005* as the lightest material on Earth.[1]

If, in an alternative process route, the gel is dried slowly in a fluid-evaporation process, the gel's structural network collapses, which creates a high-density material known as a *xerogel*. When a xerogel is further densified by sintering, a dense ceramic material forms.

As the viscosity of a sol is adjusted into a proper viscosity range, ceramic fibers can be drawn; it can be applied as a film onto a substrate by spinning, dipping, or spraying and cast into a suitable container with the desired shape (e.g., to obtain a monolithic ceramics, glasses, fibers, membranes, and aerogels); or finally, ultrafine and uniform ceramic powders may be formed by grinding of the xerogel or by slowly drying the sol.

For a silica sol formation, an appropriate chemical precursor is dissolved in a liquid, for example, tetraethylsiloxane (TEOS) in water. In this case, a silica gel is formed by hydrolysis and condensation using hydrochloric acid as the catalyst. Drying and sintering at temperatures between 200 and 600°C transforms the gel into a glass and then densification into silicon dioxide.

Alkoxides can be very reactive and are commercially available for only a select number of elements. Livermore chemists have found that organic epoxides also initiate the sol-gel reaction. With this approach, precursors that are more widely available can be used, thus increasing the number of potential materials that can be developed. In addition, the starting materials, solvents, and gelling agents used with epoxides are less expensive than those used with alkoxides.

Summarizing, sol-gel is a cheap and low-temperature technique that enables mixing of precursors at the molecular level, leading to finer control and higher purity than most other ceramic synthesis methods (even small quantities of dopants, such as organic dyes and rare earth metals, can be introduced in the sol and end up finely dispersed in the final product). The method is particularly suited for the production of nanosized multicomponent ceramic powders densified through thermal annealing (sintering at relatively low temperature) to an inorganic product like a glass or polycrystal or a dry gel. Applying the sol-gel process, it is possible to fabricate ceramic or glass materials in a wide variety of forms: ultrafine or spherical-shaped powders, thin film coatings, ceramic fibers, microporous inorganic membranes, monolithic ceramics and glasses, or extremely porous aerogel materials. Different material compositions with different porosity may be fabricated depending on the process parameters (such as temperature) and the chemicals used. Its main traditional use is for optical coatings, where the finer particles give better optical clarity, and for the manufacture of fine ceramic fibers.

Sol-gel-derived materials have diverse applications in optics, electronics, energy, space, (bio)sensors, medicine (e.g., controlled drug release), and separation (e.g., chromatography) technology.

Sol-gel methods have been used in MEMS, for example, in the fabrication of piezoelectrics such as lead-zirconate-titanate (see Volume III, Chapter 8). Also, a commercially available, room temperature chemical gas sensor (a CO fire alarm) is fabricated with the sol-gel process (available from Quantum Group Inc.; http://www.qginc.com). The Sol-Gel Gateway (http://www.solgel.com/bookstore/bookstore.htm) is an excellent take-off point for further study of the sol-gel technique on the Internet (in particular, check http://www.solgel.com/Tutorials/tutorials.htm).

Deposition and Arraying Methods of Organic Layers in Bio-MEMS

Introduction

Today, miniaturization methods are often applied to biotechnology and biomedical problems. With the growth of the "bio-MEMS" field, techniques for depositing organic materials for chemical and biological sensors, often arranged in some type of an array configuration, are gaining importance. Organic gas-permeable membranes, ion selective membranes, hydrogels, and organic monolayers are needed for the manufacture of room temperature gas sensors, ion-selective electrodes (ISEs), enzyme-based sensors, immunosensors, and DNA and protein arrays. Their deposition presents challenges not typically encountered in the integrated circuit (IC) world. Membranes may be based on classical polymers, such as PVC (polyvinylchloride), PVA (polyvinylalcohol), PHEMA (polyhydroxyethylmethacrylate), or silicone rubber, and incorporate pH and temperature-sensitive biological materials such as enzymes, antigens, and antibodies. Single layers of molecules may be deposited by Langmuir-Blodgett (LB) deposition techniques or as self-assembled monolayers (SAMs). Those LB films or SAMs may then be further used as anchor points for proteins or DNA probes, and the latter natural polymer molecules may be synthesized in situ. Not only are the materials dealt with very different, the fact that most of the bio-MEMS sensors are disposable requires new manufacturing approaches as well. Although the number of new tools available for microfabrication has grown dramatically, few methods have been gainfully applied to disposable biosensor construction for clinical applications. The low cost requirements and the tremendous variety and fragmentation of biomedical sensor applications often necessitate a nonsilicon, modular approach. The Si approach is mostly based on thin film techniques with a limited number of materials, too expensive cost, all steps tightly integrated, and too many requirements on process and materials compatibility. Having addressed materials choice and modularity, various competing manufacturing processes must be compared.

Because of the importance of this emerging field, we review the different options available to coat and pattern organic materials on various substrates for bio-MEMS in the following section. For the organic film deposition techniques reviewed earlier in this book, we provide a short summary only.

Deposition Methods for Organic Materials

Organic Film Spin Coating As we know from Chapter 1 on lithography, spin coating technology has been optimized for the deposition of thin layers of photoresist, about 1–2 μm thick, on round and nearly ideally flat Si wafers. A typical spin coater schematic is shown in Figure 1.14. Resists are applied by dropping the resist solution, a polymer, a sensitizer (for two-component resists), and a solvent on the wafer. The wafer is then rotated on a spinning wheel at high speed so that centrifugal forces push the excess solution over the edge of the wafer, and a residue on the wafer remains as a result of surface tension. In this way, films down to 0.1 μm can be made. An empirical expression relating film thickness to solution viscosity and rotation speed was given in Chapter 1 (Equation 1.3). However, biosensor substrates rarely are round or flat, and many chemical sensor membranes require a thickness considerably thicker than 1 μm for proper functioning. For example, a typical ion-selective electrode (ISE) membrane is 50 μm thick (see Volume I, Chapter 7). Consequently, spin coating technology does not necessarily fit in with thick chemical membranes on a variety of substrates, and for monolayer deposition the method is not adequate. For building ISEs, dip coating or membrane casting is preferred, and for monolayer deposition one chooses Langmuir-Blodgett or self-assembled monolayer (SAM) methods (see below). For a tutorial on spin coating, visit http://www.mse.arizona.edu/faculty/birnie/Coatings/index.htm.

In Chapter 1, we compared several alternatives to spin coating for depositing photoresist (see Figure 1.15). Obviously all these techniques can be adapted to deposit other organic coatings. This includes spray coating, curtain coating, extrusion coating, roller coating, dip coating, plasma deposited, electrodeposited, silk screening, and meniscus coating. We provide some additional information here complementing the material presented in Chapter 1.

Polymer Dip Coating In the dip-coating method a substrate is slowly dipped into and withdrawn from a tank containing the dissolved polymer, with a uniform velocity, to obtain a uniform coating. The dip-coating process may be divided in five stages: immersion, startup, deposition, evaporation, and drainage. Dip coating of a substrate in a solution of a dissolved polymer typifies the simplest method to apply an organic layer to a substrate. It is especially suited for wire-type ISEs and enzyme-based biosensors where the membrane forms a droplet at the end of a wire (see Volume I, Chapter 7). A substrate, for example, a chloridized silver wire, is dipped into a solution containing the polymer and a solvent. After evaporation of the solvent, a thin membrane forms on the surface of the sensor. To obtain pinhole-free membranes, the dipping is repeated several times, interspersed with drying periods. Even though the eventual goal is more typically the production of a planar sensor structure, a Ag wire may be applied in the research phase to quickly evaluate a new membrane composition. The method is difficult to commercialize because of the variability in coating thickness and uniformity. For further reading on dip coating, visit http://www.solgel.com/articles/Nov00/mennig.htm.

Dipping and spinning are also used in the fabrication of sol-gel layers (see Figure 8.2).

Polymer Dry Film Lamination The use of dry film lamination, such as the dry photoresist films explored in Chapter 1, is introduced as a better approach for the mass manufacture of chemical and biological sensors than spin coating in Volume III, Example 1.1. Most resists in IC and MEMS fabrication are deposited as liquids, whereas resists used in printed wiring board manufacture are usually dry film resists that come in rolls (ranging from 2–60 in. wide and 125–1000 ft. long) and are laminated onto the substrate instead of being spin-coated on it. A typical dry film lamination setup is shown in Figure 1.33. The heat and pressure of the laminating rollers cause the dry film to soften and adapt to surface topologies. The resist is then exposed to a UV light source. The lamination approach can be extended to other polymer coatings as exemplified in the manufacture of the compact disc (CD)-based fluidic platform shown in Volume III, Chapter 5. In the manufacture of this CD, we use a layering approach, with different sheets of thin machined plastic CDs (polycarbonate-PC) laminated together using pressure-sensitive adhesive layers (PSA-FLEX mount DFM 200 clear V-95). The PSA layers are as thin as 100 μm and are cut using a computer numerical controlled (CNC) cutter-plotter (in Volume III, Figure 5.27, CNC plotter, Graphtec CE-2000-60). The use of PSA layers allows for channels as narrow as 250 μm. When sandwiched between two plastic sheets, these channels in the PSA connect the larger CNC-machined reservoirs in the PC disks.

Polymer Spraying Polymer or plastic spray-coating techniques are the most widely used methods for applying organic coatings from the liquid, gas, or the solid phase. Spray coating of a liquid involves pressurization by compressed air or, in an airless method, pushing liquid mechanically through tiny orifices. Vapors are carried in an inert dry vapor carrier. In the case of a solid, a powdered plastic resin is melted and blown through a flame-shrouded nozzle. Such thermal spray coating involves heating a material, in powder or wire form, to a molten or semimolten state. The material is propelled using a stream of gas or compressed air to deposit it, creating a surface structure on a substrate. The coating material may consist of a single element but is often a composite with unique physical properties that are only achievable through the thermal spray process.

There are two main classes of powder coatings: thermosetting and thermoplastic coatings. In a thermosetting film, cross-linking occurs between the molecules in the powder during baking. This cross-linking turns the baked film into a single giant molecule that cannot melt or flow. In a thermoplastic film, thermal energy makes the binder molecules mobile enough to become entangled; thus, a continuous film forms, and this film hardens on cooling. Although a thermoplastic film can still melt or flow, it can do that only at elevated temperatures. In electrostatic spraying, a negatively charged plastic powder is spray gunned onto grounded conductive parts (see Figure 8.5).[2] Electrostatic spray is the primary technique used for thermoset powders. The particles of powder are given their electrical charge in the powder coating gun, and the target part is

FIGURE 8.5 Electrostatic spray gun from ITW Ransburg. (From http://www.itwransburg.com/products.html.)

attached to a fixture that is grounded. The electrically charged powder particles are attracted to the grounded part and build up on the surface until the part is covered with charged particles. At this point, the oncoming particles are repelled by the part, and the coating process stops. This provides for an even film thickness.

Thermoplastic and thermosetting coatings may also be formed by dipping a heated part into a container of resin particles set in motion by a stream of low-pressure air (fluidized-solid bed). This method is only of use if an inert coating is desired, for example, for biocompatibility, but not for heat-sensitive functionalized coatings. The fluidized bed is the original powder-coating technique. It is still the primary technique used for the application of thermoplastic powders.

Thermal spraying is ideally suited for large structures that otherwise could not be dipped in a polymer suspension. Unlike electrostatic powder coatings, nonconductive components can be coated, and unlike fluidized bed coatings, heat-sensitive materials (aircraft skins) can be sprayed. Polymer coatings can be repaired by heating (for remelting or curing) and by applying additional material to the desired location. Polymer coatings can be applied in high humidity and at temperatures below freezing. Certain polymers have excellent adhesion to metallic surfaces as a result of interfacial bonding. Metals, ceramics, or other polymers can be incorporated into the polymer matrix during spraying to act as a fill.

FIGURE 8.6 Yoda, typical polymer casting application.

Polymer Casting Cast polymer operations are operations where a gel coat resin is sprayed to a mold, after which a casting resin is applied without spraying. These are used in the manufacture of pools, bathtubs, marble-look countertops, masks, and toys (Figure 8.6). Casting in bio-MEMS is often based on the application of a given amount of dissolved organic material on the surface of a sensor substrate and letting the solvent evaporate. A rim structure is fashioned around the substrate, providing a "flat beaker" for the solution. This method provides a more uniform and a more reproducible membrane than dip coating. Membranes in planar ion-selective electrodes (ISEs) are often made this way. Casting is also often used to obtain thicker photoresist layers than typically possible with spin coating (see also Chapter 1). Casting is the main technology used in soft lithography (see Chapter 2).

Polymer Doctor's Blade or Knife Coating Doctor's blade or knife coating relies on a coating being applied to a substrate that then passes through a slit between a knife and a support roller (Figure 8.7). The "doctor's blade" refers to the scraping knife blade for the removal of excess substance from the moving surface being coated. The doctor's blade is adjustable with a precisely controlled height, limiting the dispensed material to a known thickness. This process can be used for high-viscosity coatings, and there are innumerable variants of this relatively simple process, which is rugged but somewhat inaccurate. It is well known in many industries, including paper,

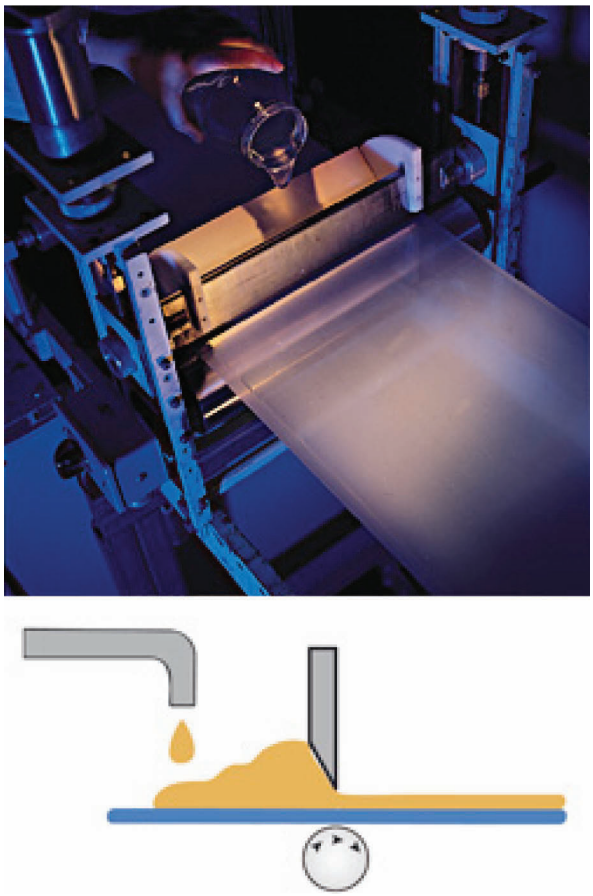

FIGURE 8.7 Doctor blading or knife coating of organic materials on a moving substrate.

plastic, and paint manufacturing. Doctor's blade technology is a continuous fabrication method, which can also be used to apply all types of organic cocktails, for example, to make enzyme-based biosensors or to deposit ceramics, in which case one also refers to tape casting and green tape technology. Howatt was the first to obtain a patent to use the technique for "forming ceramic materials into flat plates, especially useful in the electric and radio fields."[3] This is still the principal application of tape casting today, although its use extends far beyond the field envisioned in 1952 (http://www.drblade.com/history.htm). The ceramic application of doctor blading is a thermal forming process well suited for fabrication of mesoscale devices (layers with a thickness between several micrometers and millimeters) and is covered in Chapter 9 on thermal energy-based forming.

As a specific application of a doctor's blade process in bio-MEMS, consider the mass production of amperometric glucose sensors discussed in Volume III, Chapter 1. In that chapter, as an illustration of an informed choice of manufacturing options, we find out that using a silicon batch approach, it is almost impossible to make a glucose sensor for less than $1 (or any disposable biosensor for that matter!). The current industrial process, and our conclusion, is that for mass-producing glucose sensor strips, the optimal choice is doctor's blade on a continuous moving web, making a 10-cents cost per glucose sensor possible.

From this example of a glucose sensor strip, it appears that one of the major challenges in bio-MEMS is the fabrication of affordable disposable biosensors. In the case of a glucose sensor strip, this may be accomplished using doctor's blade in a continuous process. An example of a generic approach for biosensor manufacture on large plastic sheets and eventually on a moving web is shown in Volume III, Figure 1.19. The process illustrated allows for the fabrication of a sensor array composed of sensors that may otherwise have fabrication incompatibilities. We call this futuristic bio-MEMS approach "beyond batch."

Glow Discharge (Plasma) Polymerization Plasma polymerization is a type of plasma-enhanced chemical vapor deposition procedure (PECVD; see Chapter 7), in which gaseous precursor monomers, activated by the plasma, deposit on freely selectable substrates as highly cross-linked polymer layers. A polymerizable gas can, in principle, include any substance that can be brought into the gas phase at reduced pressure. The *sine qua non* for this process to take place is the presence in the gas phase of polymer-producing atoms, such as carbon, silicon, or sulfur. These react with one another and with any surface groups to form a polymer film, the chemical structure of which is dependent on the process conditions used. The monomer molecules in the plasma, for the most part, become fragmented into reactive segments, and remain only partially preserved in the chemical structure of the final product, which results in a highly cross-linked and disordered structure compared with a conventional polymer (Figure 8.8). The degree of structural preservation and cross-linking gradients in the deposit are controlled

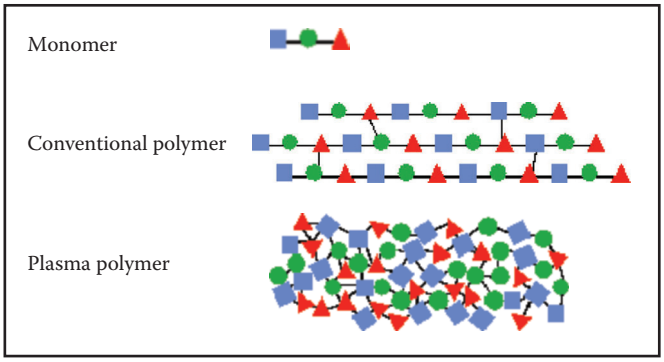

FIGURE 8.8 Polymers deposited with plasma polymerization. Comparison of the structures of plasma polymers and conventional polymers.

through process parameters, such as gas pressure, working gas flow, and the applied electrical field. For example, it has been found that pulsing the plasma in the millisecond regime constitutes a very simple and unique method to control the film chemistry.[4] Unlike the more conventional continuous wave plasma deposition processes, pulsed plasma deposition enables the polymerization of monomers containing labile groups such as amines, ethers, and anhydrides, to name but a few. By selecting the monomer type and the energy density per monomer, known as the *Yasuda parameter*, the chemical composition and structure of the resulting thin film can be varied over a wide range.[5]

The so-obtained polymer coats can be used to further attach specific molecules by conventional wet chemistry techniques. One can also construct so-called *gradient layers*, i.e., with increasing degree of cross-linking over the film thickness.

Figure 8.9 illustrates the setup we used in our own work on plasma polymerization of doped polymers. The apparatus consisted of a quartz tube reaction chamber; a gas-handling system to introduce the carrier gas, monomer, and dopant into the system, as well as to remove the unreacted material; and a power supply (operating at 27 MHz) to provide the radio-frequency (RF) energy necessary to create and maintain a plasma within the system. Despite the complex chemistry of this process, good conformal coatings often result. Guckel applied this technique to obtain deposition of poly(methylmethacrylate) (PMMA) in layers more than 100 µm thick.[6] In research at SRI International, we synthesized electroactive plasma polymers using I_2 or N_2O as dopants from the following monomers: thiophene, furan, aniline, benzaldehyde, benzene, indole, diphenylacetylene, and 1-methylpyrrole.

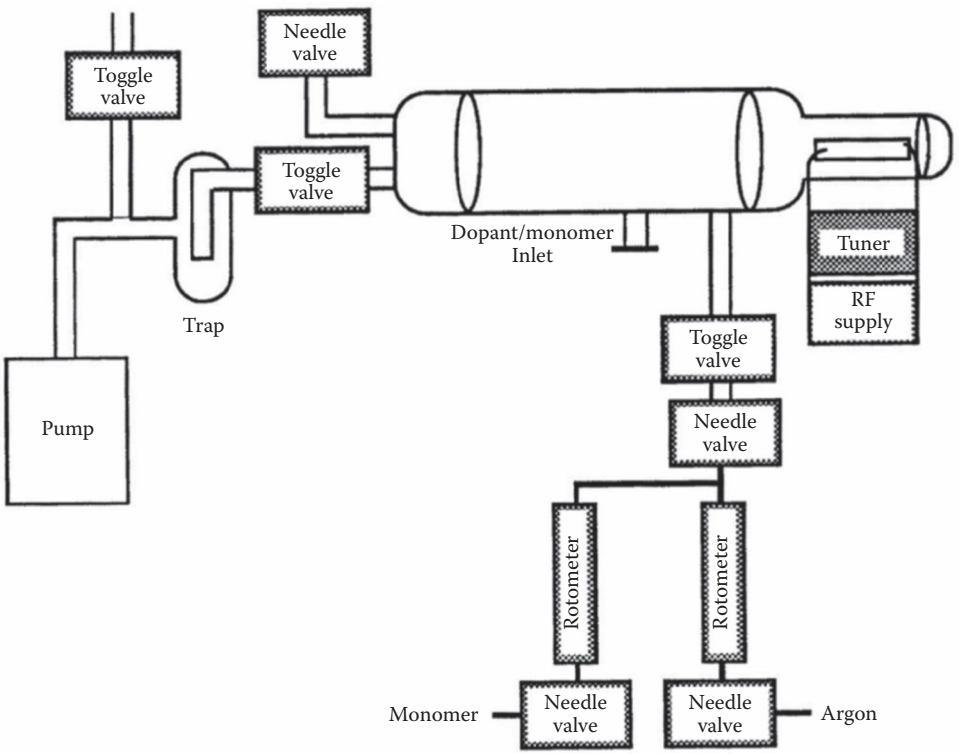

FIGURE 8.9 Schematic of plasma deposition system.

In general, plasma-polymerized materials offer the following advantages:

- The plasma-polymerized films are uniform, pinhole-free, chemically resistant, and mechanically strong.
- A thin to thick film (200 Å to >100 μm) can be formed in a flawless manner at ambient temperature onto any substrate.
- The organic films deposited by the plasma process adhere strongly to the substrate.
- The choice of monomers is unlimited; almost any organic compound convertible into vapor can be polymerized.
- The plasma process (one-step process from a vapor source) is compatible with conventional CMOS technology.
- Some functional groups can be introduced onto the surface of the organic film by subsequent glow discharge treatment in a reactive gas atmosphere.
- Highly irregular surfaces can be coated and patterned by depositing a light-sensitive polymer by plasma polymerization (e.g., polymerized PMMA).

Applications from plasma polymer coatings include scratch-resistant coatings, corrosion protection, antibonding, antisoiling coatings, barrier layers, and biocompatible coats for implants. For more details on plasma polymerization, see, for example, Yasuda[7] and *Plasma Polymer Films* edited by Biederman.[8]

Silk Screening or Screen Printing of Organics Silk screening or screen printing (also serigraphy) is an additive technique that can be used to create sharp-edged organic coatings/images using a stencil. The method is reviewed in more detail in Chapter 9, where we discuss its application for the deposition of higher temperate ceramic coats. Silk screening is popular both in fine arts and in commercial printing, where it is used to print images on T-shirts (Figure 8.10), hats, CDs, DVDs, ceramics, glass, polyethylene, polypropylene, paper, metals, and wood.

Screen printing presents a more cost-effective means of depositing a wide variety of films on planar substrates than does integrated circuit (IC) technology, especially when fabricating devices at relatively low production volumes. The technique constitutes one of several thick film or hybrid technologies used for selective coating of flat surfaces (e.g., a ceramic substrate). The technology was originally developed for the production of miniature, robust, and, above all, cheap electronic circuits. The up-front investment in a thick film facility is low compared with that of IC manufacturing. For disposable chemical sensors, recent industrial experience indicates that screen printing thick films is a viable alternative to Si thin film technologies.

FIGURE 8.10 Silk screening of T-shirts.

For biosensor applications, thick film technology based on pastes that can be deposited at room temperature is crucial. Special grades of polymer-based pastes (e.g., for carbon, Ag, and Ag/AgCl electrodes) are becoming commercially available for this purpose.[9] Polymer thick films with a thickness anywhere from 5–50 μm can be screen printed on cheap polymer substrates. In the commercial planar electrochemical glucose sensor from MediSense/Abbott sensor, the Precision QID, shown in Volume I, Chapter 7, all films are silk-screened onto a PVC substrate.

In the research phase of new chemical sensors, pastes must be developed from their pure components. Some examples follow. Pace et al.[10] screen printed a PVC/ionophore layer for a pH sensor. Belford et al.[11] investigated pH-sensitive glass mixtures and proceeded to screen print them on a multilayer metal conductor to make planar pH sensors. In Pace et al.,[12] a thick film, multilayered oxygen sensor with screen-printed chemical mem-

branes of PVA and silicone rubber is detailed (see also Karagounis et al.[13]). A thick film glucose sensor is presented by Lewandowski et al.[14] and Lambrechts et al.[15] The latter authors developed an enzyme-based thick film glucose sensor with RuO_2 electrodes. All the above thick film sensors were fabricated on Al_2O_3 substrates. Weetall et al.[16] present an extremely low-cost, silk-screened immunosensor on cardboard. Cha et al.[17] compare the performance of thick film Au and Pt electrodes with conventional bulk electrodes.

When faced with adapting a biosensor membrane to an IC process versus adaptation to a thick film process, it now seems that, once the specialty inks are available, a thick film approach is easier, less expensive, and more accessible. For in vitro chemical sensors where small size is not as important, we expect more research to result in a switch from the overly ambitious IC approach to the more realistic thick film approaches as sketched above. In Volume III, Chapter 1, we compare the pros and cons of thin and thick film technologies.

Important other driving forces for the development of new low-temperature inks for silk screening come from the exciting market opportunity of organic light-emitting diodes (OLEDs), OLED flexible displays, polymer transistors, and electronic paper. There are two types of OLED displays: the ones based on small molecule OLEDs and the polymer-based ones. The small molecule OLEDs use organic emissive materials that do not contain long polymer chains. "Small" molecules often used include organometallic chelates, flourescent and phosphorescent dyes, and conjugated dendrimers. The production of small molecule devices and dispalys usually involves thin film deposition such as a separation in a vacuum. Small molecule OLEDs are more mature, but the polymer based OLEDs have the potential of being lower cost because of the applicability of screen printing, which enables high throughput of large area devices, such as large area displays. Lifetime improvement and encapsulation are progressing fast; thus, polymer OLEDs now have the potential of being very bright, extremely thin, low power, and low cost. There is the eventual possibility of producing OLED displays using roll to roll (R2R) manufacturing (see Volume III, Chapter 1), which would dramatically further reduce their manufacturing cost. The aim is also to produce organic thin film transistors (TFTs) using printing techniques, but there are a number of issues that still need to be resolved in this case. However, reduction in cost can already be achieved today by using hybrid-processing technologies, i.e., using low-cost printing and dispensing techniques wherever it is possible, whereas other processing steps remain "conventional," such as photolithography or vapor deposition processes.

In Figure 8.11 some typical thin film organic devices are shown. Using thin sheets of plastic—similar to overhead transparencies—as the base, one can print the multiple layers of OLEDs or transistors with silk screening one layer at a time. The squeegee pushes a liquid plastic mixture over a stainless-steel mesh, and after the solvent evaporates, a new plastic feature remains.

With electronic paper, the ink is a liquid that can be printed onto nearly any surface. Within the liquid are suspended tiny microcapsules, each containing white and black particles (Figure 8.12). The relative movement of negatively charged black and positively charged white particles inside their microcapsules is controlled by the direction of an applied voltage. In an electric field, the white particles move to one end of the microcapsule and make the surface of the electronic paper appear white at that spot. An opposite electric field pulls the white particles to the other end of the microcapsules, where they are obscured by the black particles, making the surface appear dark at that spot.[18] To form an electronic ink display, the ink is screen printed onto a sheet of plastic film that is laminated to a layer of circuitry. The circuitry forms a pattern of pixels that can then be controlled by a display driver. The microcapsules are suspended in a liquid "carrier medium," allowing them to be printed using existing screen-printing processes onto virtually any surface, including glass, plastic, fabric, and even paper. Ultimately electronic ink will permit most any surface to become a display, bringing information out of the confines of traditional devices and into the world around us.

Applications of electronic ink include e-book readers capable of displaying digital versions of books and e-paper magazines, electronic pricing labels in retail shops, timetables at bus stations, and

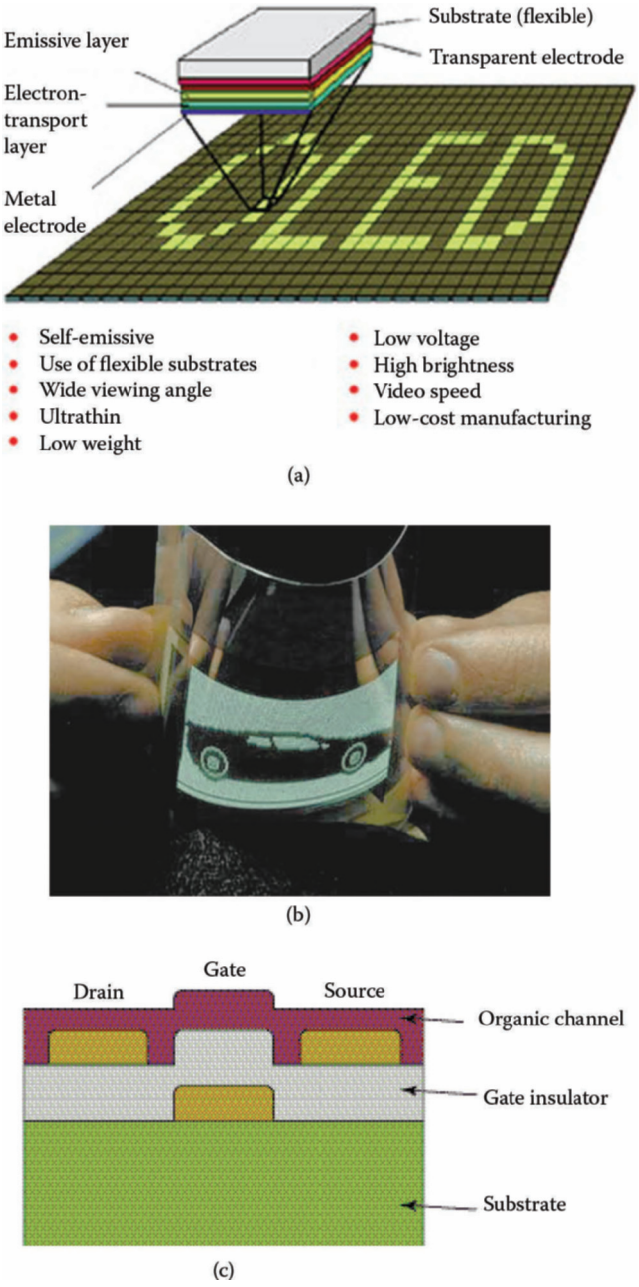

FIGURE 8.11 Organic light-emitting diode (OLED). (a) In a typical organic light-emitting device, luminescent molecular excited states are generated in the electron transport and luminescent layer near its contact region with the hole transport layer. (b) OLED display; an organic passive matrix display on a substrate of polyethylene terephthalate, a lightweight plastic, will bend around a diameter of less than 1 cm. The 1.8-mm-thick, 5 × 10-cm monochrome display consists of 128 × 64 pixels, each measuring 400 × 500 μm, and is operated at conventional video brightness of 100 cd/m^2. It was fabricated by Universal Display Corp. (Ewing, NJ), with a moisture barrier built into the plastic that prevents degradation of the pixels (http://www.universaldisplay.com). (c) Organic thin-film transistors (OTFTs) are constructed of an organic or inorganic gate insulator and an organic semiconducting channel linking the source and drain.

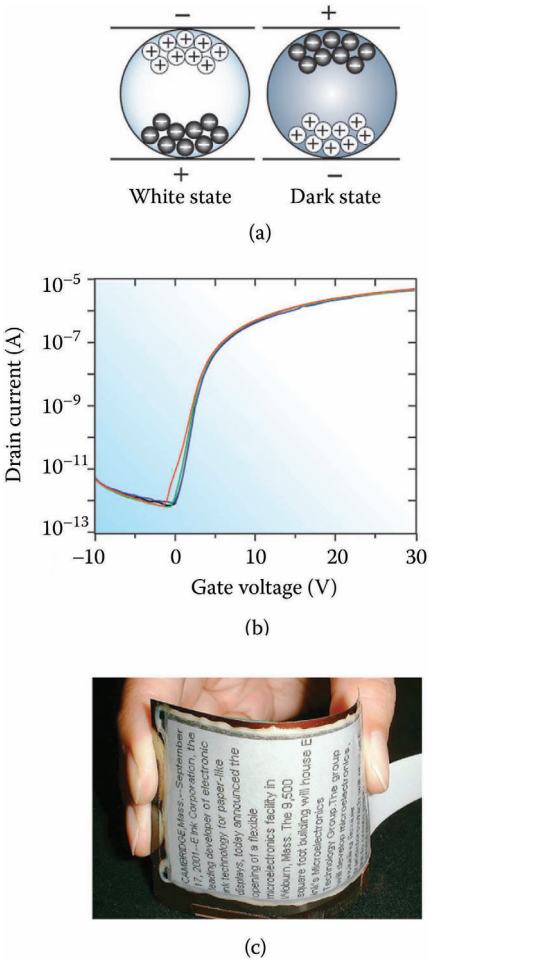

FIGURE 8.12 How electronic ink works. (a) Operating principle of electronic ink. The relative movement of negatively charged black and positively charged white particles inside their microcapsules is controlled by the direction of the applied voltage. (b) A backplane thin-film transistor measured in situ under compressive stress. The transistor is bent to three different radii of curvature: green, 2.0 cm (0.19% strain); blue, 1.3 cm (0.29% strain); and red, 1.0 cm (0.38% strain). The thin-film transistor has identical characteristics when measured without bending (black curve) and at a radius of curvature of 2.0 cm; degradation is minimal even at 1.0 cm. Results were similar under tensile stress. (c) Text image shown on a bent display whose resolution is 96 dpi and which has a white-state reflectance of 43% and a contrast ratio of 8.5:1. (From Chen, Y., J. Au, P. Kazlas, A. Ritenour, H. Gates, and M. McCreary. 2003. Electronic paper: Flexible active-matrix electronic ink display. *Nature* 423:136.[18])

electronic billboards. In February 2006, the Flemish daily *De Tijd* distributed an electronic version of the paper to select subscribers in a limited marketing study. This was the first recorded application of electronic ink to newspaper publishing.

Langmuir-Blodgett Deposition and Self-Assembled Monolayers The Langmuir-Blodgett technique, invented by Irving Langmuir and Katharine Blodgett in 1935, allows the controlled deposition of monomolecular layers on a wide variety of substrates. This ultrathin film deposition technique is limited to materials that consist of amphilic long chain molecules with a hydrophobic molecule at one end and a hydrophilic molecule at the other. In the Langmuir-Blodgett process, a monolayer of film-forming molecules (stearic acid is a model molecule) on an aqueous surface is compressed into a compact floating film and transferred to a solid substrate by passing a substrate through the water surface at a constant speed and film surface tension (Figure 8.13). Thus, layered films can be built up in thickness (up to 100 layers) by consecutive dipping in the Langmuir trough. For example, phthalocyanine thin films sensitive to oxidizing gases such as NO_2 and biological materials sensitive to odors resulted via this method. Most of the difficulties with Langmuir-Blodgett films stem from the need to make the material pinhole-free and to overcome the problem of their lack of mechanical, chemical, and thermal stability.

In the early 1980s at the Bell Labs, David L. Allara (now at Pennsylvania State University) and Ralph G. Nuzzo (now at University of Illinois, Urbana-Champaign) discovered the self-assembly of disulfide and, soon thereafter, of alkanethiol monolayers (SAMs) on metal surfaces.[19,20] SAM films, especially on Au, spontaneously assemble into stable and highly organized molecular layers, bonding with the sulfur atoms onto the gold and resulting in a new surface with properties determined by the alkane head group. The preferred crystal face for alkanethiolate SAM preparation on gold substrates is the (111) surface, which is obtained either by using single-crystal substrates or by evaporation of thin

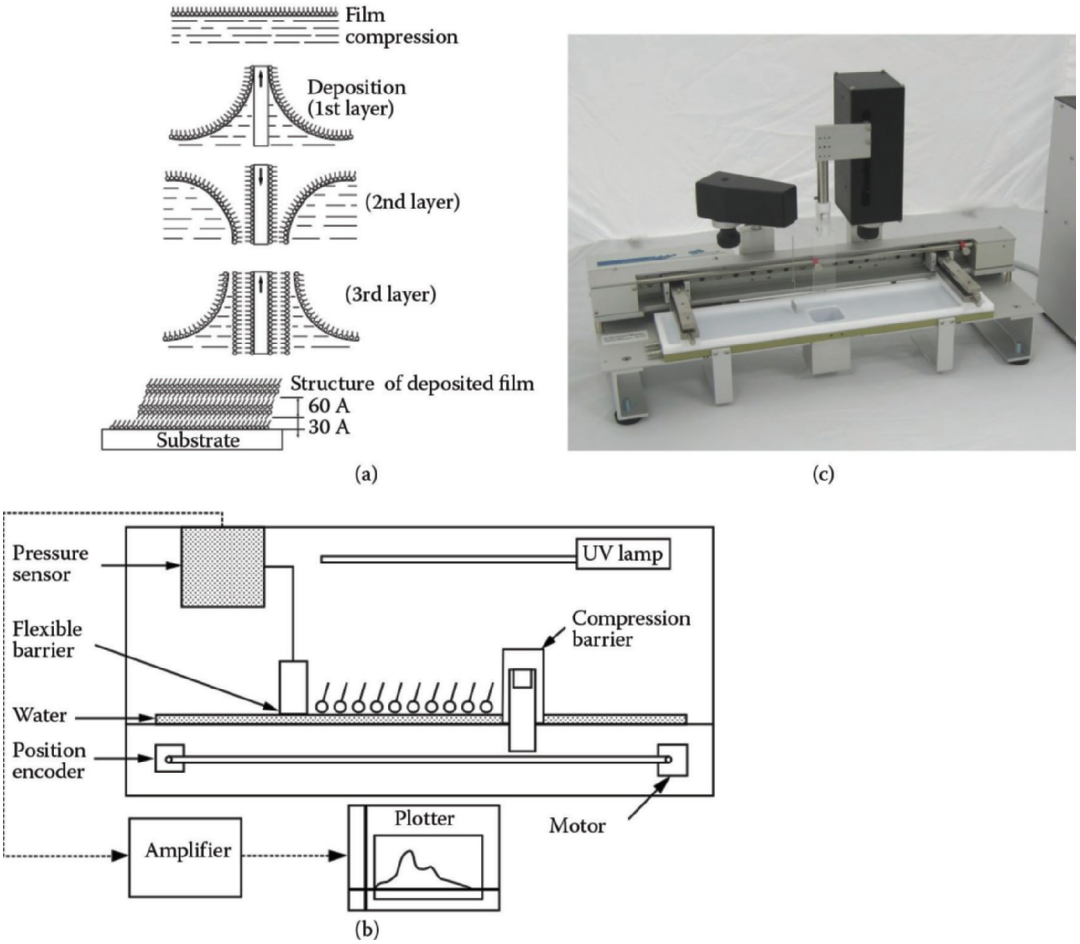

FIGURE 8.13 Langmuir-Blodgett film deposition: sequence of a deposition (a), schematic of apparatus (b), and photo of apparatus (c).

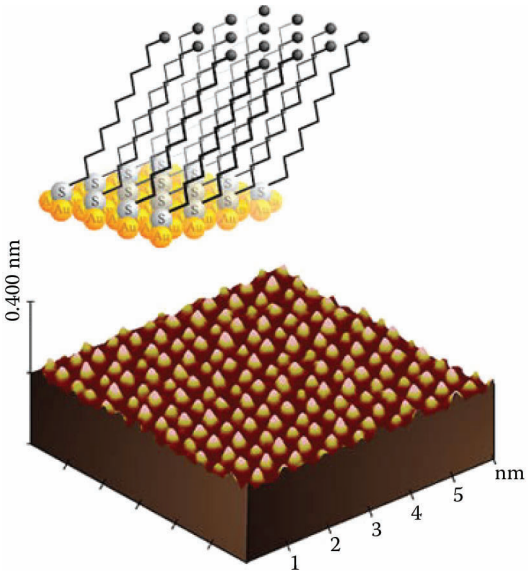

FIGURE 8.14 Preparation of SAMs. The substrate, Au on Si, is immersed into an ethanol solution of the desired thiol. Initial adsorption is fast (seconds); then an organization phase follows, which should be allowed to continue for >15 h for best results. An STM of a fully assembled SAM is also shown.

Au films on flat supports, typically glass or silicon (Figure 8.14). Several different solvents are usable at the low thiol concentrations (typically 1–2 mM) that are used in preparation of SAMs, but the most commonly used one is ethanol. It is important to minimize the water content in the solvent if the SAMs are to be used in ultrahigh vacuum (UHV) experiments. Drying the solvent limits incorporation of water into the SAM structure, which reduces outgassing and increases the repeatability of UHV experiments. Even though a SAM forms very rapidly on a Au substrate, it is necessary to use adsorption times of 15 h or more to obtain well-ordered, defect-free SAMs. Multilayers do not form, and adsorption times of 2–3 days are optimal in obtaining the highest-quality monolayers.

The tail group that provides the functionality of the SAM can be widely varied. CH_3-terminated SAMs are commercially available, and other functional groups can be easily synthesized by any well-equipped chemical laboratory, providing almost infinite possibilities. In addition, chemical modification of the tail group is also possible after formation of the SAM, expanding the available range of functionalities even further. Examples of functionalities are $-CH_3$, $-OH$, $-(C{=}O)OCH_3$, $-O(C{=}O)CH_3$, $-O(C{=}O)CF_3$, $-O(C{=}O)C_6H_5$, $-COOH$, $-OSO_3H$, and so on. SAMs on gold are generally stable and can withstand strong acids and bases; they are not destroyed by solvents and can withstand physiological environments.[21]

This method of building monolayers forms an important alternative to the Langmuir-Blodgett method. The use of monolayer electron beam resists, as discussed in Chapter 2, affords nanometer-scale lithography resolution. The chemical sensor industry exploits monolayers of organics, for example, in immunosensors and to provide anchor points for subsequent organic molecules or membranes.

Patterning of Organic Materials

Introduction

In the previous sections, we summarized some of the different methods available to deposit organic thin layers. In what follows, we will encounter some of the same techniques and introduce some new ones as we look into the process of depositing small amounts of material in a well-defined, small spot on a substrate, i.e., the patterning of organic films. Patterning of organic thin layers into discrete array elements has recently spawned a wide variety of applications. These range from sensor arrays for electronic noses and tongues to DNA and protein arrays.

Patterning through Photolithography

Patterning of Hydrogels, Gas-Permeable Membranes and Ion-Selective Electrodes Spinning, UV exposure, and development of resists are well-known, low-cost, mass-production patterning procedures in photolithography for IC fabrication. Naturally, this approach became one of the first methods to be applied to the patterning of other organic materials. However, photosensitized organic materials such as hydrogels, gas-permeable membranes, and ion-selective electrodes (ISEs), e.g., to fabricate a biosensor array, are usually not commercially available. To cope with this problem, photosensitive materials from high-purity materials must be prepared. For example, to pattern a hydrogel, e.g., a water-soluble polymer like polyvinyl alcohol (PVA), a photosensitizer such as $(NH_4)_2Cr_2O_7$ must be added.[15] After spin coating, the polymer film is

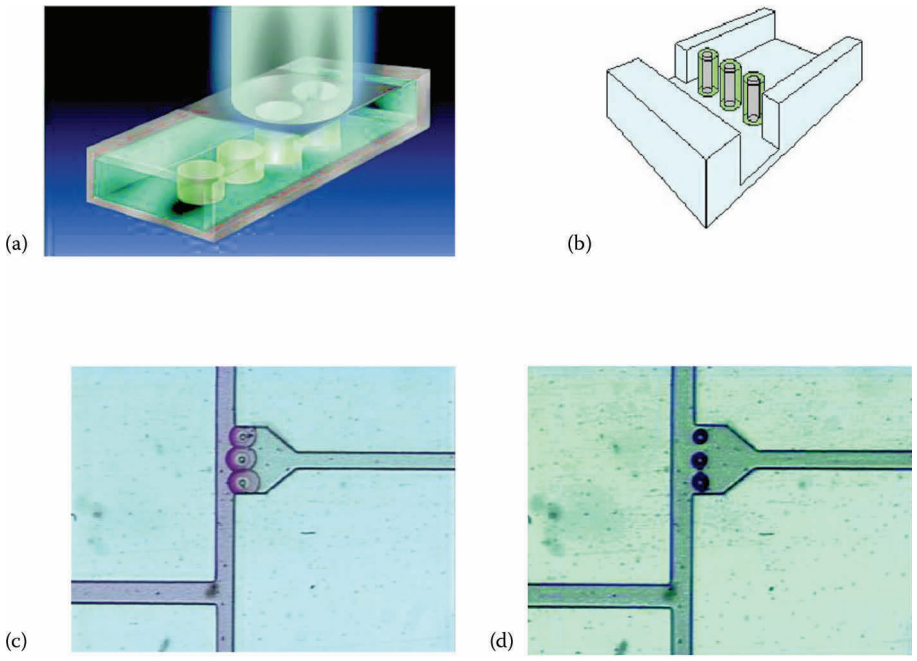

FIGURE 8.15 Patterning hydrogels. (a) Schematic showing the in-channel photo-polymerziation technique. (b) Schematic of a 2D shut-off microvalve consisting of hydrogel "jackets" (50 μm thick) around three prefabricated SU-8 posts. (c) Micrograph of the hydrogel jackets blocking the regulated channel (pH 7) in their expanded state in a pH 12 solution (dyed). photochemically cross-linked by UV light. In the exposed regions, an insoluble hydrogel materializes. The development or removal of unexposed regions is carried out in warm water. An example of patterning a hydrogel actuator material inside a fluidic network through the use of photolithography is described by Liu et al.[22] The actuator hydrogel, after in situ photopolymerization, responds to changes in local pH by changing its volume and thus provides a means for valving action in the fluidic network.[23] The in situ polymerization of these polymeric valves and their function in a fluidic network are demonstrated in Figure 8.15.[22]

An alternative approach to patterning organic materials without modifying the material through the addition of a photosensitizer is through lift-off. Lift-off to lithographically pattern hard to etch materials (e.g., Pt), or in general to pattern materials that are not photosensitive, was introduced in Chapter 1. At one time, a problem with lift-off for patterning organic materials was the thickness required for the patterning photoresist layer. As discussed in Chapter 1, a typical resist layer used to measure only about 1 μm thick, whereas the thickness needed for the organic layers involved in chemical sensors frequently can reach up to 50–100 μm, demanding resist layers that are thicker. The many new thick resist technologies (e.g., SU-8) now available make this approach feasible today. However, a remaining problem with lift-off is that it can be used only with materials resistant to the solvent necessary for the resist removal; therefore, this technology probably will be limited to specific cases.

Hydrogels, gas-permeable membranes, and ISEs are all relatively thick, from several micrometers to 100 μm. Next we consider patterning of much thinner organic layers, such as monolayers of DNA and proteins.

Very Large-Scale Immobilized Polymer Patterning and Synthesis Affymetrix's *very large-scale immobilized polymer synthesis* (VLSIPS) is illustrated in Figure 8.16. The technique patterns and synthesizes biopolymers at the same time.[24] In light-directed oligonucleotide synthesis for DNA arrays (GeneChips), a solid support (e.g., a 1.28 cm × 1.28 cm Si chip) is derivatized with a covalently linked aminosilanated layer and terminated with a photolabile protecting

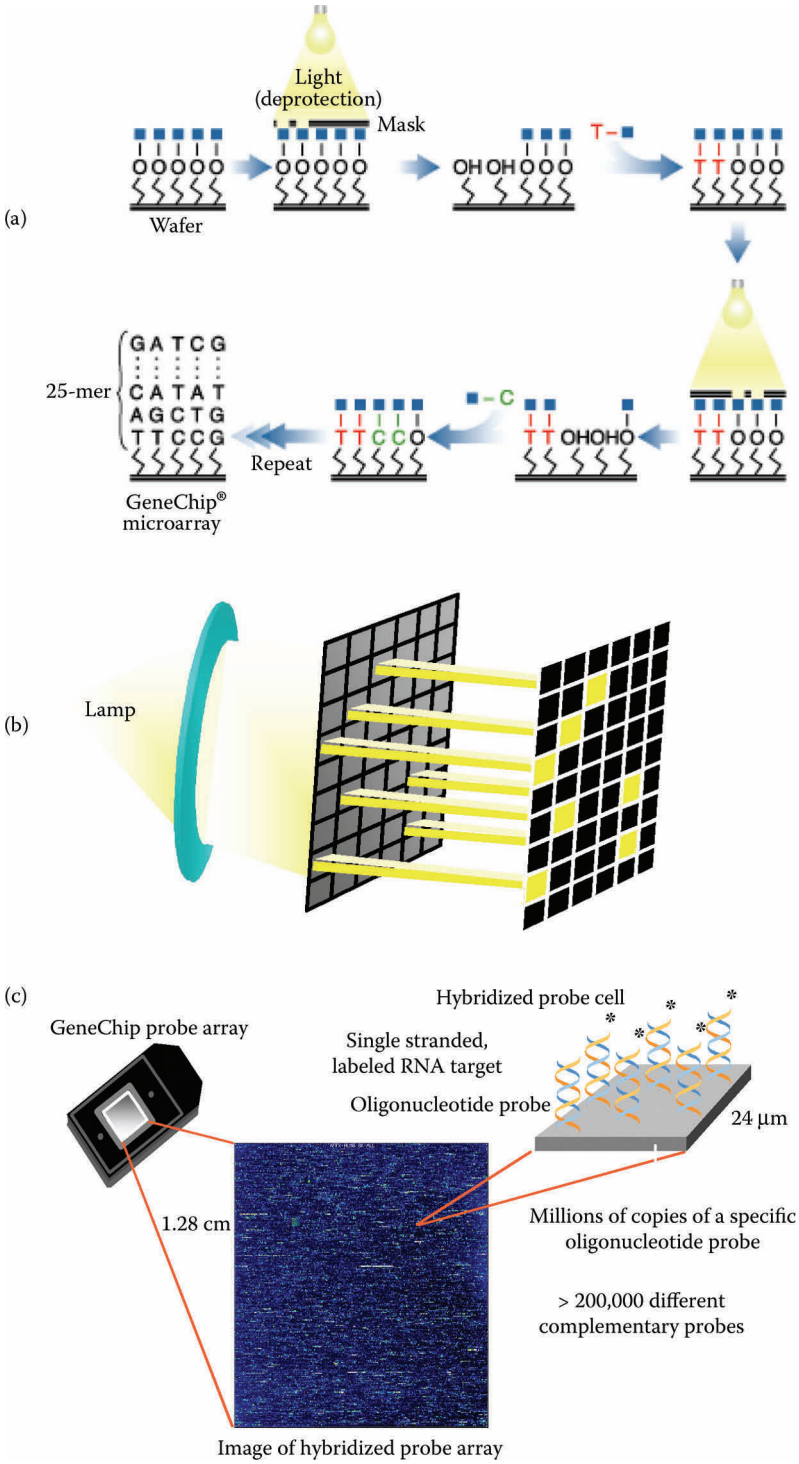

FIGURE 8.16 Very large-scale immobilized polymer synthesis (VLSIPS). Light-directed oligonucleotide synthesis. (a) A solid support is derivatized with a covalent linker molecule terminated with a photolabile protecting group. Light is directed through a mask to deprotect and activate selected sites, and protected nucleotides couple to the activated sites. The process is repeated, activating different sets of sites and coupling different bases, allowing arbitrary DNA probes to be constructed at each site. (b) Schematic representation of the lamp, mask, and array. (From Fodor, P. A. S., J. L. Read, M. C. Pirrung, L. Sryer, A. T. Lu, and D. Solas. 1991. Light-directed, spatially addressable parallel chemical synthesis. *Science* 251:767–73.[24]) (c) Finished GeneChip probe array with a fluorescent image of a hybridized probe array and details of an individual hybridized probe cell (24 µm).

group. The on-chip combinatorial synthesis proceeds by photolithographically deprotecting all array elements that are to receive a common nucleotide, coupling that nucleotide by exposing the entire array to the appropriate phosphoramidite, and then after the oxidation and washing steps, repeating the procedure for the next nucleotide. The in situ synthesis of oligonucleotides occurs in parallel, resulting in consecutive addition of A, C, G, and T nucleotides to the appropriate gene sequences on the array. To make an array of N-mers requires 4N cycles of deprotection and coupling, one for each of the four bases, times N base positions. This photolithographic method requires 4N masks, which are specific to the pattern of sequences on the array but can be used to make many copies of the array. The masks add considerable expense, and the procedure is best suited for generating large numbers of identical arrays. By going through 32 iterations of the oligonucleotide synthesis, 65,536 oligos containing eight units can be fabricated in about 1 day.

In Figure 8.17 we show how an Affymetrix oligo microarray can be used to establish the amount of messenger RNA (mRNA) in a sample. mRNA is extracted from a cell and is converted to complementary DNA (cDNA) using reverse transcriptase. After transcription, the cRNA is biotin-labeled and fragmented. This single-stranded and labeled RNA target is then put in contact with the GeneChip with millions of copies of different complementary probes. After hybridization, the chip is washed and stained, and the array is scanned and quantitated. Each gene is represented on the GeneChip using 16–20 (preferably nonoverlapping) 25-mers, and each oligonucleotide has a single-base mismatch partner for internal control of hybridization specificity.

The combinatorial approach described here to fabricate DNA arrays can also be used for peptide synthesis to create an assortment of peptides of almost any length. The approach is a generic and powerful method to create large numbers of compounds in a very small area in a reasonable amount of time.

Proteins Patterning with Lithography A wide range of proteins has been patterned with features in the micrometer range by making a surface locally hydrophobic or hydrophilic through lithography (see Chapter 2, "Very Thin Resist Layers"). Such patterns may be observed by a number of techniques including fluorescence microscopy, atomic force microscopy (AFM), and the growth response of cultured cells.[25] There are also efforts to produce nanopatterned protein arrays by using proteins that self-assemble into molecular lattices, such as the bacterial S protein. Douglas et al.[26] used metal-decorated crystals of the S proteins of *Sulfolobus acidocaldarius* as a

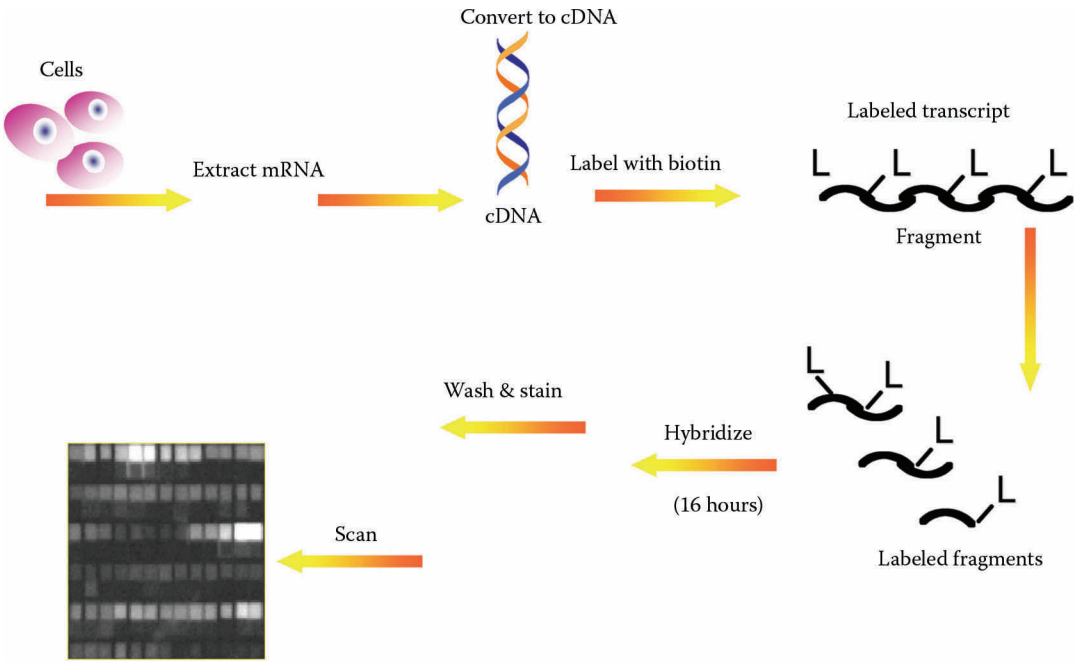

FIGURE 8.17 How an oligo microarray works.

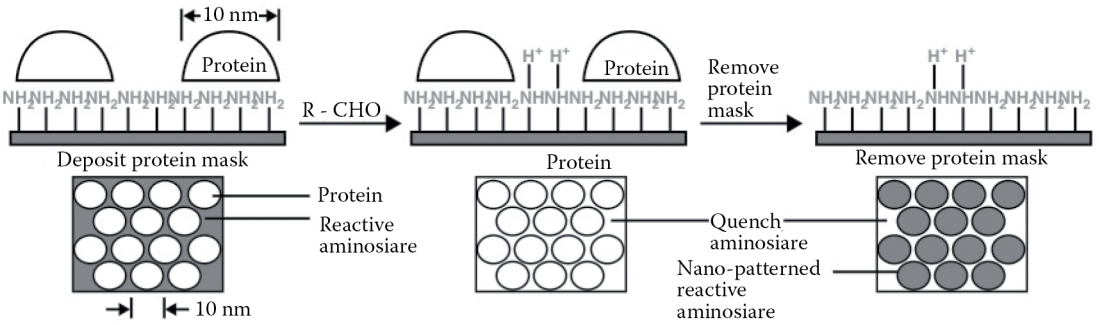

FIGURE 8.18 Nanopatterning of surface chemistry using a self-assembled protein mask. (From Douglas, K., G. Deavaud, and N. A. Clark. 1992. Transfer of biologically derived nanometer scale patterns to smooth substrates. *Science* 257:642–44.[26])

protein mask to pattern hexagonal arrays of 10-nm-diameter holes onto graphite surfaces. Figure 8.18 demonstrates how the self-assembled protein lattice may be used for nanopatterned protein surfaces.

UV lithography, in some special cases, may also work directly for patterning thin protein layers as demonstrated in Example 8.1. In this example a protein grating was created by shining UV, in the presence of oxygen, through a grating photomask. Besides UV lithography, soft and hard x-rays, e-beam, and ion projection lithography can all be used for direct protein film structuring.

Digital Mirror Array Patterning With VLSIPS (see above), a DNA chip of 25-mers may require as many as 100 different masks, leading to a very high cost and a too-long fabrication time.

Singh-Gasson et al.[27] came up with an elegant maskless fabrication alternative for light-directed oligonucleotide microarrays by using a digital micromirror array. Specifically, this group used the digital micromirror device (DMD) from Texas Instruments (http://www.dlp.com/dlp/default.asp), the fabrication of which is described in Chapter 7. This specific DMD consists of a 600 × 800 array of 16-µm-wide micromirrors (the same type used in projection systems). The tiny mirrors are individually addressable and can be used to create any given pattern or image in a broad range of wavelengths. With a 1:1 imaging system, the DMD can be exploited to address 480,000 pixels on a 10 × 14-mm area. This maskless array synthesizer (MAS) or virtual mask array synthesizer is shown in Figure 8.19. An added benefit of this clever approach is that the active surface of the glass substrate can be mounted in a flow cell reaction chamber connected to a DNA synthesizer. Chemical coupling cycles follow light exposure, and these steps are repeated with different virtual masks to grow desired oligonucleotides in any desired pattern. It is obvious that the MAS can also be used for other array patterning/synthesis experiments.

Virtual masks were discussed in Chapter 1 under "Inexpensive Masks and Maskless Optical Projection Lithography for Research and Development." A maskless imaging method was also used by Bertsch et al.[28] at the Swiss Federal Institute of Technology (EPLF) in microstereolithography. This research group uses a computer-controlled liquid crystal display (LCD) as a dynamic pattern generator in microstereolithography (see further below).

Ink Jetting and Microspotting

Introduction Drop delivery systems present an alternative mechanical approach to pattern organic materials on a planar substrate. Although resolution is lower than with lithography methods, these mechanical methods are fast and less expensive.

Ink-Jet Printing Drop delivery in bio-MEMS is based on the same principles as commercial ink-jet printing. The ink-jet nozzle is connected to a reservoir filled with the chemical solution and placed above a computer-controlled *x-y* stage. Depending on the ink expulsion method, even temperature-sensitive enzyme formulations can be delivered. The substrate to be coated is placed on the *x-y* stage, and under computer control, liquid drops (e.g., 50 µm in diameter) are expelled through the nozzle onto a well-defined place on the wafer (see Figure 8.20).

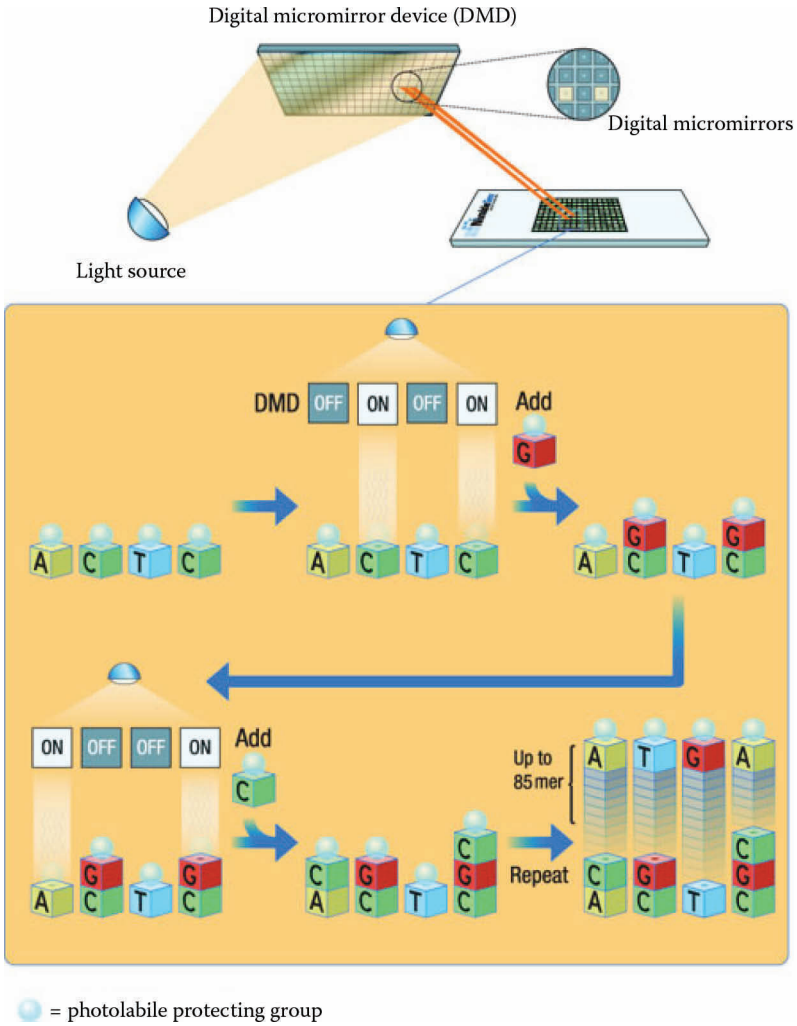

FIGURE 8.19 Schematic of the maskless array synthesizer (MAS). A UV light source is used to illuminate the digital micromirror array. A set of reflective OFF/ON mirrors and a 1:1 imaging system with a numerical aperture (NA) of 0.08 form an image of the pattern on the digital micromirror array on the active surface of the glass substrate. The glass substrate is enclosed in a flow cell connected to a DNA synthesizer. (Courtesy of Dr. R. Green, NimbleGen Systems.)

Different nozzles may print different spots in parallel. Although these drop delivery systems are serial, they can be very fast, as evidenced by epoxy delivery stations in IC manufacturing lines.

The ink-jet mechanism in Figure 8.20 is thermal and is often called a *bubble jet*, with droplets as small as a few picoliters (2–4 pL).[29] Some ink-jet printers can vary the drop size. Five years ago a typical drop size was 30–50 pL; today drop sizes of 2–4 pL are state of the art. This is comparable to the size difference between a softball and a ping pong ball. Smaller drops produce smoother-looking prints because they make smaller dots on the paper. Hewlett Packard's (HP) thermal ink jet (TIJ) represents the state of the art in this arena. In the TIJ, tiny resistors are used to rapidly heat (1,000,000°C/s) a thin (0.1 μm) layer of liquid ink to about 340°C. A superheated vapor explosion vaporizes a tiny fraction of the ink to form an expanding bubble that ejects a drop of ink (and any trapped air) from the ink cartridge onto the paper or other substrate. It is noteworthy that the ink does not boil. The bubble collapse and break off draws fresh ink over the resistor. The bubble formation, expansion, break off, and refill (all very fast) are illustrated in Figure 8.21a. The HP TIJ has all the active power electronics and orifice addressing integrated on the same Si chip with the drop generator as shown in Figure 8.21b. The orifices may be spaced at 300/in. in a single column for a 300-dpi printhead, or for a 600-dpi printhead,

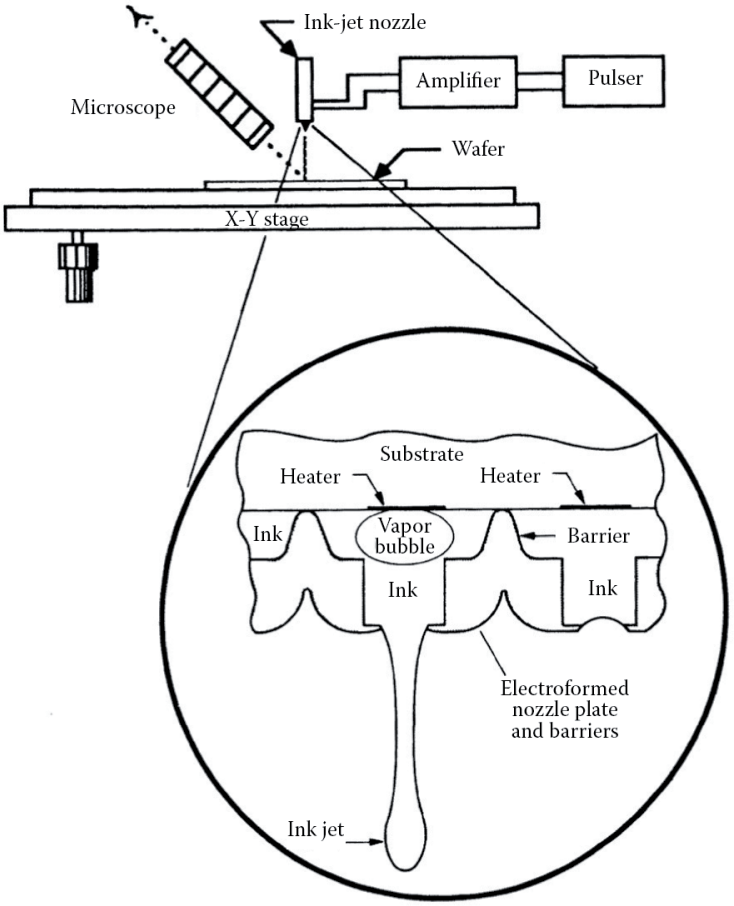

FIGURE 8.20 Ink-jet deposition system.

two offset columns of 300 orifices may be used. It is even possible to put 600 TIJ orifices/in. in a single column. Current piezo ink jets (see next paragraph) only have 90 orifices/in. The TIJ technology is a remarkable piece of engineering. To put this in perspective, engineers trying to develop a commercial ion-sensitive field effect transistor (ISFET) have struggled for more than 30 years to integrate liquids with electronics with little success or market acceptance until very recently (see Volume I, Chapter 7 and Volume III, Chapter 10). Not only did HP succeed in integrating liquid with electronics, they were also able to find an effective method of repeatedly heating the liquid (ink). This way HP has also carved out a very lucrative business in disposable ink cartridges. Perhaps their efforts will also pay off in other fluidic areas, and it may even be worth reconsidering the ISFET using HP technology.

A piezoelectric ink-jet head is used for another type of ink-jet printing and consists of a small reservoir with an inlet port and a nozzle at the other end. One wall of the reservoir consists of a thin diaphragm with an attached piezoelectric crystal. When voltage is applied to the crystal, it contracts laterally, thus deflecting the diaphragm and ejecting a small drop of fluid from the nozzle. The reservoir then refills via capillary action through the inlet. One, and only one, drop is ejected for each voltage pulse applied to the crystal, thus allowing complete control over when a drop is ejected. Such devices are inexpensive and can deliver drops with volumes of tens of picoliters at rates of thousands of drops per second. In conjunction with a computer-controlled x-y stepping stage to position the array with respect to the ink-jet nozzles, it is possible to deliver different reagents to different spots on the array. Arrays of 150,000 spots can be addressed in less than 1 min, with each spot receiving one drop of reagent. As pointed out above, thermal ink jets have a higher orifice density than piezoelectric printing. For more details on both types of ink-jet printing, visit http://www.hp.com/oeminkjet/tij/about.htm.

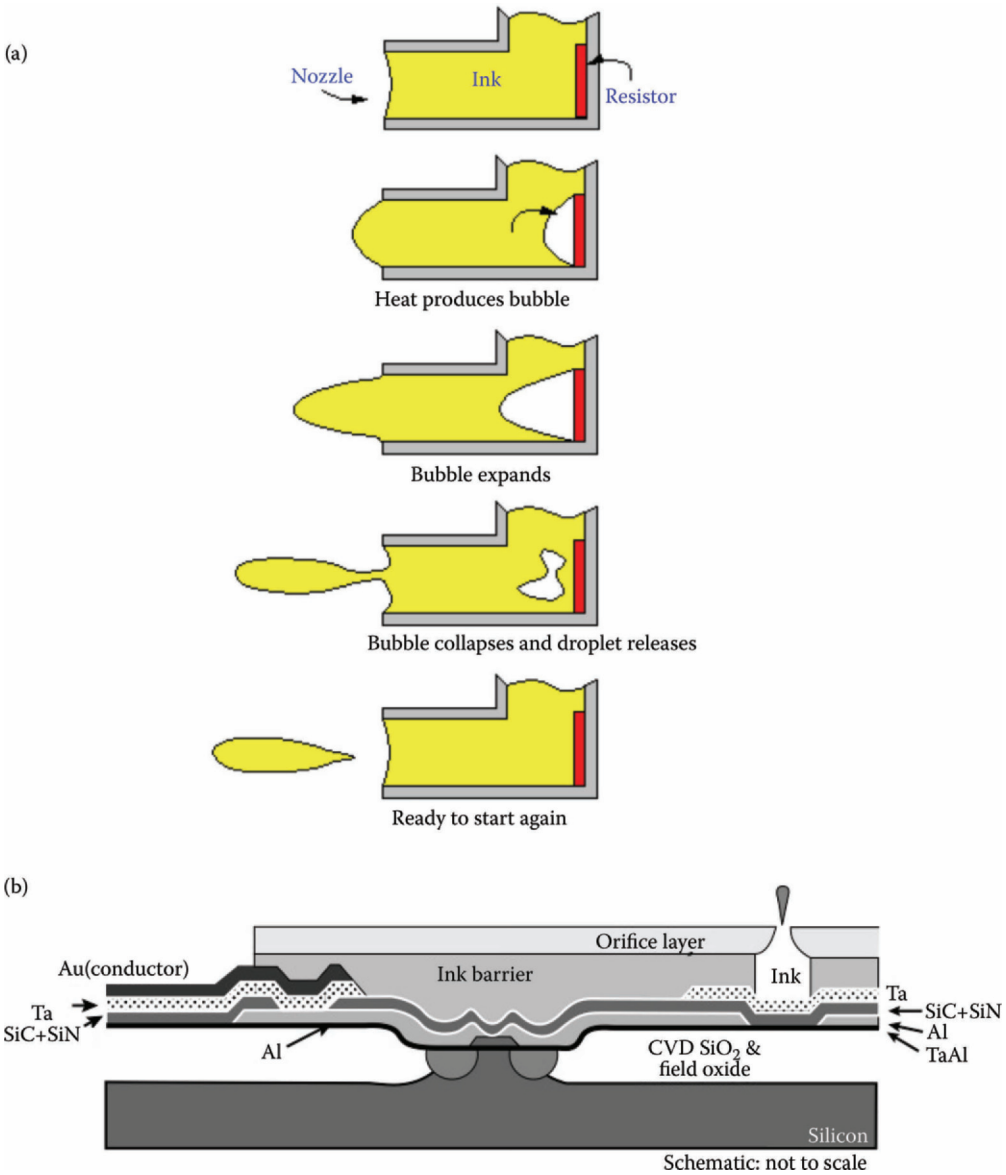

FIGURE 8.21 HP's thermal ink-jet (TIJ) technology. (a) Bubble formation, expansion, collapse, and refill. (b) Integrated power electronics and orifice addressing.

Because a computer controls the pattern of reagents as an array is being made with ink jetting, it is as easy to make 10 arrays with different sequences as it is to make 10 identical arrays. This flexibility is perhaps the main advantage of the ink-jet approach. Achieving high density with the ink-jet approach requires one more trick. Two drops of liquid applied too closely together on a surface will tend to spread into each other and mix. For 40-pL drops, the minimal center-to-center spacing is about 600 μm. This limits the array density achievable with the ink-jet method. One way around this is to engineer patterns in the surface chemistry of the array to produce spots of a relatively hydrophilic character surrounded by hydrophobic barriers. At the small length scales involved (approximately 100 μm), surface tension is the dominant force on a drop of liquid, and a hydrophobic surface will effectively prevent a drop from spreading out beyond the confines of the hydrophilic surface. There are several ways to engineer such a surface. Modern techniques use fluorinated alkyl silanes, which covalently couple to glass and present an extremely hydrophobic surface. They can be patterned by masking the areas to remain hydrophilic, derivatizing the exposed surface with the appropriate silane and then removing the mask by dissolving

it with various organic solvents. The mask itself can be formed by a photolithographic process wherein the array is covered with a thin, uniform layer of photoresist, which is then exposed to light through a photographic negative to define the array. The photoresist is developed, leaving behind a pattern of protective photoresist to act as a mask. Alternatively, a "Whitesides" rubber stamp can be used to apply either the protective mask or the hydrophobic silane itself. Any of these methods will easily produce 100-µm-diameter hydrophilic wells separated by 40-µm hydrophobic barriers, or 5,000 array sites/cm^2. Ink-jet technology has been used to prepare microarrays of single cDNA at a density of 10,000 spots/cm^2.

On a somewhat larger scale, epoxy-delivery systems used in the IC industry similarly deliver drops in a serial fashion on specific spots on a substrate. A typical commercial drop-dispensing system (e.g., the IVEK Digispense 2000) delivers 0.20–0.50 µl in a drop and has a cycle time per dispense of 1 s. A vision system verifies substrate position and accurate dispense location to within ±25 µm of a specified location.

Mechanical Microspotting Mechanically microspotting, as developed by Brown et al. (Stanford University), is simpler than ink-jet printing. In this approach, a popular and inexpensive method for making DNA arrays, a prepared DNA sample (e.g., cDNA or a PCR product) is loaded into a spotting pin by capillary action, and a small volume is transferred to a solid surface by physical contact between the pin and the solid substrate (see Figure 8.22). After a first spotting cycle, the pin is washed, and a second sample is loaded and deposited to an adjacent address. Robotic control systems and multiplexed printheads allow automated microarray fabrication. This very flexible mechanical drop delivery technique takes a small amount of liquid from a 96- (or 384-) well plate and places a tiny (1 nL) drop onto a microscope slide. Because the machine is fully automated, it requires little extra work to make additional slides. One can typically make 120 slides at a time. The microspotted microarrays currently manufactured contain as much as 10,000 groups of cDNA in an area of 3.6 cm^2.

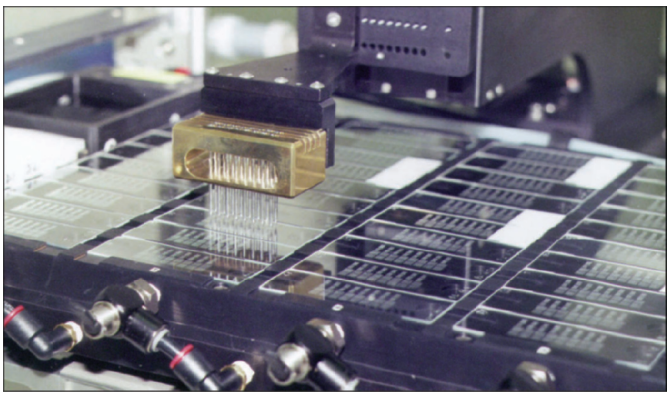

FIGURE 8.22 Spotted arrays of cDNA on 50 glass slides.

As sketched in Figure 8.23, a cDNA array as fabricated with the equipment shown in Figure 8.22 may be used to establish the relative amount of messenger DNA expression in a biological sample (see also Volume III, Chapter 2). For example, we might want to compare the gene expression levels for two cell populations (e.g., from tumor and normal cells) on a single microarray. For that application, both sample (tumor cell) and control DNA (normal cell) are used as targets. One first extracts mRNA from both sample and control and converts the mRNA to cDNA using reverse transcriptase. In a subsequent step, the cDNA is amplified using PCR. DNA probe molecules are then deposited onto the glass slide substrate. Finally, target DNA from tumor and healthy cells are fluorescently tagged (Cy3, Cy5; see Volume I, Chapter 7), and an equal amount of each is added to the cDNA probe array. Depending whether there is a match between target and probe DNA, hybridization does or does not take place. If no hybridization occurs, no color results. If the sample (red) DNA hybridizes and the control does not, a red color results, and if only control (green) DNA hybridizes, a green color results. If both hybridize equally, a yellow color results. The color intensity measured in a fluorescence reader reflects the abundance of the mRNA in the sample. The assumption in this experiment is that cellular mRNA levels directly reflect gene expression.

In Table 8.1 we compare the procedure for measuring mRNA as depicted in Figure 8.23, where we use a spotted cDNA array, with the one in Figure 8.17, where we use a lithographically synthesized oligo array.

In Figure 8.24, we compare three arraying methods: lithography, microspotting, and ink jetting.

TABLE 8.1 Spotted cDNA Array versus Synthesized Oligo Array

	Microarray: Spotted	DNA Chips: Synthesized
Probes	Probes (0.6–2.4 kb) are PCR-amplified full-length cDNA sequences	Probes are 20–25 deoxyoligonucleotides
Manufacture	Spotted by "robo-arms" on nonporous, solid support	Synthesized on glass by solid-phase DNA synthesis coupled with selectively masked light protection and deprotection (photolithography)
Number of spots	About 10,000 "spots" on a microscope glass slide. Maximum 24,000 features per array	Commercial GeneChips have about 300,000 probes on 1.28 × 1.28 cm surface; experimental versions exceed 1,000,000 probes per array
Quality of spots	Variability in spot quality from slide to slide	High quality with little variability between slides
Gene representation	Each gene represented by its purified PCR product	Each gene represented multiply using 16–20 (preferably nonoverlapping) 25-mers
Internal control	Simultaneous analysis of two samples (treated vs. untreated cells) provides internal control	Each oligonucleotide has single-base mismatch partner for internal control of hybridization specificity
Gene expression amount	Relative	Absolute
Cost/flexibility	More flexible and cheaper, homemade	More expensive yet less flexible

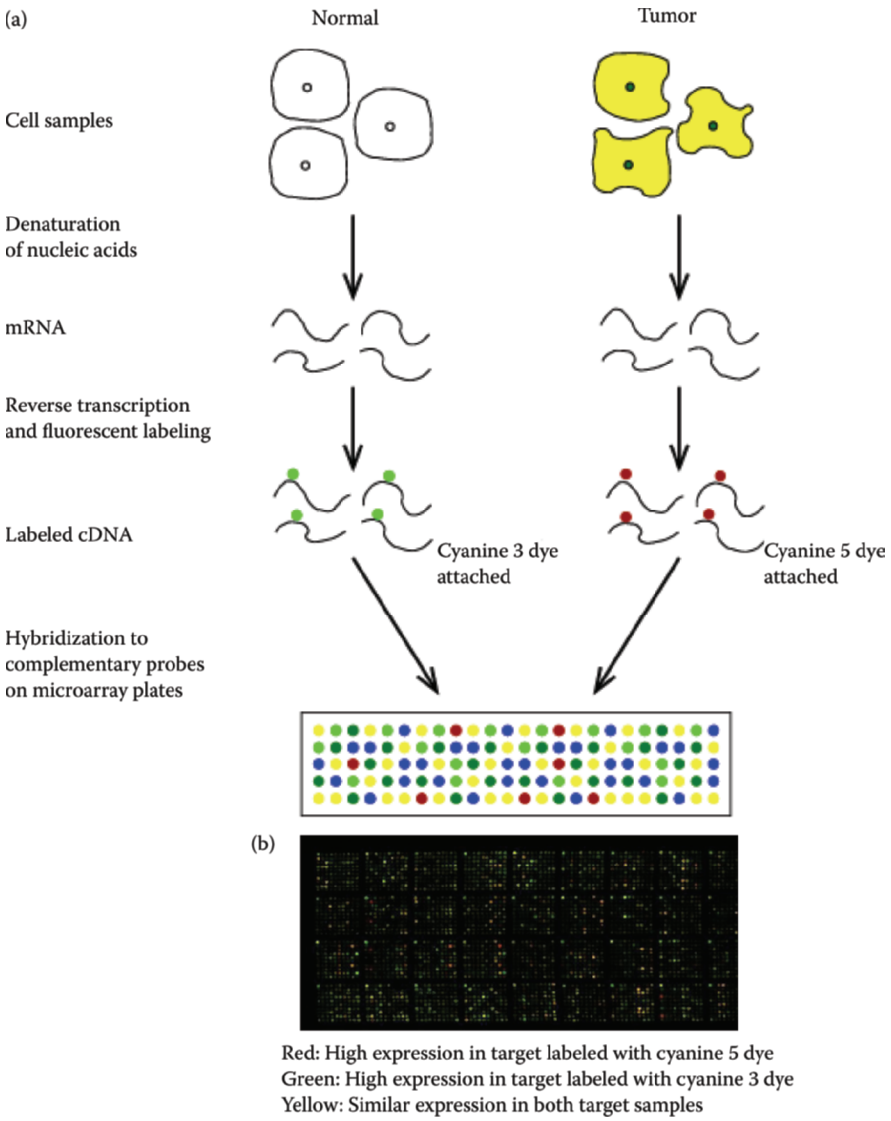

FIGURE 8.23 Example of spotted cDNA microarray analysis: experimental procedure (a) and microarray image (b).

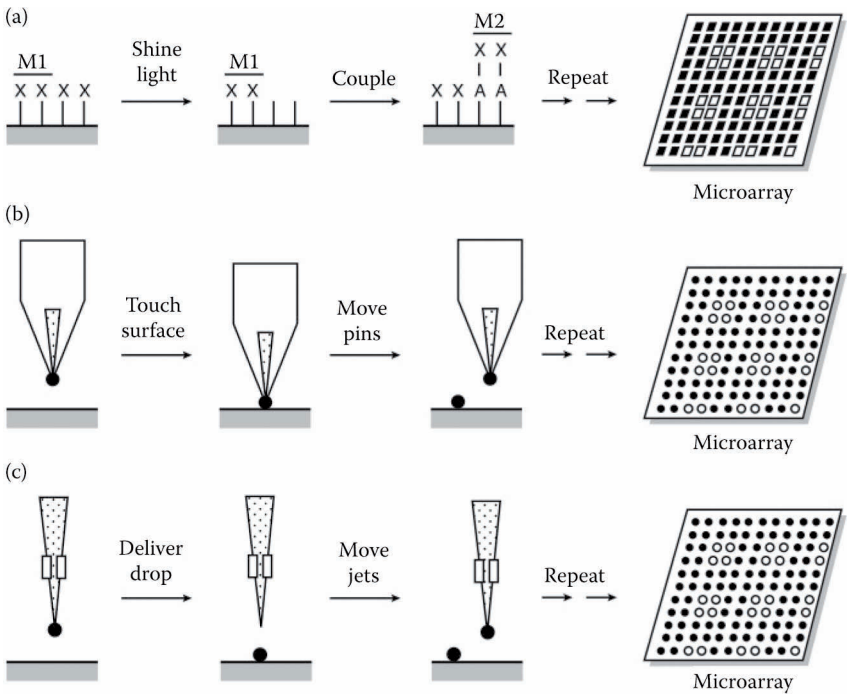

FIGURE 8.24 The three main arraying methods: lithography (a), microspotting (b), and ink-jetting (c).

One disadvantage of microspotting and ink jetting compared with VLSIPS is that each sample must be synthesized, purified, and stored before microarray fabrication.

Some good web sites for further information on arraying technology are Stanford University's *Brown's Lab Guide to Microarraying* at http://cmgm.stanford.edu/pbrown/mguide and BASF's Leming Shi's http://www.gene-chips.com.

Microcontact Printing Micro- or nanocontact printing with a polydimethylsiloxane stamp was reviewed in detail in Chapter 2. In this approach, a Si master is created using a high-resolution lithography technique (e.g., e-beam). Curing an elastomeric prepolymer on this master subsequently forms an elastomeric stamp. The resulting stamp can be inked, for example, with thiols that can be subsequently transferred to a solid support, forming highly localized structured monolayers (see Figure 2.53). Scanning tunneling microscope (STM) studies of the transferred SAMs reveal an achievable monolayer order indistinguishable from that found for SAMs prepared from solution. The technique has been used, for example, to build an antibody grating on a Si wafer by inking the rubber stamp with an antibody solution.[30] The antibody grating alone produces insignificant diffraction, but on immunocapture of cells, the optical phase change produces diffraction. This is an alternative method to make an immunograting than the one described in Example 8.1.

Conductive Polymer Patterning Polymers that can be electropolymerized may also be deposited and patterned by first patterning a thin film metal electrode in a desired pattern on the substrate. In the late 1980s, this author patterned conductive polymers such as polypyrrole and polyaniline with lithography techniques. In one example, arrays of conductive polymer posts were formed on a conductive substrate. Increased ion access to individual conductive polymer posts as compared with access to a uniform film of the same polymer leads to higher electrochemical reversibility, which might find applications in faster polymer battery electrodes, electrochromic devices, enzyme-based biosensors, and microelectronic or molecular electronic devices. Figure 8.25 depicts the procedure for fabricating 3D arrays of electronically conductive polymers and an SEM micrograph of the resulting patterned conductive polymer posts.[31,32]

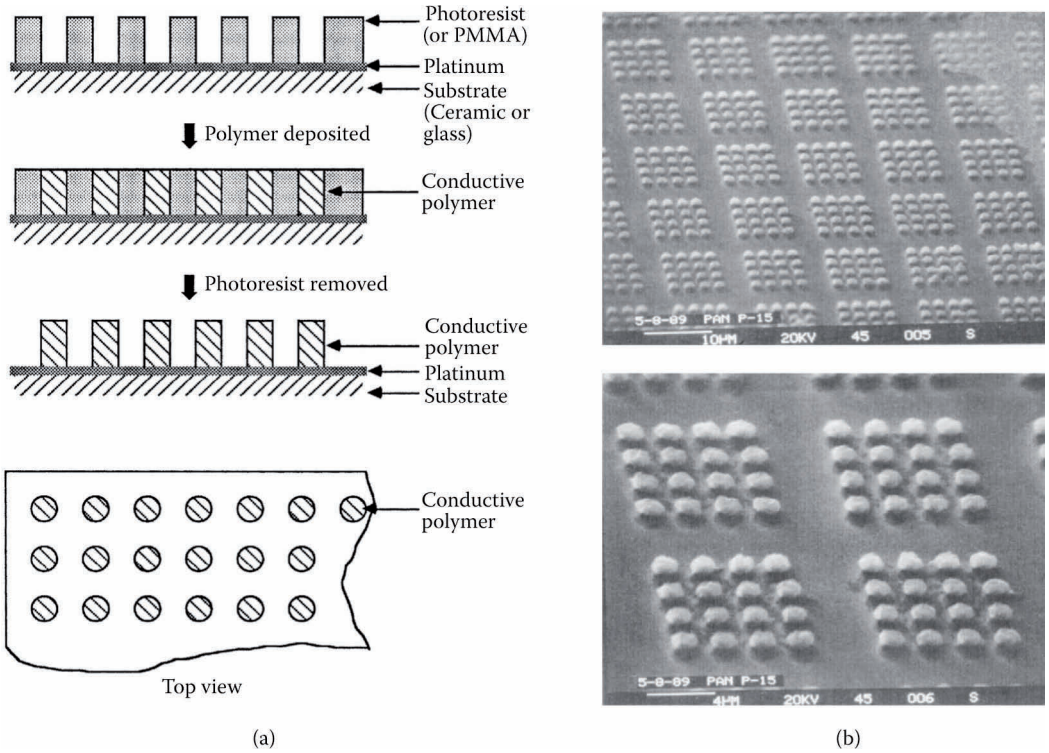

FIGURE 8.25 Micropatterning of conductive polymers. (a) Process sequence. (b) SEM micrograph of conductive polymer submicrometer electrode array (polyaniline doped with tosylate).

Table 8.2 summarizes some of the most popular membrane deposition and patterning techniques.[15] At first glance, photolithography seems very promising, but the chemistry is complex and few results have been obtained to date, the most important exceptions being the i-STAT Abbott Point of Care blood electrolyte and blood gas sensors (http://www.abbottpointofcare.com/) and the Affymetrix DNA arrays (http://www.affymetrix.com). More array developers today are opting for microspotting, ink-jet printing, and screen printing as the safest and least expensive approach.

Photochemical Forming

Introduction

In photochemical forming the energy at the work piece is provided by photons. A prominent example is photolithography, where negative-tone photoresists are cross-linked by photons of the right energy (Chapters 1 and 2). Traditional photolithography techniques result in projected shapes. A photoresist structure can take on any shape in the x-y plane and possess some limited height (in the z-direction), but

TABLE 8.2 Deposition and Patterning Techniques for Planar Chemical Membranes

	Typical Use	Thickness Range (μm)	Cost	Uniformity	Reproducibility	Patterning
Dip coating	Wire ISEs	0.1–50	Low	Poor	Poor	No
Casting	Planar ISEs	0.1–>100	Low	Moderate	Moderate	No
Photolithography	Planar sensors (PVA,PHEMA)	1–10 μm	Moderate	Good	Good	Yes
Lift-off	Immunosensors	0.1–3 μm	Moderate	Moderate	Good	Yes
Plasma etching	PVC, Teflon	1–10 μm	High	Good	Good	Yes
Ink-jet printing	Universal	1–5 μm	Moderate	Poor	Moderate	Yes
Screen printing	Universal	5–50 μm	Low	Moderate	Moderate	Yes

they remain projected shapes that are not truly 3D because the method does not lend much control over the resist sidewalls along the *z*-axis; such structures are sometimes referred to as 2 1/2D. In miniaturization science, truly 3D lithography is the subject of increased research. Here we review methods of photochemical forming of truly micro- and even nano-3D shapes, including stereolithography or microphotoforming and its newest embodiments such as two-photon polymerization and parallel stereolithography. We start this section with a brief summary of rapid prototyping techniques. In rapid prototyping, additive layering or 3D polymerization techniques have long played an important role for quickly making a nonfunctional mock-up of a real component. Recently improved versions of those methods have also became promising candidates for micro- and nanomanufacturing. It is also important to notice that the term rapid prototyping is less and less the right word to use. Indeed quite often these additive or 3D polymerization manufacturing processes are leading more and more to final functional products rather than nonfunctional prototypes. We classify free-photoforming additive as either chemical or thermal, depending on the primacy of the chemical reaction or the heat application. Thus, low-temperature polymer photoforming is covered in this chapter, whereas the higher-temperature laser-assisted chemical vapor deposition process is covered in Chapter 9.

Rapid Prototyping

The past 20 years witnessed the emergence of a set of new manufacturing techniques with parts made on a layer-by-layer basis or by 3D polymerization. With these technologies, manufacturing time for even the most complex parts is measured in hours instead of days or weeks. Hence these technologies are called *rapid prototyping* (RP). RP, based on layered manufacturing (LM), and direct 3D polymerization in two-photon lithography where no layering is needed form a set of manufacturing techniques by which a solid physical model of a structure is made directly from 3D computer-aided design (CAD) model data, without any special tooling. The CAD data may be generated from 3D CAD modelers, computer tomography (CT),* and magnetic resonance imaging (MRI) scans or model data created by 3D digitizing systems. Although there is no limit to the prototype's complexity, its size is limited by the size of the manufacturing bed. The same data used for the rapid prototype creation can be used to go into production, eliminating all types of sources of human errors.

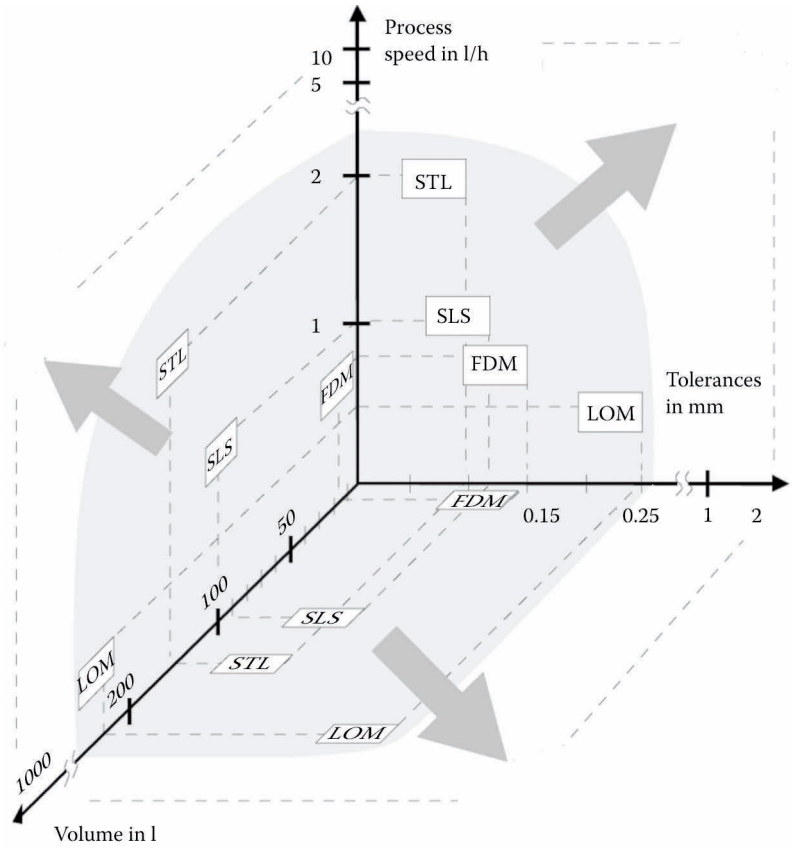
Besides 3D modeling, RP needs specific fluids, powders, wires, or laminates, as well as a machine tool that builds the desired 3D prototypes using different physical principles such as lasers, laminators, and 3D printers. This type of fabrication is referred to as additive manufacturing versus the subtractive manufacturing of milling and turning. Some very new RP methods combine additive and subtractive techniques. For example, the laser sintering/milling hybrid machine, the LUMEX 25C, developed by Matsuura Machinery Corporation, successfully combines freeform manufacturing and high-speed milling (see the photo in the heading of Chapter 9 on thermal energy-based forming).

The first commercial RP method appeared on the market in 1987 from 3D Systems (http://www.3dsystems.com) and was based on stereolithography (SL) where liquid polymers are solidified when exposed to UV light. Stereolithography remains the best known RP system and is widely used in automotive and aerospace industries to fabricate parts from basic design for "show and tell" before the parts are produced. As listed in Table 8.3, there are many different RP methods available that offer varying degree of accuracy, speed, product size (see Table 8.3, inset), as well as a large choice of materials. Two-photon lithography, the newest RP technique that does not rely on layering the part under construction, is dealt with separately below and is not listed in Table 8.3. In all RP methods listed in Table 8.3, a designer, using CAD software, exports a model of the intended product to a standardized portable file format for 3D objects, such as the stereolithography

* Computer tomography (CT) is a powerful nondestructive evaluation (NDE) technique for producing 2D and 3D cross-sectional images of an object from flat x-ray images. Characteristics of the internal structure of an object (such as dimensions, shape, internal defects, and density) are readily available from CT images.

Table 8.3 Rapid Prototyping Techniques

- SL: Stereolithography (see below for details).
- SLS: Selective laser sintering laser beam melts the layer of metal powder to create solid objects (see Chapter 9).
- 3DP: In 3D printing layers of ceramic (plaster) powder are glued to form objects. 3DP uses ink-jet printer technology (e.g., the Z402c from the Z Corporation) to print fine patterns of glue onto a smooth bed of plaster powder (so smooth it looks like paper). The bed is lowered, and a roller spreads a very fine layer (0.004″) over it to print a new layer.
- LOM: Sheets of material (paper, plastic), either precut or on a roll, are glued (laminated) together and laser cut in the laminated object manufacture process.
- FDM: In fused deposition modeling each cross-section is produced by melting a plastic filament (ABS) that solidifies on cooling. The FDM (e.g., the Stratasys FDM 1650) builds layers by extruding a hot, viscous strand of ABS plastic through a very fine nozzle,like squeezing toothpaste out of a tube. The fine strands (0.012″) stick together as they cool.



software (http://stl-software.qarchive.org) that interfaces with the RP machines, analyzes the surface vectors (boundary) of the model, and "slices" the part into many thin layers. Stereolithography files describe only the surface geometry of a 3D object without any representation of color, texture, or other common CAD model attributes. RP machines make parts by producing one of these layers at a time and eventually building up a complex, 3D object. As mentioned earlier, in two-photon lithography there is no need for this layering step.

Stereolithography (SL) is a photoforming-based RP process, and its application to MEMS and NEMS, as well as its newest embodiments such as two-photon polymerization and parallel stereolithography, is detailed below. Selective laser sintering (SLS)

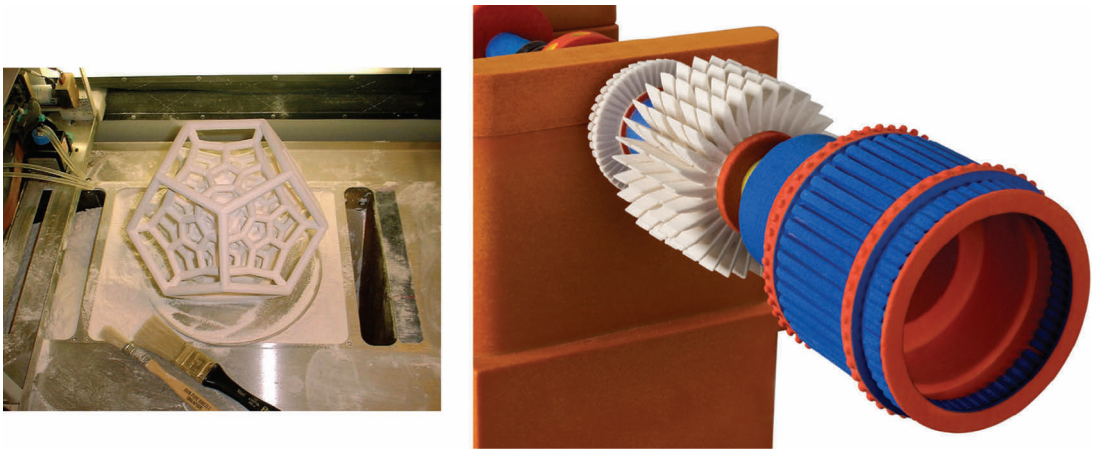


FIGURE 8.26 A 3D-printer by Z Corporation that creates models from plaster powder (http://www.zcorp.com).

is a thermal additive technique expanded on in Chapter 9. A brief explanation of how the other RP techniques listed in Table 8.3 work follows.

Ink-jet printing, discussed earlier, is essentially a 2D method; an important new direction in RP is the concept of 3D printing. In one approach to 3D printing (3DP), layers of ceramic powder (plaster) are glued/bound to form objects. 3DP uses ink-jet printer technology (e.g., from the Z Corporation; http://www.zcorp.com) to print fine patterns of glue onto a smooth bed of plaster powder (so smooth it looks like paper). In a first step the printer covers the bed with a 1/8th inch (3.18 mm) layer of a powder as support so that the parts when finished rest on this base for easy removal. The bed is then lowered, and a roller spreads a next very fine layer (0.004″) over it to print a first layer (Figure 8.26). Z Corporation first introduced high-resolution, 24-color, 3DP (HD3DP™) in 2005 (600 dpi). The printer accurately and precisely deposits colored binder in the desired areas. The binder solidifies the powder in that cross-section of the model, leaving the rest of the powder dry for recycling. The 3D printers control the printhead movement while positioning the head extremely close to the powder, reducing inaccuracies related to fanning of the binder spray.

Sheets of material (e.g., paper, plastic, ceramic, composite), either precut or on a roll, are glued (laminated) together and laser cut in the laminated object manufacture (LOM) process. The laminated part is constructed on a platform with vertical incremental movement. Above the platform, a heated roller heats and compresses each new sheet to the top of the construct. A laser scans the upper surface of the laminated stack to cut the very top layer. Scrap pieces of the laminate remain on the platform as the part is built. The scrap material is diced by the laser into cross-hatched squares that serve as support for the part under construction. The product then comes out as a rectangular block of laminated material containing the prototype and the scrap cubes. The scrap, support material—resulting from the cross-hatch cut by the laser—is easily separated from the prototype part. LOM is a relatively high-speed process (Figure 8.27), and parts can be used immediately after the process because no postcuring is required. Also, no additional support structure is required because the part is supported on its own.

The fused deposition modeling (FDM) technology was developed by S. Scott Crump in the late

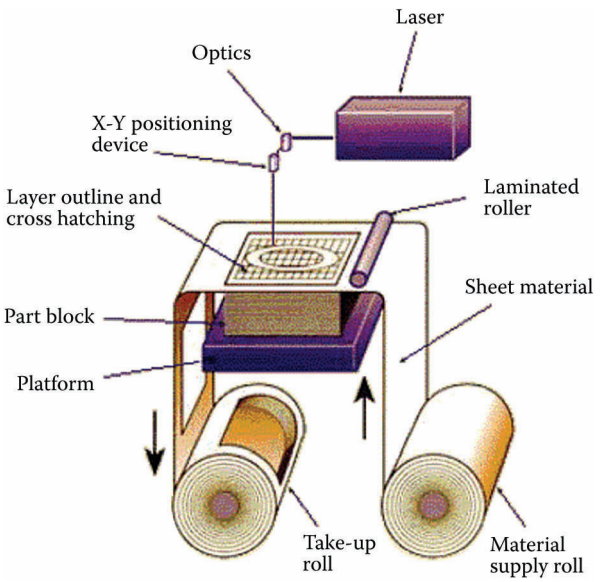

FIGURE 8.27 LOM process.

1980s and was commercialized in 1990. The FDM technology is marketed commercially by Stratasys Inc. (http://www.stratasys.com/selectapart.html). Stratasys-patented technology builds solid models by melting a continuously supplied plastic wire (see Figure 8.28). The supplied wire typically is acrylonitrile butadiene styrene (ABS, a thermoplastic) with a 0.012-in. diameter and is extruded as a hot, viscous strand through a fine nozzle (like squeezing toothpaste out of a tube). A computer controls the nozzle movement along the x- and y-axes, and each cross-section of the prototype is produced by melting a plastic filament (ABS) that solidifies on cooling. After one layer is done, the stage is moved downward, and another layer of deposition starts. The newest FDM models feature two nozzles; one carries the construction material and the other a support wax that can easily be removed afterward, allowing construction of more complex parts. Marketed under the name WaterWorks by Stratasys, this soluble support material is dissolved in a heated sodium hydroxide solution with the assistance of ultrasonic agitation.

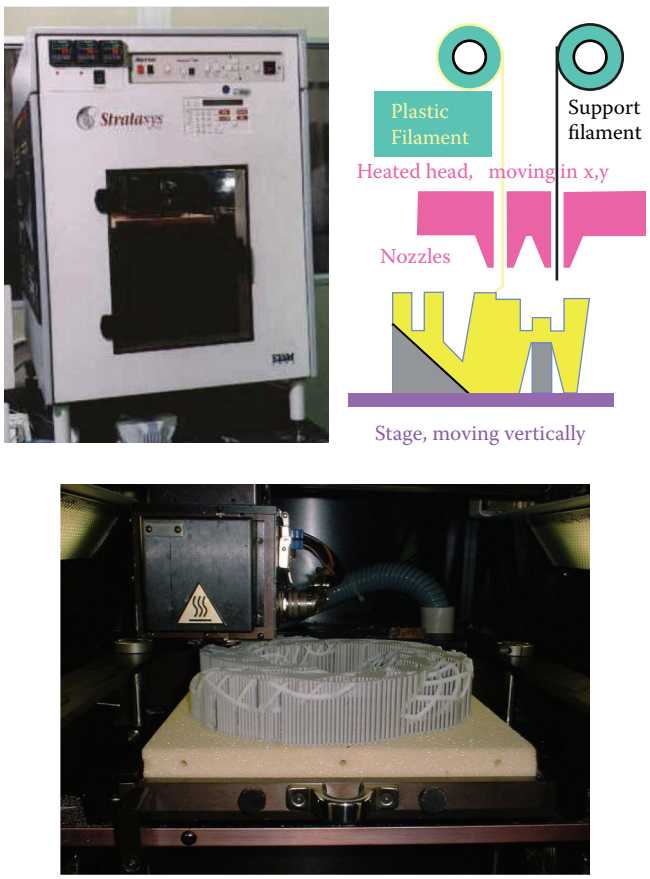

FIGURE 8.28 FDM machine; models are made from molten ABS plastic (http://www.stratasys.com).

The FDM method is environmentally friendly but has a somewhat restricted accuracy because of the nozzle size, which needs to accommodate a viscous material. Also, few types of materials can be incorporated in FDM.

Stereolithography/ Microphotoforming Process

Introduction

The application of rapid prototyping (RP) techniques to MEMS and NEMS requires higher accuracy than what is normally achievable with commercial RP equipment. From the RP techniques listed in Table 8.3, laminated object manufacturing (LOM), fused deposition modeling (FDM), and selective laser sintering (SLN) all must be excluded as microfabrication candidates on that basis. Only stereolithography has the potential to achieve the fabrication tolerances required to qualify as a MEMS or NEMS tool. In this section we explore the basic principles underlying stereolithography and detail the latest enhancements that have made it an attractive high-resolution micro- and nanofabrication method.

Basic Principles Underlying Stereolithography and Microstereolithography

In stereolithography, light exposure solidifies a special liquid resin into a desired 3D shape. Besides producing industrial 3D mockups (see above under RP), micromachinists are exploring this same technology for the production of functional micro- and nanomachines. Some basic concepts illustrating stereolithography are shown in Figure 8.29. A liquid resin is kept either in the free surface mode (see Figure 8.29b) or in the fixed surface mode (see Figure 8.29c). The latter has a resin container with a transparent window plate for exposure. The solidification happens at the stable window/resin interface. An elevator is pulled up over the thickness of one additional layer above the window for each new exposure (Figure 8.30). In the case of free surface, solidification occurs at the resin/air interface, and more care needs to be taken to avoid waves or a slant of the liquid surface. Microstereolithography, derived from conventional stereolithography, was

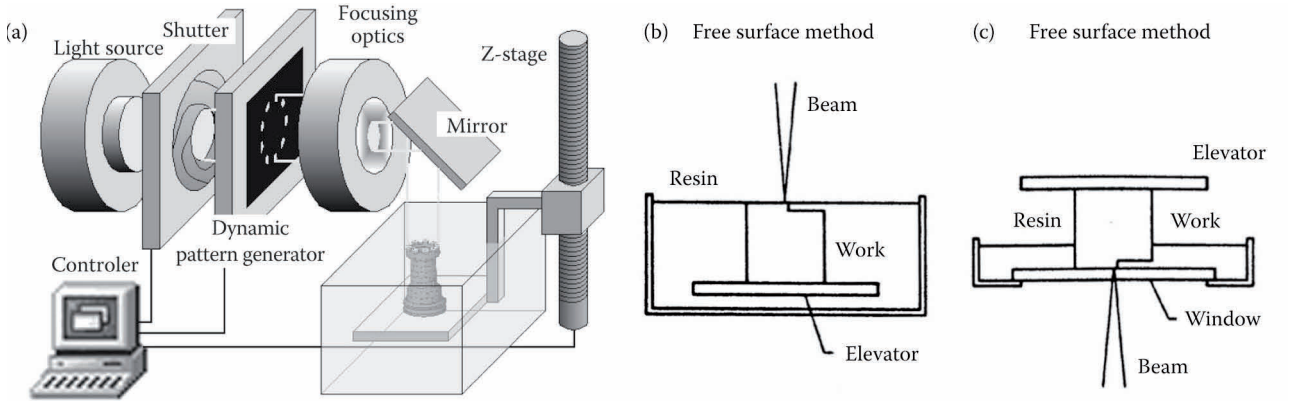

FIGURE 8.29 (a) Stereolithography or photoforming. Free surface method (b) and fixed surface method (c).

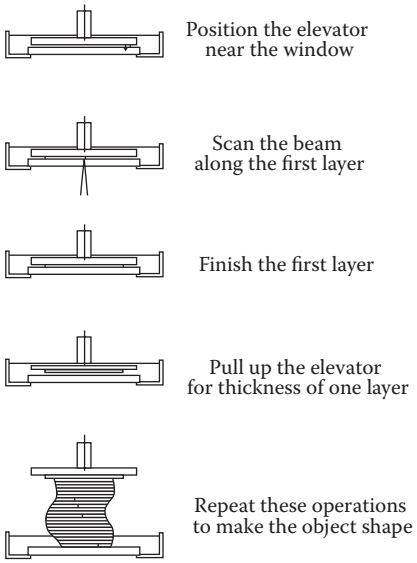

FIGURE 8.30 Stereolithography forming process with the fixed surface method.

introduced by Ikuta et al.[33] in 1993. Whereas in conventional stereolithography the laser spot size and layer thickness are both in the 100-µm range, in microstereolithography, a UV laser beam is focused to a 1–2-µm spot size to solidify material in a thin layer of 1–10 µm. The monomers used in RP and microstereolithography are both UV-curable systems, but the viscosity in the latter case is much lower (e.g., 6 cPs vs. 2000 cPs). In microstereolithography the viscosity should be as low as possible for optimal flat layer formation because high surface tension hinders both efficient crevice filling and flat surface formation in the microscale. Another difference resides in the fact that in microstereolithography the solidified polymer is light enough so that it does not require a support as is required for the heavier pieces made in RP. In Table 8.4 we summarize this comparison between RP and microstereolithography.

Ikuta's group named their scanning microstereolithography "integrated harden polymer stereolithography" or the "IH process." The original IH process used single-photon polymerization to develop a photo-curable polymer with an UV laser beam. A glass slide was placed above the layer being cured, and raising the glass slide small distances above the previously solidified layer generated an extremely thin layer (fixed surface method mode; see Figure 8.29c and Figure 8.30). The IH process resolution in Ikuta's lab was 5 µm in 1992, and, through the various enhancements discussed below, is better than 100 nm at present.[34]

The two major types of stereolithography are scanning stereolithography and projection stereolithography. The scanning stereolithography parts are constructed in a point-by-point and line-by-line

TABLE 8.4 Comparison of Rapid Prototyping and Microstereolithography

	Rapid Prototyping	Microstereolithography
Need for a support	Yes	No
Layer thickness	Hundreds of micrometers	Several micrometers to tens of micrometers
Spot size	Hundreds of micrometers	Micrometer or submicrometer
Type of monomers	UV curable	UV and visible light curable
Viscosity of monomer system	High	Low

fashion, with the sliced shapes written directly from a computerized design of the cross-sectional shapes by a beam in the liquid (Figure 8.30). Projection stereolithography is a parallel fabrication process that enables sets of truly 3D solid structures made of a UV polymer by exposing the polymer with a set of 2D cross-sectional shapes (masks) of the final structures. These 2D shapes are either a set of real photomasks used to subsequently expose the work (Figure 8.31), or they involve a dynamic mask projection system instead of a physical mask. We will compare two types of dynamic mask projection systems for their merit in microstereolithography: a liquid crystal display (LCD) and a digital micromirror display (TI's DMD chip). As we saw in Chapter 1, the DMD chip is also used in maskless lithography (see Chapter 1).

Scanning Microstereolithography, Parallel Microstereolithography and Two-Photon Polymerization

Most of the microstereolithography practiced today is based on the scanning laser beam approach introduced by Ikuta et al.[33] from Nagoya University (Japan) in 1992. The scanning method has the advantage of point-by-point controllability, thereby avoiding unevenness of solidification, which leads to nonuniform shrinking of the work piece. When applying the scanning technique, a laser beam (e.g., a He-Cd laser) is used to solidify one microscopic polymer area at a time to arrive at complicated 3D shapes by stacking thin films of hardened polymer layer upon layer. Process control in this case simply is directed from a CAD system containing the "slice data." The laser beam is focused down to a spot size of a few micrometers into the polymer through a glass window (Figure 8.30).

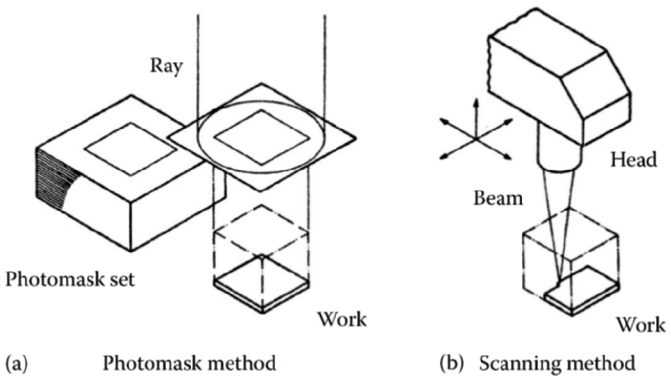

FIGURE 8.31 Exposure with photomask set (a) and exposure with a scanning beam (b). [From Ikuta, K., and K. Hirowatari. 1993. *Proceedings: IEEE micro electro mechanical systems (MEMS '93).* Fort Lauderdale, FL: IEEE;[33] and Ikuta, K., K. Hirowatari, and T. Ogata. 1994. *IEEE international workshop on micro electro mechanical systems (MEMS '94).* Oiso, Japan: IEEE.[35]]

Ikuta et al. used an x-y stage to move the work piece rather than galvanometric mirrors to deflect the laser beam, and this led to a smaller focus spot. They attached the glass window to the z-stage for precise layer thickness control. The position accuracy for the laser beam spot (5-μm diameter in the early days) reached 1 μm in the z-axis and 0.25 μm in the x- and y-directions. Takagi et al.[36] obtained an 8-μm resolution with their photoforming setup, and Ikuta et al.[33,35] reported a minimum solidification unit size of $5 \times 5 \times 3$ μm and a maximum size of fabricated structures of $10 \times 10 \times 10$ mm. As we will learn, this technique has undergone several improvements since these early days.

In scanning microstereolithography, no physical contact occurs between tools and works, and a very large number of layers can be achieved (e.g., 1000 layers) with typical machining times ranging from 30 min to 1 h. High-aspect ratio and very complex shapes, including curved surfaces, can be made with this type of desktop microfabrication method. The objects realized this way used to feature a medium-range accuracy of 3–5 μm.

Professor Ikuta's group and other researchers have introduced various IH process enhancements, including a "mass IH process," a "hybrid IH process," a "super IH process," and finally the "two-photon IH process."

Given the serial nature of the IH process, fabrication speed is a concern, and in 1996 Ikuta et al. introduced a mass IH process. In the mass IH process, multiple parts are produced in parallel, using multiple scanning fiberoptic beams.[37] An array of five single-mode optical fibers (4-μm core diameter) was used to demonstrate this concept. The mass IH process needs to be further developed using optical fiber arrays and by improving the resolution.

In a hybrid IH process other non-IH microcomponents are introduced in the IH structure. As an example of a hybrid IH process, consider Takagi et al.'s work[36,38] wherein a combination of IH with

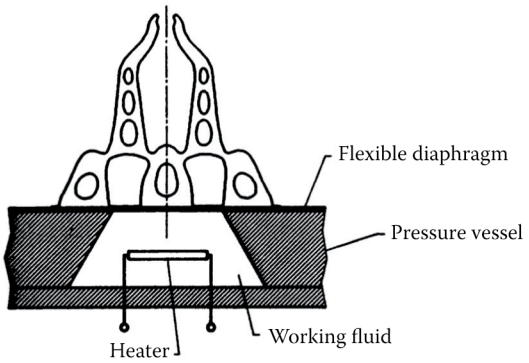

FIGURE 8.32 Thermally driven microclamping tool. The clamping tool is made by photoforming, and the silicon substrate is by silicon bulk micromachining (see text for dimensions). [From Takagi, T., and N. Nakajima. 1994. *IEEE international workshop on micro electro mechanical systems (MEMS '94).* Oiso, Japan: IEEE. With permission.[38]]

more traditional Si micromachined substrates is introduced. In Figure 8.32, a schematic for a photoformed plastic clamp anchored to a Si substrate is represented. The photoformed plastic clamp measures about 2 mm long and 2 mm high and is 250 μm thick. The Si substrate is bulk micromachined to hold a working fluid reservoir and a heater element to actuate the polymer clamp. On heating the working fluid in the micromachined chamber, the thin Si membrane cover bulges out and opens the clamp. Cooling down closes the clamp.

The original IH process and the mass IH process both involve laser scanning and layer preparation. Two major drawbacks associated with this layer-by-layer approach are the limited depth resolution (limited by the thickness of the stacked layers) and the viscosity of the liquid UV-curable monomers (limited form filling and deformation of solidified structures in the microdomain). In 1997, Ikuta and his team upgraded the IH and mass IH process to the "super IH process." [39] The enabling technology for this new process was "deep site pin-point solidification" of a UV polymer. Unlike the typical rapid prototyping (RP) stereolithography process, the polymer in this super IH process is cured below the polymer/air surface where the UV beam is focused. The entire structure is cured into a single body by moving the laser focus, and the curing occurs not only at the liquid surface but also at arbitrary locations inside the liquid resin. A shallow focus lens is used [low depth of focus (DOF) and large numerical aperture (NA) lens] such that the beam's energy is small enough not to cure polymer outside of its focal point. A 3D microstructure is made by scanning the focused laser beam in 3D space into liquid UV monomers, enabling 3D fabrication without any support or sacrificial layers. Because no layer preparation steps are involved, viscosity and surface tension influences are minimized. The properties of the UV-curable monomer system are precisely tuned to ensure that polymerization only happens in the focal point of the laser beam. The UV monomer system used in the super IH process is a mixture of urethane acrylate oligomers, monomers, and photoinitiators. Microparts with freely moving parts can be made this way—no assembly is necessary—allowing for a more advanced type of MEMS device. The resolution of the super IH process is less than 1 μm.

Summarizing, the super IH process has several advantages compared with the layer-by-layer method, such as 1) higher resolution, 2) movable 3D microstructures can be fabricated without supporting or sacrificial layer, and 3) the influence of viscosity or surface tension can be ignored during fabrication.

In 1997, "nanostereolithography" based on two-photon absorption was implemented.[40,41] As we learned in Chapter 2, in the section on quantum lithography, the use of linear absorption of laser light for cross-linking a monomer limits the resolution roughly to the wavelength of the laser. Moreover, deep penetration of the light into the resin is difficult because of the strong photon absorption; therefore, unless very tight focusing of the laser is used as in super IH (see above), the process must be carried out thin layer by thin layer (see Figure 8.30). Using two-photon excitation, one can penetrate deeper into the bulk of the resin and enhance the resolution even further than with super IH. It has been demonstrated that quantum lithography with entangled N-photon states beats the Rayleigh diffraction limit by a factor of N, and in two-photon lithography the resolution is thus improved by a factor of two (as if one used a classical source with wavelength $\lambda/2$).[42,43] When high-intensity light shines on a material, the probability for two-photon simultaneous absorption is proportional to the square of the field intensity, and thus is greatest at the center of a Gaussian laser spot. Subwavelength structures can

be produced because the absorption profile for the two-photon process is narrower than the beam profile. Using a high-NA (e.g., 0.85) lens, the laser spot can be made less than 1 μm in diameter, and significantly narrower structures can be obtained because a certain threshold of intensity must be reached to initiate polymerization. With a femtosecond laser beam, tightly focused into a resin, photo-induced reactions such as polymerization occur only in the close vicinity of the focal point, allowing the fabrication of subwavelength 3D polymer structures by directly writing 3D patterns. Importantly, because the energy required to initiate polymerization is twice that of the incoming radiation, it is possible to excite deep into the monomer as the material is transparent to one-photon excitation, whereas at the focus, where the intensity is high, two-photon excitation occurs. The 3D resolution has reached 140 nm in the two-photon IH process.

In two-photon stereolithography, one often works with epoxy resins and urethane acrylates. Several two-photon photoinitiators with very large two-photon absorption cross-sections to be added to the base polymers have been developed.[44] In these photoinitiator molecules, the photon energy that is absorbed is emitted as photons of a higher energy (up-converted fluorescence). These IH processes can be widely used for making polymeric microdevices. Some examples of 3D two-photon lithography were shown in Figure 2.37 (see also the inset in the heading of this chapter). Two-photon 3D lithography has also been used to make photonic crystals.

Microstereolithography is not limited to polymers: micro- or even nanoceramic and metallic powders can be mixed with the photosensitive resin in microstereolithography of ceramics[45] and metals.[46]

Projection Microstereolithography

In projection microstereolithography, a reduced-size image of complicated patterns is reproduced onto a photoresist. Similar to photolithography, an image is transferred to the liquid photopolymer by irradiating UV light through a patterned mask. The photomask approach, which solidifies a whole layer at the time, is significantly faster than the point-by-point technique but requires a large number of expensive photomasks. In dynamic mask projection microstereolithography, a dynamic mask generator is used instead of a real mask. We compare two types of dynamic mask projection systems: a liquid crystal display (LCD) and a digital micromirror display (DMD).

Bertsch et al.[28] at the Swiss Federal Institute of Technology (EPLF) pioneered an interesting variation on the photomask approach, which, given the many layers involved, is often impractical. This research group uses a computer-controlled LCD as a dynamic pattern generator. A light beam passes through the LCD, and a beam reducer focuses it on the surface of a polymerizable medium. Selective polymerization takes place in the irradiated areas corresponding to the transparent pixels of the LCD. Between the irradiation steps, a shutter blocks the beam, and a new layer of fresh resin (about 5 μm thick) spreads over the object under construction. Complex objects, with a resolution better than 5 μm in the *x*-, *y*-, and *z*-directions, as illustrated in Figure 8.33, have been made this way.[47] The same research group pioneered the combination of planar UV/LIGA lithography (e.g., using SU-8) with microstereolithography—to add nonvertical structures with curved and conical surfaces in a postprocessing step onto planar structures without the need of microassembly.[48] The surfaces of the parts made by microstereolithography are smooth enough to enable conformal electroplating to make a metal mold from the obtained 3D microobject. Polymer replication, of course, remains limited to convex and nonreentrant structures (see Chapter 10).

A comparison of the resolution between conventional stereolithography and small-spot and layer-by-layer microstereolithography was presented by Bertsch et al.[49] in *Rapid Prototyping Journal.* To further improve the lithography—3D photoforming in this case—it is necessary to better understand the shape of a "solidified cell," which depends on both the characteristics of the beam and the resin.

In 2005, Sun et al. introduced another dynamic projection microstereolithography approach using TI's DMD chip as the mask generator (Figure 8.34).[50] The authors point out that the LCD technique from Bertsch et al. has some serious disadvantages compared with their higher-resolution DMD approach.

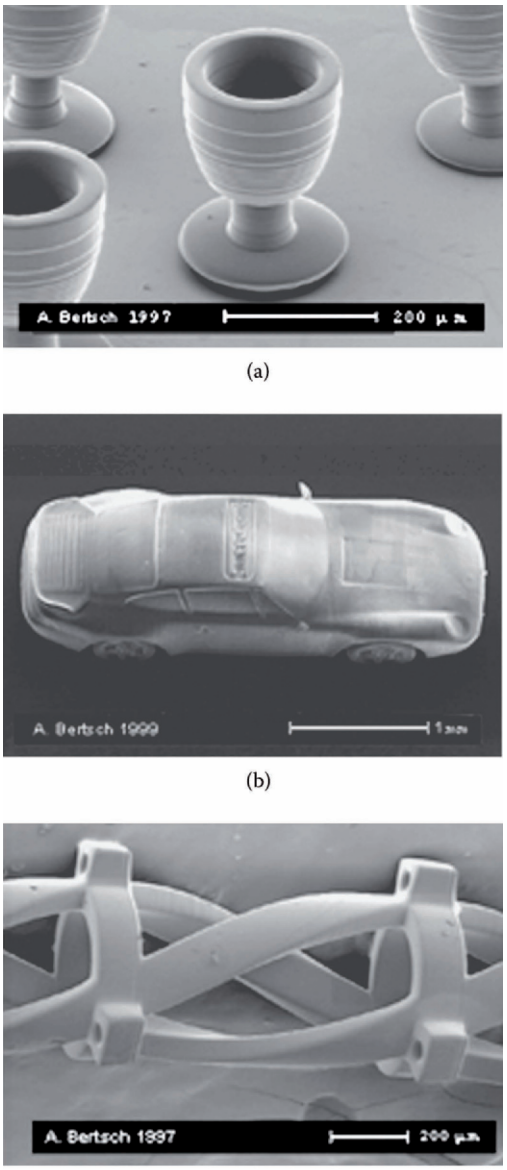

FIGURE 8.33 Examples of objects made by microstereolithography. SEM photos of microcups (80 layers × 5 µm, external diameter is 200 µm) (a); Porsche (673 layers × 5 µm, the diameter of a wheel is 400 µm) (b); microspring (1000 layers × 5 µm, external diameter is 500 µm) (c).

An LCD display not only features larger pixels and a lower filling factor (pixels vs. space between) than a DMD display, but it also has a slower switching speed (~20 ms), and the low optical density of the refractive elements in the off cycle makes for poor contrast. Moreover, the LCD is inserted between four glass plates that are opaque to UV light, restricting its use to visible light where fewer resins are available. Sun et al. made 3D structures with a smallest feature size of 0.6 µm.

Summarizing, microphotoforming offers several advantages over more classical photolithography-based micromachining processes:

1. The turnaround from CAD to prototype takes only 1 h or less.
2. Photoforming is an additive process accommodating virtually any shape.
3. It is a fully automatic process.
4. It requires a small capital investment (less than $30,000).
5. There is no need for a clean room.

This direct-write lithography technique might well represent an alternative to LIGA in cases where 3D shape versatility outweighs accuracy. As with the LIGA technique, the plastic shapes made by stereolithography may be used as a cast for electroplating metals or for other materials that can be molded into the polymer structures.

Electrochemical Forming Processes

Introduction

Both subtractive and additive electrochemical processes are of extraordinary importance in miniaturization science. Subtractive electrochemical techniques were reviewed in Chapter 4; here we review additive/forming electrochemical techniques. Electrochemical forming includes electroless and electrodeposition, and we analyze pros and cons of both. We add information on electrodeposition through masks, working with instant masks in electrochemical fabrication (EFAB) and maskless metal deposition methods. Today, there is a strong push in the IC industry and in micromachining toward dry processing, and deep dry-etching developments are particularly swift. Electrochemical machining, on the other hand, despite its many uses, is often still considered a "black art" and "dirty," with lack of cleanliness and creation of waste particles making it an unacceptable technique. In reality, besides its major technological advantages, electrochemistry offers several intrinsic advantages, such as low capital equipment, high deposition and etch rates, and relatively simple operation. In the sections below, we learn that there are many cases in which only wet

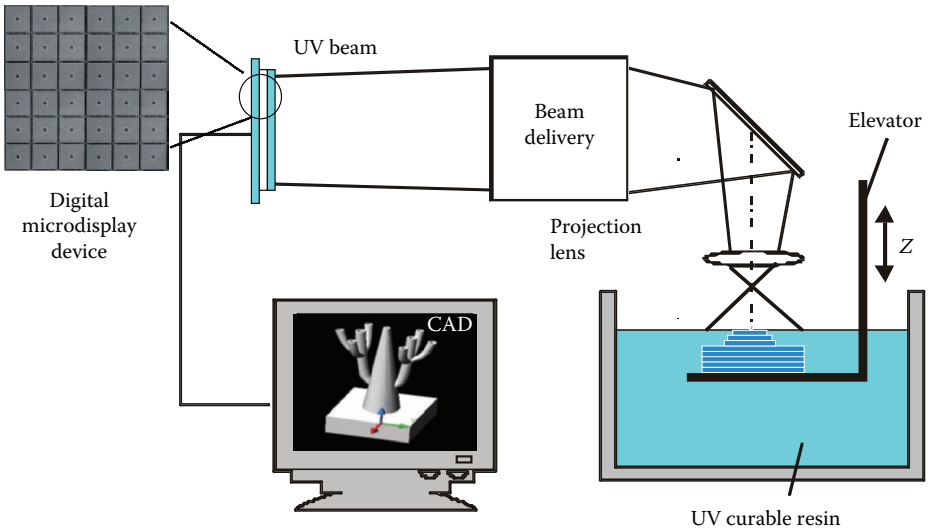

FIGURE 8.34 A dynamic projection microstereolithography approach using TI's DMD chip as the mask generator. (From Sun, C., N. Fang, D. M. Wu, and X. Zhang. 2005. Projection micro-stereolithography using digital micro-mirror dynamic mask. *Sensors Actuators A* 121:113–20.[50])

chemical and electrochemical processes are feasible; for example, line-of-sight deposition techniques cannot readily be used on curved or irregular surfaces or to plate into via holes or blind vias. CVD often leaves voids when metallizing (e.g., tungsten) in a high-aspect-ratio structure, whereas with electrodeposition such voids can be avoided completely. Multilayer PCBs with through holes connecting the individual metal layers would not be possible without electroless or electrochemical technology. As long as a solution can wet and fill a cavity to be plated, a metal pattern can be generated precisely, replicating the mold down to angstrom dimensions. In Table 8.5, many applications of electrochemistry are reviewed, and

TABLE 8.5 Situations for which an Aqueous Electrochemical or Chemical Technique Is the Only Means to Obtain the Desired Result

• Uniform plating on irregular surfaces
• Leveling of rough surfaces
• Plating of via holes and blind vias
• Formation of alloys of metastable phases
• Compositionally modulated structures
• Amorphous metal films
• Maskless, high-speed, selective deposition of metals and alloys
• Most faithful reproduction of features of polymeric masks
• Smallest dimension features with highest height-to-width aspect ratio (highest packing density of conductors)
• Metal deposits with incorporated particles (e.g., diamond, WC, TiC, Al_2O_3, Teflon, oil)
• Wear-resistant surfaces

in Table 8.6, we define several situations in which an aqueous chemical or electrochemical technique may be the only means by which a desired property or quality of a deposit can be achieved.

Electroless Metal Deposition

Underlying Principles

To continuously build thick deposits by chemical means without applying a voltage and without consuming the substrate, i.e., electroless plating, it is essential that a sustainable oxidation reaction be used instead of the dissolution of the substrate itself as in the case of immersion plating. In an immersion plating bath, the electrons for the metal deposition are supplied by the base metal, and effectively the base metal is the reducing agent. As the base metal donates electrons to the metal being plated, the base metal itself is oxidized and goes into solution, which is why this is also called a *replacement reaction*. The key characteristics of the immersion plating bath is that it is self-limiting, which means that once the base metal, e.g., copper, in the case of a printed circuit board (PCB), is covered with the new metal, the plating ceases. This results in a very thin, dense, nonporous coating, which is very economical, from a bath that is extremely stable. In an "electroless" plating bath, on the other hand, the electrons are donated by a reducing agent that is already in the bath. In Figure 8.35, the difference between immersion plating and electroless deposition is illustrated by comparing deposit thickness versus time; immersion plating is self-limiting, but electroless plating is not.[53] In an electroless copper bath, the formaldehyde is the reducing agent. In electroless Ni, it is either hypophosphite or dimethyl amine borane.

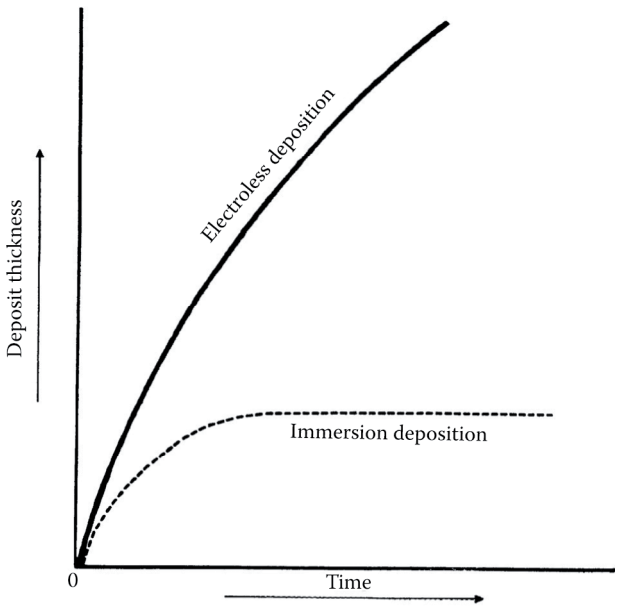

FIGURE 8.35 Thickness versus time comparison between electroless and immersion deposition. [Based Mallory, G. O., and J. B. Hadju, eds. 1990. *Electroless plating: fundamentals and applications.* Orlando, FL: American Electroplaters and Surface Finishers Society (AESF). With permission.[53]]

The reduction of Ni ions (Reaction 8.1) is fed electrons by an oxidation reaction such as that of hypophosphite (Reaction 8.2), resulting in an overall reaction for Ni deposition given by Reaction 8.3.

Reduction:

$$Ni^{2+} + 2e^- \rightarrow Ni \qquad \text{Reaction 8.1}$$

Oxidation:

$$H_2PO_2^- + H_2O + 2e^- \rightarrow H_2PO_3^- + 2H^+ + 2e^- \qquad \text{Reaction 8.2}$$

Overall reaction:

$$Ni^{2+} + H_2PO_2^- + H_2O \rightarrow Ni + H_2PO_3^- + 2H^+ \qquad \text{Reaction 8.3}$$

Reaction 8.1 continues (in principle) until all the hypophosphite in solution is consumed (Reaction 8.2). In immersion deposition, Reaction 8.1 stops as soon as the whole substrate surface is covered with Ni metal and there is no further dissolution of uncovered substrate possible. In parallel to Reaction 8.1, more or less severe hydrogen reduction goes on:

$$2H^+ + 2e^- \rightarrow H_2 \qquad \text{Reaction 8.4}$$

Copious hydrogen evolution can upset the quality of the depositing metal film and should be avoided. The hydrogen evolution rate is not directly related to that of the metal deposition and mainly originates from the reductant molecules. Stabilizers (i.e., catalytic poisons) are needed in electroless deposition baths because the solutions are thermodynamically unstable; deposition might start spontaneously onto the container walls. Substances that poison hydrogenation* catalysts such as thiourea, Pb^{2+}, and mercaptobenzothiazole function as stabilizers in such electroless baths. Besides stabilizers, the metal salt, and a reducing agent, electroless solutions may contain other additives such as complexing agents, buffers, and accelerators. Complexing agents exert a buffering action and prevent the pH from decreasing too fast. They also prevent the precipitation of metal salts and reduce the concentration of free metal ions. Buffers keep the deposition reaction in the desired pH range. Accelerators, also termed *exaltants*, increase the rate of deposition to an acceptable level without causing bath instability. These exaltants are anions, such as CN^-, thought to function by making the anodic oxidation process easier. In electroless copper, for example, compounds derived from imidazole, pyrimidine, and pyridine can increase the deposition rate to 40 μm/h. The electroless deposition must occur initially and exclusively on the surface of an active substrate and subsequently continue to deposit on the initial deposit through the catalytic action of the deposit itself. Because the deposit catalyzes the reduction reaction, the term *autocatalytic* is often used to describe the plating process. Electroless plating is an inexpensive technique enabling plating of conductors and nonconductors alike (plastics such as ABS, polypropylene, Teflon, and polycarbonate are plated in huge quantities). A catalyzing procedure is necessary for electroless deposition on nonactive surfaces such as plastics and ceramics. The most common method for sensitizing those surfaces is by dipping into $SnCl_2$/HCl or immersion in $PdCl_2$/HCl.[53] This chemical treatment produces sites that provide a chemical path for the initiation of the plating process.

Metal alloys such as nickel-phosphorus, nickel-boron, cobalt-phosphorus, cobalt-boron, nickel-tungsten, copper-tin-boron, and palladium-nickel can be produced by codeposition. In the case of Ni deposits, with or without phosphorus and boron incorporated, different electroless solutions are used to obtain optimum hardness, effective corrosion protection, or optimum magnetic properties. Recent experimental results show that composite material also can be produced by codeposition. Finely divided, solid particulate material is added and dispersed in the plating bath. Electroless Ni with alumina particles, diamond, silicon carbide, and PTFE have reached the commercial market. Table 8.7 presents a list of electroless plating baths.[53]

Methods to determine the electroless deposition rate can be split into two categories: electrochemical and nonelectrochemical. Electrochemical techniques include Tafel extrapolation, DC polarization, AC impedance, and anodic stripping. Nonelectrochemical methods include weight gain, optical absorption, resistance probe, and acoustic. For more details on each of these techniques, see Ohno[55] and references therein.

* *Hydrogenation* is a class of chemical reactions that result in an addition of hydrogen, usually to unsaturated organic compounds.

Table 8.7 Typical Electroless Plating Baths

Component	Concentration (per L)	Application/Remark	pH	Temp (°C)
Au	1.44 g $KAu(CN)_2$, 6.5 g KCN, 8 g NaOH, 10.4 g KBH_4	Plate beam leads on silicon ICs, ohmic contacts on n-GaAs	13.3	70
Co-P	30 g $CoSO_4 \cdot 7H_2O$, 20 g $NaH_2PO_2 \cdot H_2O$, 80 g Na_3citrate$\cdot 2H_2O$, 60 g NH_4Cl, 60 g NH_4OH	Magnetic properties	9.0	80
Cu	10 g $CuSO_4 \cdot 5H_2O$, 50 g Rochelle salt, 10 g NaOH, 25 mL conc. HCHO (37%)	Printed circuit boards	13.4	25
Ni-Co	3 g $NiSO_4 \cdot 6H_2O$, 30 g $CoSO_4 \cdot 7H_2O$, 30 g Na_2malate$\cdot 1/2H_2O$, 180 g Na_3citrate$\cdot 2H_2O$, 50 g $NaH_2PO_2 \cdot H_2O$		10	30
Ni-P	30 g $NiCl_2 \cdot 6\ H_2O$, 10 g $NaH_2PO_2 \cdot H_2O$, 30 g glycine	Corrosion and wear resistance on steel	3.8	95
Pd	5 g $PdCl_2$, 20 g Na_2EDTA, 30 g Na_2CO_3, 100 mL NH_4OH (28% NH_3), 0.0006 g thiourea, 0.3 g hydrazine	Plating rate is 0.26 μm/min		80
Pt	10 g $Na_2Pt(OH)_6$, 5 g NaOH, 10 g ethylamine, 1 g hydrazine hydrate (added now and then to maintain this concentration)	Plating rate is 12.7 μm/h		35

Electroless Plating in the IC Industry

The IC industry applies electroless metal deposition for a wide variety of applications, some of which are incorporated in Tables 8.5 and 8.6. In Figure 8.36, we single out the schematic for the electroless Cu deposition of a buried conductor as an illustrative example of an IC application. The fabrication of this buried conductor illustrates many of the processes we have studied so far; lithographic patterning of a dielectric material (Figure 8.36a), pattern transfer by anisotropic dry etching of a groove in the dielectric substrate (Figure 8.36b), evaporative deposition of an Al seed layer (Figure 8.36c), seed layer patterning with lift-off (Figure 8.36d), trench filling with electroless copper (Figure 8.36e), and spin-on glass dielectric layer deposition for planarization (Figure 8.36f).

Electroless Plating in Microfabrication

In micromachining applications, electroless deposition is used for the same purposes as in the IC

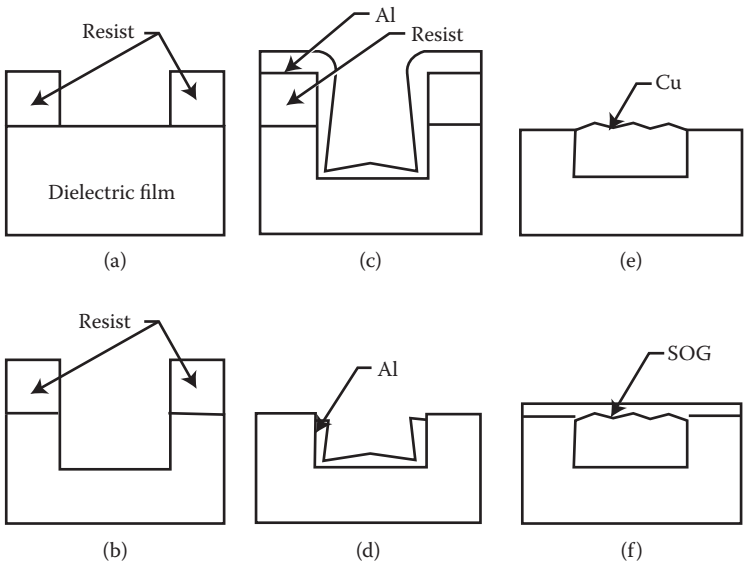

FIGURE 8.36 Schematic of a buried Cu conductor process. (a) Photoresist pattern over a dielectric. (b) Pattern transfer by anisotropic dry etching. (c) Deposition of a thin aluminum seed layer. industry, as well as to make higher-aspect-ratio structural microelements from a wide variety of metals, metal alloys, and even from composite materials. These applications often include polymer molds and introduce new challenges in terms of uniformity of plating rates and removal of the metal form from the master photoresist mold. Electroless plating may be elected above electrodeposition due to the simplicity of the process because no special plating base (electrode) is needed. This represents a major simplification for combining LIGA and pseudo-LIGA structures with active CMOS electronics, where a plating base could short out the active electronics. In addition, electroless Ni exhibits less stress than electrodeposited Ni, a fact of considerable importance in most mechanical structures. The major concern is the temperature of the electroless plating processes, which is often considerably higher than for electrochemical processes. Few studies of electroless plating in LIGA molds have been reported.[56]

We add two interesting MEMS applications of electroless plating: electroless plating of beveled structures and electroless plating using microfluidic structures. Usually, electroless plating is an isotropic process with no means to control the profile of plated features. However, van der Putten et al.[57,58] were able to induce anisotropy in the plating process by taking advantage of the increased poisoning effect a stabilizer has at the edges of any given pattern (see Figure 8.37a). Because the edges of a given pattern experience additional deposition from nonlinear diffusion, mass transport to these edges is enhanced compared with material supply to the bulk of a substrate. As a result, the surface concentration of the adsorbed stabilizer (Pb^{2+}) is higher at these edges. By choosing the proper Pb^{2+} concentration, the edges can be selectively poisoned: bevels can be grown with an angle, α, which is a function of the stabilizer concentration in the solution (see Figure 8.37b). More important, van der Putten's bevel-plating technique eliminates the commonly observed lateral overgrowth of resist patterns, and it might have broader applications in the area of micromachining. The technique is less controllable than Maciossek's maskless electrodeposition, discussed further below, but does not require a patterned plating base.[59]

Whitesides et al. introduced a means of depositing and patterning metal electrodes inside prefabricated channels by flowing plating and etching solutions as shown in Figure 8.38. Under conditions of laminar flow, reactions, including electroless plating, can take place at the interface between two or more liquids flowing side by side down a channel. In the example in Figure 8.38, the fabrication of a three-electrode system is demonstrated. Two gold electrodes are formed by etching a previously deposited gold strip. The silver reference electrode is formed using a two-phase laminar flow arrangement.[60]

Electrodeposition

Underlying Principles

Electroplating, we saw in Volume I, Chapter 7, takes place in an electrolytic cell. The reactions involve current flow under an imposed bias. As an example, consider the deposition of Ni from $NiCl_2$ in a KCl solution with a graphite anode (not readily attacked by Cl_2) and a Au cathode (inert surface for Ni deposition). With the cathode sufficiently negative and the anode sufficiently positive with respect to the solution, Ni deposits on the cathode and Cl_2 evolves at the anode. The process differs from electroless Ni deposition in that the anodic and cathodic processes occur on separate electrodes and that the reduction is affected by the imposed bias rather than a chemical reductant. Important process parameters are pH, current density, temperature, agitation, and solution composition. The amount of hydrogen evolving and competing with metal deposition depends on the pH, the temperature, and the current density. Important causes of defects in electrodeposited metallic microstructures are the appearance of hydrogen bubbles, and these three parameters need very precise control. Besides typical impurities, such as airborne dust or dissolved anode material, the main impurities are metal hydroxide formed at increased pH values in the cathode vicinity and organic decomposition products from the wetting agent. The latter two can be avoided to some degree by monitoring and controlling the pH and by adsorption of the organic decomposition products on activated carbon.

G. de Bakker. 1993. Anisotropic deposition of electroless nickel-bevel plating. *J Electrochem Soc* 140:2229–35. With permission.[57])

Electrodeposition in ICs, MEMS, and NEMS

Through-Mask Electroplating

Overview In a typical electrodeposition through a polymer mask in IC applications, metal conductors must be deposited on a dielectric substrate. The dielectric is usually made conductive first by sputtering a thin adhesion metal layer (e.g., Ti, Cr) and then a conductive seed layer (e.g., Au, Pt, Cu, Ni, and NiFe). The thickness of the thin refractory metal adhesion layer may be as small as 50–100 Å, whereas the thickness of the conducting seed layer can range from 150–300 Å.[61] The key requirement for the seed layer is that it is electrically continuous and offers low sheet resistance. After forming a pattern in a spin-coated polymer by UV exposure, e-beam, or x-ray radiation and developing away the exposed resist, electrical contact is made to the seed layer, and electrodeposition in the resist mold is carried out. The use of a solvent-containing development agent ensures a substrate surface free of grease and ready for plating. The metal layer growing on the substrate fills the gaps in the resist configuration, thus forming a complementary metal structure. Pollutants may cause hydrogen bubbles to cling to the resist structures, resulting in pores in the metal deposit; thus, the bath must be kept clean, for example, by circulating through a membrane filter with 0.3-μm pore openings.[56]

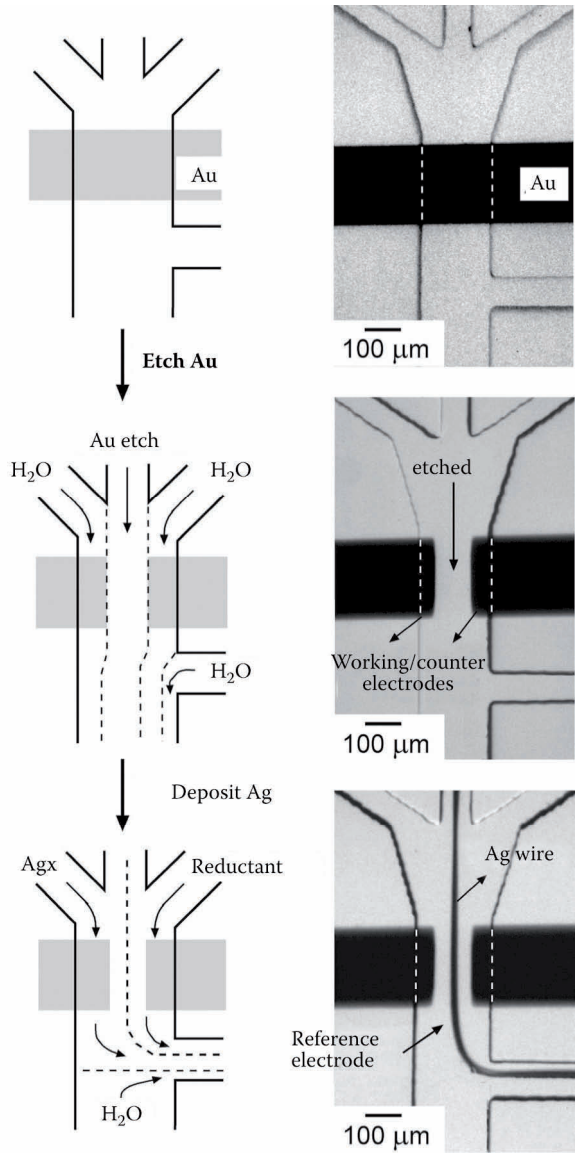

FIGURE 8.38 The formation of a three-electrode system within a channel as shown by optical micrographs. Using a three-phase laminar flow system, two gold electrodes are formed by etching a previously deposited gold strip, and using a two-phase laminar flow system, a silver reference electrode is fabricated. (Courtesy of Dr. G. Whitesides, Harvard University.)

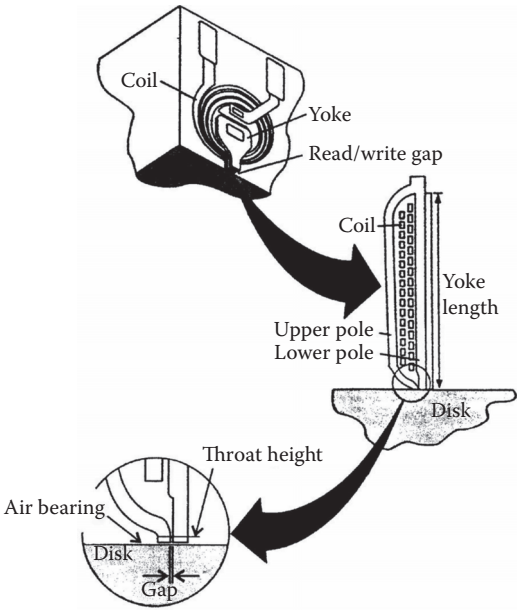
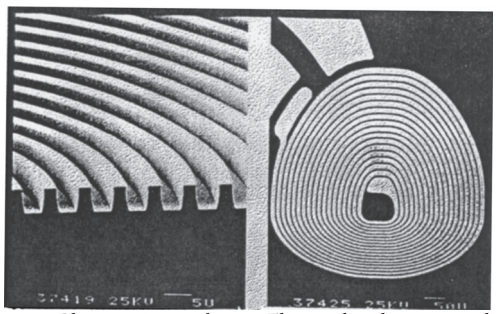
Plating through-mask technology is successfully used in volume production of beam leads and bumps on IC wafers, fabrication of thin film magnetic heads, fabrication of PCBs, x-ray lithography mask gratings, and diffraction gratings. Electrodeposition in general has been used extensively in the electronics industry in many stages of the manufacturing process, from the device stage, chip carriers, and PCB to corrosion protection and electromagnetic shielding of the electronic enclosures (see Tables 8.5 and 8.6). Processes include electrodeposition and electroless deposition of copper, nickel, tin, tin-lead alloys, and precious metals such as gold, gold alloys, palladium, and palladium alloys, as well as NiFe, CoP, NiCoP, and other magnetic alloys.[51]

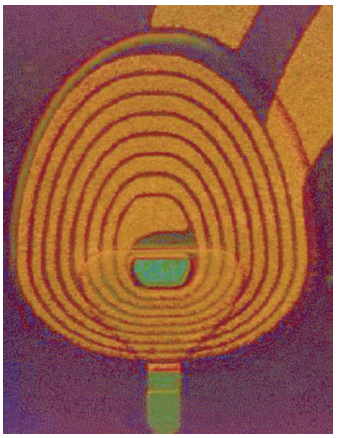
Whereas PCBs use electroless or electroplated Cu, contacts and connectors use electroplated Au and Au alloys or alternatively low-cost precious metal substitutes such as Pd, PdNi, PdAg, NiP, NiAs, and NiB with a thin gold overcoat. Separable, low-force, low-voltage contact applications require a contact finish whose resistance is stable for the projected contact life and which has sufficient wear resistance to withstand the projected number of insertions. The surface of one of the two mating parts is usually pure soft gold, whereas the other is a hard gold alloy. In less-critical applications, tin and tin-lead alloys are used as contact materials. Connecting chips with chip carriers or packages also often involves Au contacts. Gold does not adhere directly to silicon dioxide or silicon nitride, and Ti is typically used as an adhesion layer. Because Au and Ti form intermetallics, a Pt barrier is usually deposited between titanium and gold.

Copper Electroplating for Thin Film Read-Write Heads In one of many pioneering IBM MEMS efforts, Romankiw used plating through-mask technology to make thin film read-write heads as shown in Figure 8.39.[62] The development of batch-produced, thin film heads is an excellent example of how micromachining has been gainfully practiced in industry—with a definite, practical, well-specified application in mind and using the machining tools best suited for the problem.

Read-write heads, which initially were horseshoe magnets hand wound with insulated copper wire, are of utmost importance in magnetic storage. The fabrication of traditional ferrite heads reached its limit more than 20 years ago, and its further extension was hard to imagine. IBM's objective was to build the next-generation read/write heads using batch fabrication and lithography techniques as much as possible. To develop a multiturn head as shown in Figure 8.39a, it was necessary to develop a technology that would handle dimensions between those of PCBs and semiconductor devices. Plating of copper conductors through thick resist masks (Figure







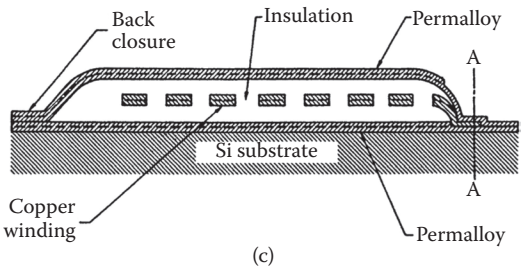


FIGURE 8.39 Thin film read-write head. (a) Schematic of a multiturn (32) thin film read-write head with inset of pole tip structure on the air-bearing surface. (b) Resist mold and electrodeposited copper coil after resist removal. (c) Schematic cross-section of an eight-turn thin film head. (Romankiw, L. T., I. M. Croll, and M. Hatzakis. 1970. Batch-fabricated thin-film magnetic recording heads. *IEEE Trans Magn* 6:597–601.[62])

8.39b) and of thin films of nickel-iron alloys of 80:20 nominal composition (Permalloy) (Figure 8.39c) made these thin film heads possible. The copper coils in Figure 8.39b carry considerable current and have to be at least 2–3 μm thick and nearly square in cross-section. The more turns in a given length, the higher the writing field at the pole tip gap and the higher the read back signal. The head in Figure 8.39c has eight turns; the 3380-K IBM head has 32 turns (Figure 8.39a). The Permalloy plating in the

thin film head is particularly challenging. Because of the very high sensitivity of composition to agitation of the plating solution, a plating cell had to be developed that assured uniform agitation over the entire part. This was achieved by a specially shaped paddle, which moves at a predetermined frequency with a precisely defined separation from the surface being plated. With the right choice of conditions, it was eventually possible to achieve both thickness and composition uniformity better than ±5%.[63] As a dielectric, hard-baked AZ photoresist was used, greatly simplifying the fabrication process. As a substrate, Si was used in the early days; today, Al_2O_3TiC is used.

Without these new micromachined thin film heads, the large increases in the areal densities* of magnetic media in the past few years would not have been possible. According to the data storage market research firm Peripheral Research Inc., market demand for thin film heads was projected to grow nearly 75% from 913 million units in 1998 to more than 1.5 billion units by 2001. This feat makes it probably the most successful micromachined device to date.

As the need for still more memory capacity increased, thin film inductive heads were replaced by newer technologies such as magnetoresistive (MR) heads (introduced in 1991 by IBM) and giant magnetoresistive (GMR) heads (introduced in 1997; see Volume III, Chapter 1). In MR heads, the read-back function is now performed by an MR sensor. The inductive portion of the head is used only for the write portion of the data-recording operation.[64]

In Volume III, Chapter 10, we learn that it is projected that read-write heads still will represent around 51% of the total MEMS market in 2009. Whereas traditional application of read-write heads in PCs will grow only moderately, the read-write head market is experiencing a renaissance in consumer electronics as hard disks are entering music players (e.g., in every iPod), smart phones (Samsung introduced the first cell phone with HDD in 2004), as well as digital video cameras, set top players, and DVD recorders. Of course, even further down the road we can envision all HDDs may be replaced by flash memory that can support today already up to 8-GB disk space, which is 5600 times more than a 1.44-MB floppy disk (see Volume III, Chapter 10)!

Copper Electroplating in Printed Circuit Boards

A PCB is made of layers, typically 2–10, that interconnect components via copper pathways. The main PCB in a system is called a *system board* or *motherboard*, whereas smaller ones that plug into the slots in the main board are called *boards* or *cards*. A typical multilayer PCB (which constitutes most of the PCBs used to implement complex circuitry) consists of a sandwich of conducting and insulating layers. Today's PCBs may consist of as many as five to six layers of metals and dielectrics. In Figure 8.40, a typical six-layer PCB is illustrated. By having the signals running on the inside of the board, more components can be more tightly integrated on the board to give a more compact design. PCB fabrication uses either an all electroless copper process or a combination of electroless and electroplating processes. The continuing effort to make active devices smaller and faster, to minimize the length of connecting wire, and to make them narrower and thicker (with smaller spaces between) necessitates more layers per board and smaller diameter holes with a larger ratio of hole length to diameter. A hole length-to-diameter ratio of 10:1 is routine and 20:1 is feasible. Without electrochemical copper plating technology, such a degree of integration would not have been possible.

Single and Dual Damascene Processes Copper wiring on IC chips was introduced by IBM in September 1997 with the "damascene process."[65]

* Areal density is used as a primary technology growth rate indicator for the memory storage industry. Areal density is defined as the product of the linear bits per inch (BPI) measured along the length of the tracks around a disk, multiplied by the number of tracks per inch (TPI) measured radially on the disk. The results are expressed in units of Mbit per square inch (Mbit/in.^{2}). Current high-end 2.5-in. drives record at areal densities of about 1.5 Gbit per square inch (Gbit/in.^{2}). Prototype drives with densities as high as 10 Gbit/in.^{2} have been constructed, allowing for capacities of more than 20 GB on a single 2.5-in. platter for notebook drives. Areal density (and, therefore, drive capacity) has been doubling approximately every 2–3 years, and production disk drives are likely to reach areal densities of 10 Gbit/in.^{2} before the end of 2001. A drive built with this technology will be capable of storing more than 10 GB of data on a single 2.5-in. platter, allowing 20- or 30-GB drives to be constructed that fit in the palm of your hand. The primary challenge in achieving higher densities is manufacturing drive heads and disks to operate at closer tolerances, which clearly is an area in which MEMS could have an impact.

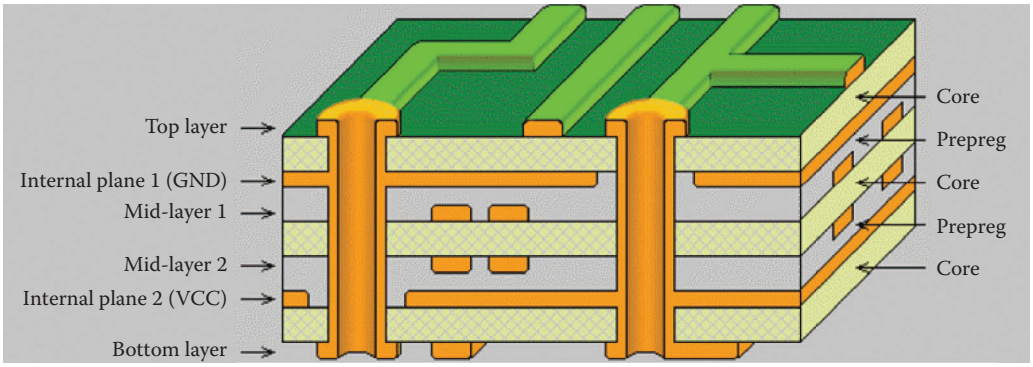

FIGURE 8.40 A typical six-layer printed circuit board. VCC stands for the positive supply voltage applied to the collectors of a transistor circuit. A "prepreg" is an epoxy-coated glass fabric.

The expertise with copper plating at IBM dates back to the late 1960s at Watson, when Romankiw succeeded in electroplating narrow wires of copper onto thin film read-write heads for memory, using a masking method that deposited the copper only in circuit patterns where it was needed (see above). Copper wires conduct electricity with about 40% less resistance than traditional aluminum wires, leading to faster microprocessors. Copper wires are also less prone to electromigration that ultimately induces wiring failure. Called *damascene* in reference to the metallurgists in Damascus who produced the finest polished swords in medieval times, the technique was initially used to form "vias" linking separate layers of wiring in chips. In the original damascene patterning, the pattern of vias was first formed by etching a silicon dioxide or other insulator layer. The metal was deposited second, and the excess metal was removed by polishing. Electrodeposition was selected as the metal deposition method of choice despite the fact that some people thought the copper patterns would be filled with bubbles, or that the process was too "dirty." It turned out to have a faster rate of deposition, and the evenness of the copper film was better than in the case of electroless deposition. Also, copper CVD, an early favorite option, ran into other severe problems. To polish the copper at an acceptable rate while controlling corrosion, erosion, and other defects in the patterns, IBM pioneered a special chemical-mechanical process (CMP) that proved critical to the copper technology. The latter process is detailed in Chapter 1. The damascene process can also be applied to other good via and interconnect materials such as Al.

In Figure 8.41 we compare through-mask copper plating with the damascene process. Through-mask plating (Figure 8.41a) uses a masking material on top of the seed layer. Electroplating occurs only on those areas of the seed layer that are not covered by the mask. The masking material and the surrounding seed layer are subsequently removed. Damascene plating (Figure 8.41b), in contrast, involves deposition of the seed layer over a patterned material, which, in the case of interconnect structures, is the insulator, a functional part of the device that remains in place. The plated metal covers the entire surface, and excess metal must be removed by CMP.

Damascene electroplating it turned out is ideally suited for the fabrication of complex interconnect structures because it enables inlaying of metal in via holes and overlying lines at the same time in a process called *dual damascene*, as illustrated in Figure 8.42. In a dual-damascene structure as shown here, only a single metal deposition step is used to simultaneously form the main metal lines and the metal in the vias. That is, both trenches and vias are formed in a single dielectric layer. The vias and trenches are defined using two lithography steps. Trenches are typically etched to a depth of 4000–5000 Å, and the vias are typically 5000–7000 Å deep. After the via and trench recesses are etched, the via is filled in the same metal-deposition step that fills the trench. After filling, the excess metal that is deposited outside the trench is removed by a CMP process, and a planar structure with metal inlays is achieved. The process starts with depositing a thin layer (~250 Å) of silicon nitride (Si_3N_4) on the silicon surface and between layers of a low

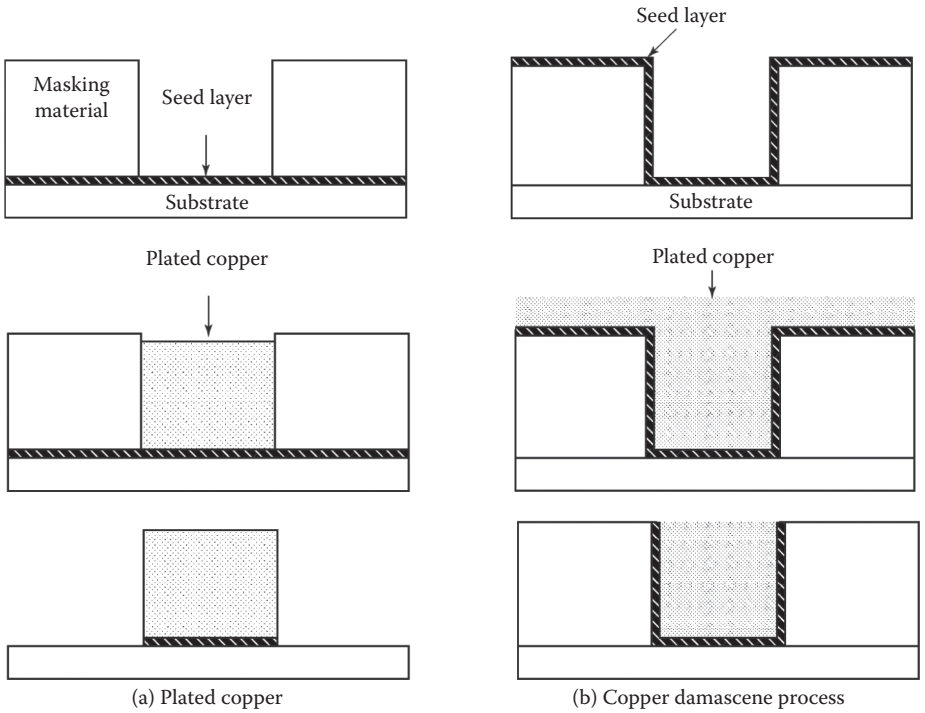

FIGURE 8.41 (a) Standard copper plating: seed layer deposited, mask layer deposited and patterned, copper plated up, mask layer removed, and seed layer etched away. (b) Damascene process used to obtain highly planar surfaces: dielectric layer (insulator) deposited and patterned, seed layer deposited, copper plated, and surface polished with CMP.

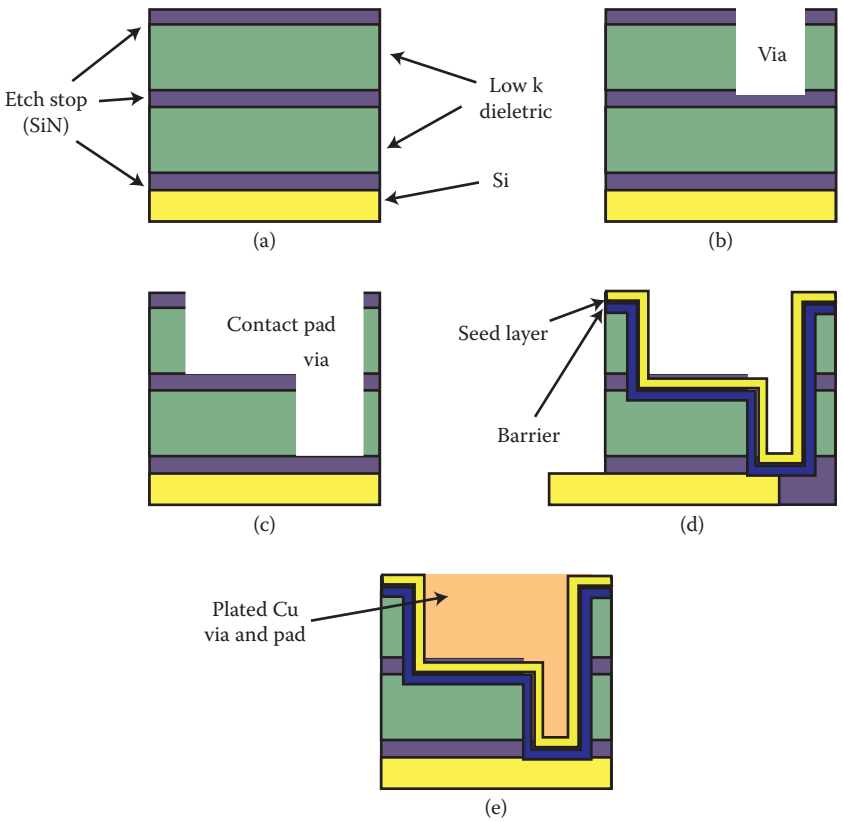

FIGURE 8.42 Dual-damascene process: process steps for a via and a line. (a) Insulator, low *k* dielectric deposition. (b) Via definition. (c) Line/contact pad definition. (d) Barrier and seed layer deposition. (e) Plating and CMP.

k dielectric, using CVD. The Si_3N_4 serves as an etch stop layer during via and trench formation. To overcome copper's tendency to diffuse in silicon, a metal diffusion barrier (e.g., Ta or TaN), preventing atoms from migrating out of a copper wire into surrounding chip material, is deposited next. Then follows a thin layer of copper deposited via CVD as a precursor to the subsequent electrodeposition of copper in both vias and trenches. The term "dual" refers to the formation of second channels, vias, within trenches. Further, it is compatible with the requirement for a barrier layer between the seed layer and the insulator.

As in conventional patterning, the damascene process is repeated many times to form the alternating layers of wires and vias that form the complete wiring system of a silicon chip. In Figure 8.43, an example copper dual-damascene structure is shown.

Anodization Anodization is an oxidation process performed in an electrolytic cell. The material to be anodized becomes the anode (+), whereas a noble metal is the cathode (–). Depending on the solubility of the anodic reaction products, an insoluble layer (e.g., an oxide, perhaps TiO_2) results, or in the case of a soluble reaction product, the electrode etches. The process can be either global or local through a masked area. If the primary oxidizing agent is water, the resulting oxides generally are porous, whereas organic electrolytes may lead to very dense oxides, providing excellent passivation.[66] Good oxides have been produced this way on W, Al, and Ta. In Volume I, Chapter 4, in the section on thermal oxidation, we learned that anodic oxidation of Si has not led to a commercially acceptable process, mainly because the interface state density at the SiO_2/Si interface is prohibitively high for IC applications. As a sacrificial layer, anodic SiO_2 plays a role in micromachining and leads to uniquely structured films that cannot be obtained by chemical means. For example, anodization of Si in a highly concentrated HF solution (excellent etchant for the anodic oxidation product SiO_2) leads to porous Si and very high-aspect-ratio pores, with diameters ranging from 20 Å to several micrometers. The growth rate and degree of porosity of the Si can be controlled by the current density (see Chapter 4). Similarly porous aluminum oxide films can be prepared by anodization of aluminum foils.[67]

Through an appropriate choice of electrolyte, films other than oxides can be produced by anodization. For example, sulfide and selenide layers can be produced by anodization of Cd and Zn electrodes, and polymerization of redox polymers can be induced from solutions containing the monomers.

Conclusions on Electroless and Electroplating through Polymer Masks Electrochemistry through polymer masks represents one of the most powerful techniques available for formation of very high-density patterns and circuits with extremely large height-to-width ratios. Most other methods, such as chemical isotropic etching, sputter etching, ion milling, and reactive ion etching, cannot be used to produce metal patterns with better than 1:1 height-to-width aspect ratios. To understand this contrasting behavior, we must look into the fundamental nature of the different approaches. In nonelectrochemical technologies, a polymeric or inorganic mask is used to cover the existing metal, whereas either a chemical solution or an active gas phase removes the metal from the open areas. Hence the limitation in the height-to-width aspect ratio, the maximum circuit density, and the fidelity of reproduction of the features are caused by shadowing, which is the mechanism by which the patterning takes place. In contrast, with electrochemical techniques, one

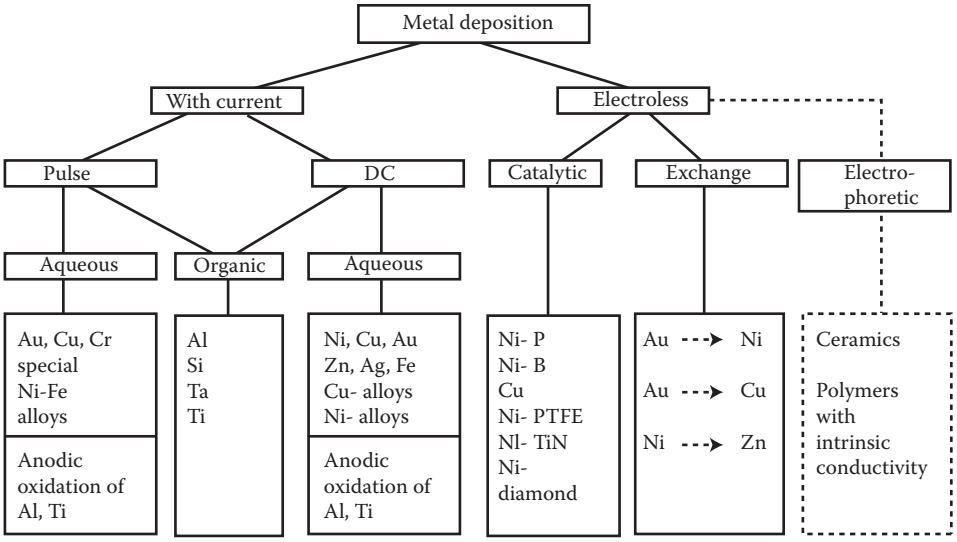

FIGURE 8.44 Processes and materials for through-mask metal deposition. (From Ehrfeld, W. 1994. Notes from handouts. Banff, Canada. With permission.[68])

obtains the exact replication of the recesses in the mask.[52] Thus, electrodeposition reproduces the finest features of the mask with the greatest fidelity. This is not surprising, considering that, in plating, metal ions discharge from solution present inside the mold. In so doing, the metal displaces the solution from the mold atom by atom, conforming to the smallest features that exist in the mold.[51] A comparison of conventional subtractive etching with electrochemical additive processes was presented as early as 1973 by Romankiw et al.[61] For the fabrication of highly miniaturized magnetic bubble memory devices, this IBM group showed clearly that the additive plating process is superior to dry etching-based techniques.

Figure 8.44 features a list of choices for material deposition using electrochemical and electroless techniques.[68] The first metal LIGA structures (see Chapter 10) consisted of nickel, copper, or gold electrodeposited from suitable electrolytes.[69] Nickel-cobalt and nickel-iron alloys were also experimented with. A nickel-cobalt electrolyte for deposition of the corresponding alloys has been developed especially for the generation of microstructures with increased hardness (400 Vickers at 30% cobalt) and elastic limit.[70] The nickel-iron alloys permit tuning of magnetic and thermal properties of the crafted structures.[70,71] From Figure 8.44 it is obvious that many more materials could be combined with through-mask metal deposition.

Instant Masking in Electrochemical Fabrication

Instant masking is a selective electroplating technique similar in some ways to through-mask plating. However, through-mask plating involves up to 10 separate steps, multiple pieces of equipment, multiple liquids, and is time consuming and difficult to automate. Obviously it is not a technique that is very suitable for automatically building complex 3D microdevices consisting of hundreds of layers or more. On the other hand, instant masking operates much more like printing, in which prefabricated plates transfer ink onto a substrate. In instant masking, instead of inks, one deposits materials electrochemically.

Instant masking is the enabling technology of electrochemical fabrication (EFAB), a solid, free-form fabrication technology that creates complex, miniature 3D metal structures impossible or impractical to manufacture using other MEMS technologies, such as electrical discharge machining (EDM), laser machining, or silicon micromachining.[72] The automated EFAB process creates metal structures by electroplating multiple, independently patterned layers. The process is similar in concept to rapid prototyping (RP) techniques, such as stereolithography (SL), in that multiple patterned layers are stacked to build structures. However, unlike stereolithography, EFAB is a batch process suitable for volume production of fully functional devices, not just models and prototypes.

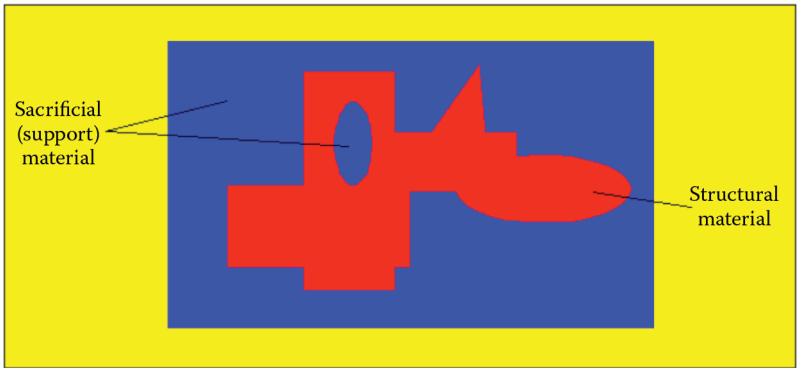

FIGURE 8.45 EFAB layer example. This 5-μm-thick layer consists of a structural material (e.g., Ni) and a sacrificial (support) material (e.g., Cu). (http://www.isi.edu/efab.)

Furthermore, EFAB provides greater accuracy than stereolithography. The EFAB process was invented at the University of Southern California with funding from the Defense Advanced Research Projects Agency and is commercialized by MEMGen Corp., a company founded in August 1999 (MEMGen Corp. changed its name to Microfabrica in 2003; http://www.microfabrica.com).

The three major fabrication steps in EFAB that are repeated are 1) the instant masking and selective electroplating, 2) blanket deposition, and 3) planarization. The manufacturing process starts with a substrate and grows devices layer by layer. Each thin layer, perhaps 5 μm thick, consists of a structural material (e.g., Ni) and a sacrificial material (e.g., Cu) as shown in the example in Figure 8.45. Microdevices are built by stacking many of these layers (as many as desired). To fabricate a multilayer device, the geometries of the layer cross-sections are automatically determined based on the desired 3D geometry, and a set of instant masks is generated that includes all the unique cross-sections of the device. The device under construction, composed of structural material, is imbedded within the sacrificial material, which, like a scaffold, supports it during fabrication and is later removed. Additional materials can be deposited over entire layers without constraint. Such geometrical freedom makes possible monolithically fabricated assemblies of discrete, interconnected, and rotating parts and eliminates the need for subsequent bonding or assembly steps.

The instant mask consists of an insulator pattern, made, for example, by patterning a resist layer on an anode plate using photolithography. A series of such masks, each representing a thin cross-section through the part being built, is fabricated in a separate process before the formation of the part. Instant masking then patterns a substrate by pressing this insulator pattern on the anode against the cathode substrate (e.g., Ni), and the assembly is immersed in an electrochemical bath (e.g., a Ni bath). Electroplating from the nickel salt solution between anode and cathode only deposits metal (Ni) between the insulator parts on the anode. The result is a layer that has been rapidly deposited and patterned in a single step. After the nickel plating, the mask is removed, and the substrate with its nickel pattern is copper plated, filling in areas left by the insulator. The two materials are then polished flat, providing a smooth layer for the next mask. The process can be repeated indefinitely, which creates the potential for defining arbitrarily complex shapes. Once the final plating has taken place, the sacrificial copper is removed by chemical etching, leaving a 3D nickel structure.

The complete process flow is shown in Figure 8.46. In Figure 8.46a, the first material is patterned onto a substrate, producing a patterned layer. In Figure 8.46b, the second material has been blanket deposited over the first material so that it contacts the substrate in those regions not covered with the first material. Then, as shown in Figure 8.46c, the entire two-material layer is planarized to achieve precise thickness and flatness. After repetition of this process for all layers, the embedded multilayer structure shown in Figure 8.46d is etched to yield the desired device as shown in Figure 8.46e.

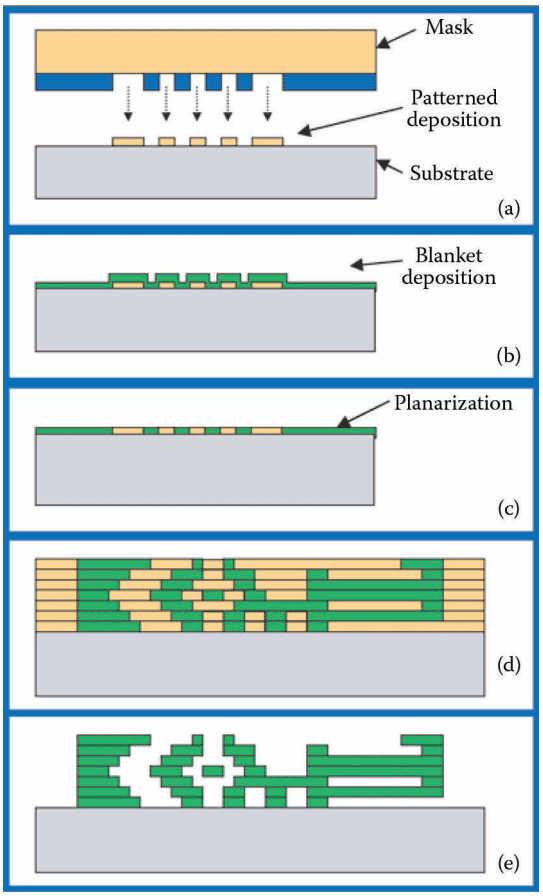

FIGURE 8.46 The EFAB process. (a) First material is patterned onto a substrate, producing a patterned layer. (b) Second material is blanket deposited over the first material. (c) The entire two-material layer is planarized. (d) Repetition of the process steps (a)–(c). (d) Embedded multilayer structure. (e) Sacrificial material is etched to yield the desired device as shown.

The instant masking process is fast, which makes it possible to fabricate devices with a dozen or more completed layers in 1 day.

The precision EFAB technology allows miniature and microdevices to be generated from 3D computer-aided design (CAD) data. The system uses data from any standard CAD package to determine device cross-sections. These cross-sections are then used to fabricate the instant masks that are then used to rapidly create the devices. EFAB is a precision manufacturing technology that can be used to form structures from any metal or alloy that can be electrodeposited. The only constraint is that the accompanying sacrificial metal can be selectively etched after the layers are formed. EFAB, depending on the lithography used to make

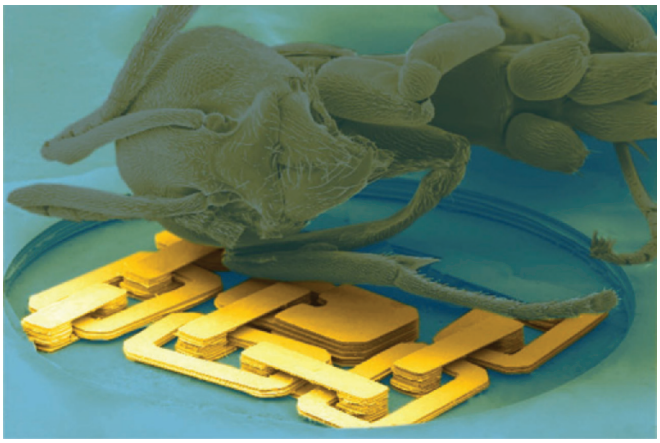

FIGURE 8.47 A small household ant lies over a 12-layer microchain with independently movable links, fabricated in nickel in a single process without the need for assembly. The chain is about ~100 μm high (about the thickness of a sheet of paper; http://www.isi.edu/efab/Resources).

the instant masks, can produce parts with feature sizes less than 0.001 in. and tolerances better than 0.0001 in. Such precision is difficult to obtain with mechanical precision machining technology. Like a machine tool, the EFAB process is suitable for a wide range of applications (see example microchain in Figure 8.47). Applications include radiofrequency (RF) electronic components such as high-Q inductors and transmission lines, optical components, microfluidic networks, and mold tooling for plastic devices.

Maskless Plating

Microjet Plating and Laser-Enhanced Jet Plating Through-mask electrochemical deposition, although a very important MEMS technique, is costly and requires extra steps, and several electrochemical deposition techniques have been proposed that obviate the need for masks.

One of the simpler approaches to avoid using masks in electrodeposition uses impinging microjets of electrolyte. This increases the mass transport greatly, and plating selectivity is achieved by virtue of the fact that the jet serves as the current path. The smallest spot size of the area being plated is usually limited to twice the diameter of the jet, which can be operated, if filtering the solution carefully, without too frequent plugging. The nozzle orifice diameter may be anywhere from 1 mm to as little as ~0.01 mm in diameter. The lower limit depends strongly on the

degree of filtration of the solution. Micromachining of nozzles will further impact obtainable microjet-plating resolution in the future.

The setup in Figure 4.15 for laser-enhanced jet etching can also be used for faster plating. The local heating of the substrate by the laser (up to 150°C) results in highly increased deposition. Using this technique, plating enhancement of up to 1000 times has been obtained with gold. Plating spots and lines as small as 2 μm wide have been observed. Laser enhancement also works with electroless deposition. Current densities of up to 15 A/cm^2 and copper plating rates of 50 μm/s have been obtained. For more background on jet plating and laser-enhanced jet plating, refer to the review by Romankiw et al. and references therein.[51]

Pulse plating, introduced in Chapter 10 in the context of plating in LIGA molds, represents only one of many emerging electrochemical plating techniques considered for microfabrication. For more background on techniques such as laser-enhanced plating, jet plating, laser-enhanced jet plating, and ultrasonically enhanced plating, refer to the review of Romankiw et al.[51] and references therein.

Localized Electrochemical Deposition Truly 3D microstructures can be formed using localized electrochemical deposition. The tip of a sharp electrode placed in a plating solution is brought near the substrate where deposition occurs when applying a potential between the tip and the substrate. The electric field is confined to the area beneath the tip, and the spatial resolution is determined by the size of the electrode. Deposition rates of Ni are as high as 6 μm/s, two orders of magnitude higher than in conventional electroplating.[73] The tip of a scanning electrochemical microscope (SECM) can be used for both local etching and deposition with high resolution in the x-, y-, and z-dimensions, basically forming a high-resolution electrochemical machining setup (Figure 4.16).

Slanted and Curved Plated Metal Shapes As a final example of maskless electrodeposition, we consider the work by Maciossek, who relies on overplating of a patterned plating base to create a variety of novel slanted and curved metallic microstructures.[59] The angle of the deposited wedge shapes is adjustable in a range from 0–45°. Besides linearly increasing structure profiles, a sinusoidal or parabolic surface can also be generated. The angles of the deposited wedges depend on the distance between and the width of a set of parallel metallic strips on the plating substrate as illustrated in Figure 8.48A. At the start of the plating process, only a central metal strip is biased, and during the isotropic growing process, the outlying metal strips are contacted one at a time by the electrodepositing metal. When the contact has been made, electrodeposition will occur also in this area, whereas further deposition in the original contact area (the central strip) results in a higher deposit on that first electrode. This innovative 3D fabrication process enlarges the MEMS arsenal of tools. The Maciossek method may be used to fabricate slanted and curved absorber patterns for x-ray masks (see Chapters 2 and 10). Two example Maciossek structures are shown in Figure 8.48B.

Three-dimensional metal structures on a substrate may also be produced by electrodeposition through a suitably prepared gelatin layer in a process similar to photolithography. Angus et al.[74] exposed a layer of gelatin on a Cu surface through a gray mask. Cross-linking of the gelatin occurs in the exposed areas, and unexposed material is washed away in a water/isopropanol solution. Thickness of the hardened gelatin layer, and hence the rate of diffusion of depositing metal ions through it, depends on the exposure dose. Metal electrodeposition through the developed gelatin layer film occurs more rapidly at the less exposed sites, thus generating a 3D metal structure on the substrate with a thickness and configuration governed by the exposure time, the mask thickness, and the deposition time.[75] As the mask is permeable to the plating solution, we treat this technique here as a "maskless" technology.

Example 8.1: Protein Patterning

Microlithographic techniques can be applied successfully to the field of protein patterning. In this first example, we show how clever use of lithography may help solve the problem

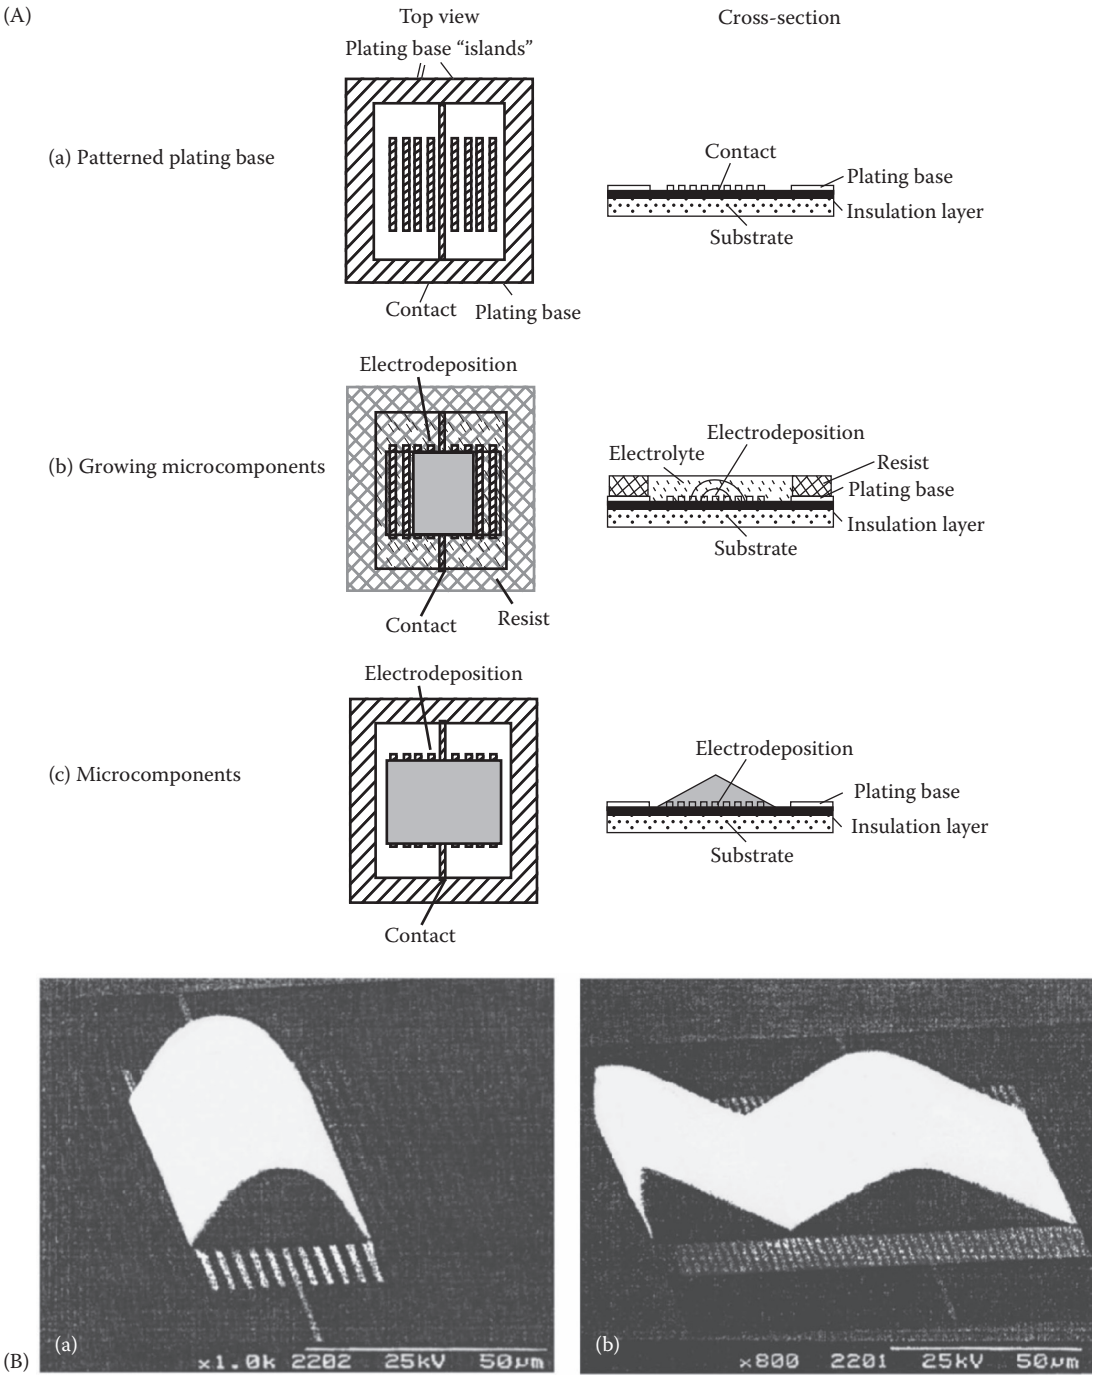

FIGURE 8.48 (A) Maciossek plating schematic: exposing the patterned plating base (Aa) to a plating solution, the isotropic growing process starts at the contact area and extends until the neighboring plating base islands are contacted. (Ab) Once contacted, electrodeposition also occurs in this area, whereas further deposition in the former contact area results in a higher structure there. On continuing the electroplating process, consecutive outlying "island" electrodes are reached, and electroplating starts later so that wedge-shaped microcomponents are formed (Ac). (B) Electroplated profiles show a very smooth and bright surface. The perpendicular sidewalls are made by a thick surrounding resist. (Ba) Gold microstructure, 18 µm height; (Bb) electroplated gold with two electrical contacts.

of nonspecific protein adsorption competing for detection sites in immunosensors. Proteins bind with considerable avidity to a wide range of surfaces, and a reference surface in an immunosensor should adsorb all the same proteins except for the protein of interest. The best way to avoid nonspecific binding effects in immunosensors is to make the reference surface as similar to the sensing surface as possible, i.e., a reference substrate, subject to all the same

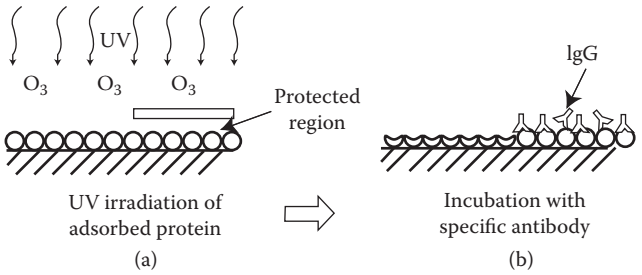

FIGURE 8.49 UV radiation of antigens leads to bands of "live/dead" protein. (a) Preadsorbed layer of antigen is briefly exposed, in air, to an intense UV source, resulting in the production of ozone (O_3). The combination of UV damage and ozone results in partial oxidation of the adsorbed protein. The area of protein shielded from the irradiation is not oxidized. (b) Following this treatment the protein-coated substrate is incubated with antiserum specific to the adsorbed antigen. The partially oxidized protein layer is no longer antigenic, and IgG molecules are able to bind only to the previously shielded portion of the antigen layer. (Clementi, E., G. Corongiu, M. H. Sarma, and R. H. Sarma, eds. 1985. *Structure and motion: membranes, nucleic acids, and proteins.* Guilderland, NY: Adenine Press.[76])

nonspecific protein binding phenomena as the sensor surface itself, except for the antigen-antibody of interest. This way, measuring differentially enables the best possible correction for nonspecific binding. An interesting way of implementing this idea is to create an optical grating pattern, with the antigen-antibody coupling providing the grating structure. This can be realized, for example, based on the loss of antigenicity on UV radiation of thin layers of antigen as observed by Panitz and Giaver.[76] Panitz and Giaver found that the antigenic sites on proteins display sensitivity to UV radiation in air and that a small dose of UV radiation can destroy the antigenicity of antigens (Figure 8.49). One presumes that the UV light breaks up chemical bonds in the adsorbed protein layer and simultaneously produces ozone. The broken bonds are targets for the highly reactive ozone, resulting in the progressive oxidation of the protein layer. The protein can be completely removed from the surface by too long an irradiation (e.g., 10 min). With a short radiation time the optical density does not change, but antibodies will no longer bind to the antigenetic sites. This scheme was put to use in the fabrication of an elegant biograting for immunosensing as shown in Figure 8.50.[77] By using a photomask grating and inactivating alternating bands of antibodies, a biological diffraction grating is created. In this device, the antigen-antibody coupling itself constitutes the grating structure, causing diffraction only if the target antigen is present. A CD-type He-Ne laser beam diffracts from the grating with an intensity related to the antigen concentration. The above grating device comes close to embodying an ideal relative reference because the radiated protein bands are almost identical to the active surface except for being incapable of reacting with the target complementary protein.[78]

It is easy to imagine arrays with several different enzymes, antibodies, or DNA probes immobilized precisely onto a transducer surface as a diagnostic panel for clinical diagnosis, high-throughput drug screening, or for environmental monitoring.[79]

Example 8.2: The Nanogen Chip

A schematic representation of an open electrophoretic DNA hybridization chip from Nanogen is shown in Figure 8.51a. In this chip DNA, which is negatively charged at most pHs, is collected at biased electrodes through electrophoresis. An array of 25 metal electrodes with a diameter of 80 μm is pictured. Arrays of

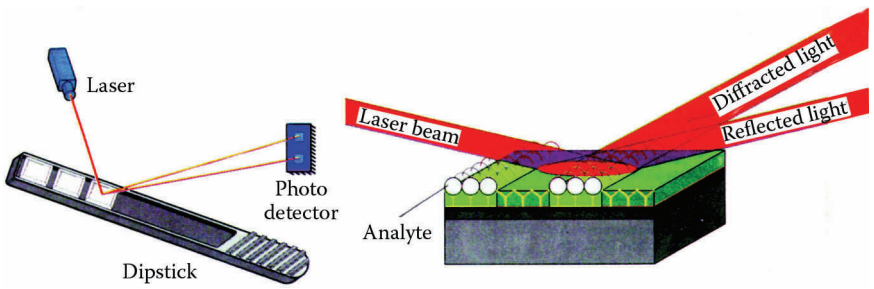

FIGURE 8.50 Idetek, Inc. immunosensor based on biological grating (Editorial. 1993. Biograting. *Res Dev* 51; Courtesy of Mark Platshon, Idetek, Inc., Sunnyvale, CA.[77])

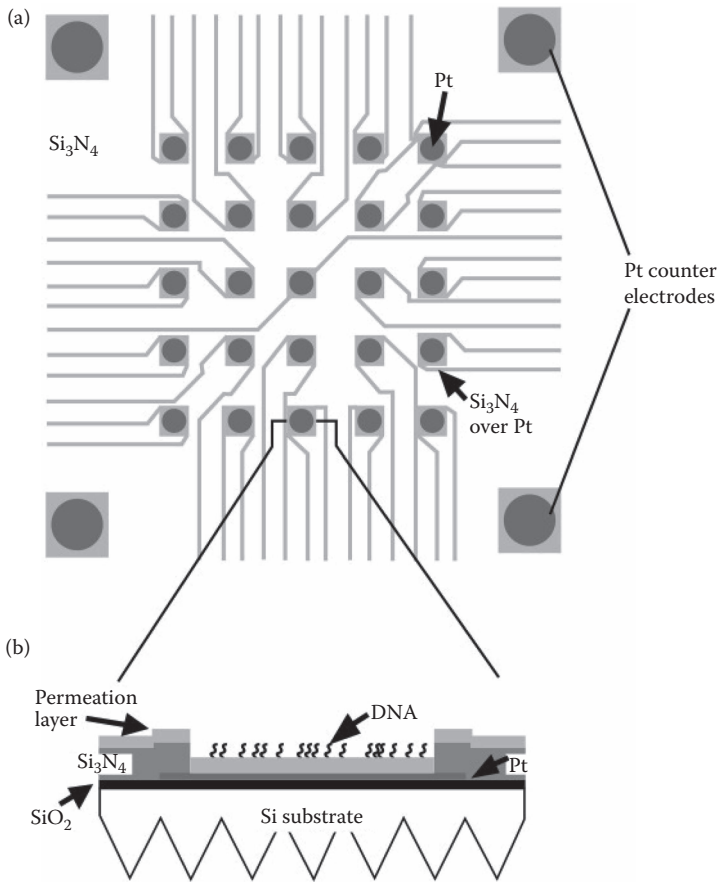

FIGURE 8.51 Nanogen DNA chip. (a) Electrode array region of the chip. The central 1 × 1-mm test site array region consists of four large (160-μm diameter) corner electrodes and 25 central 80-μm electrodes. Pt, exposed Pt test sites; Si_3N_4, dielectric; Si_3N_4 over Pt, and Pt insulated by Si_3N_4. (b) Cross-section of an electrode test site. Location of section is indicated by lines extending from (a). Pt, Si_3N_4, Pt insulated by Si_3N_4; SiO_2, dielectric layer; Si substrate, wafer material; permeation layer, agarose layer containing streptavidin; DNA, biotinylated oligonucleotides bound to streptavidin.

100 (80-μm diameter), 400 (50-μm diameter), and 10,000 (30-μm diameter) elements have been made as well.[80] Each of the metal electrode sites (microlocations) is a discrete, insulated, and addressable working electrode forming part of an electrochemical cell. An outer group of counter electrodes provides encompassing electric fields for concentrating DNA from the bulk sample solution to specific working electrodes. In Figure 8.51a, there are four such outer electrodes with a diameter of 160 μm. The microlocations are all electrically connected via the overlying electrolyte solution and protected with a permeation layer hydrogel (e.g., agarose or polyacrylamide) (Figure 8.51b). The permeation layer is a 1–10-μm hydrogel layer deposited by spin coating and permits water and ion flow, provides a matrix to attach molecules such as DNA, RNA, or proteins, and separates those sensitive biomacromolecules from the potentially damaging electrochemical reactions that occur on the active Pt electrodes (current levels >100 nA and voltages >1.2 V are possible with such hydrogel layers without damaging the biomacromolecules). Attachment of molecules to the permeation layer such as DNA probes can be achieved, for example, by impregnating the permeation layer with affinity binding substances such as avidin or streptavidin for subsequent attachment of biotinylated DNA or RNA probes.

Net negatively charged molecules such as DNA and RNA are moved to positively biased microlocations, whereas they are repelled from negatively biased ones by electrophoresis. For the electric field to be high enough throughout the solution for electrophoresis to take place, the solution must be desalted. Only low conductivity buffers may be used. The positive microlocations may concentrate target DNA sequences in a

very short time (because they reach those sites through electrophoresis rather than by diffusion), and if this location has complementary DNA capture probes, hybridization of the target DNA can occur. The concentrating effect on the positive microlocations facilitates the hybridization as a result of the law of mass action (hybridization in seconds rather than hours). Details of DC current and voltage level, solution conductivity, and buffer species for hybridization can be found in Edman et al.[81] This directed electrophoretic transport and addressing process can be carried out simultaneously at test sites that have different capture sites. Detection of successful hybridization can be accomplished using fluorescent probes and a color, charge-coupled detector (CCD). By reversing the polarity at a microlocation after hybridization, nonspecific sample DNA and unhybridized probes may be selectively removed. The electric field can be adjusted just so to affect selective dehybridization of the DNA sequences from the attached complementary probe. This is called *electronic stringency control.* Discrimination between single base pair mismatches in DNA has been demonstrated this way;[82] for example, Gilles et al. developed a rapid assay for single-nucleotide polymorphisms (SNPs) in a gene implicated in increased susceptibility to infection in pediatric patients.[83]

The power of this open-chip approach was further demonstrated by separating *Escherichia coli* from a mixture containing blood cells by means of dielectrophoresis, lyzing the isolated bacteria by a series of high-voltage pulses, and proteolytic digestion with proteinase K—all on the same chip. The microlocations on the Nanogen chip can be powered with DC and AC.[84] Even more exciting is the demonstration of amplification and detection of multiple targets in this same open format [multiplex strand displacement amplification (SDA)]. SDA is an isothermal (60°C) DNA amplification method. In a regular multiplex amplification in solution, nonspecific interactions between different primer sets reduce the amplification efficiency. Electronic anchoring of sets of amplification primers in distinct areas reduces their interaction, and sets of distinct zones of amplification that only share reagents and enzymes are generated, increasing the efficiency of the multiplex amplification reactions. Isothermal SDA, which uses the combined effects of a restriction endonuclease and DNA polymerase, asynchronously amplifies DNA exponentially and was shown to be ideal for use on the open electrophoresis chip.[85]

Questions

8.1: Describe two methods to make DNA arrays using a virtual mask approach.

8.2: Briefly sketch the sol-gel technique. Why is this technique so important for nanotechnology?

8.3: Compare Langmuir-Blodgett deposition with self-assembled monolayers (SAMs).

8.4: Sketch the dual damascene process. Where is it used?

8.5: Outline the EFAB process. Where is it used?

8.6: Why is DNA hybridization so much faster in an electronic DNA (Nanogen) than in a passive hybrydization chip?

8.7: Describe how you could make beveled metal structures using both electroless plating and electroplating.

8.8: Describe briefly different types of rapid prototyping (RP) and discuss how they can be scaled down. Which RP technique is of most interest to micromachinists?

8.9: Compare three major arraying methods for making DNA and protein arrays.

8.10: Detail the difference between scanning microstereolithography, parallel microstereolithography, and two-photon stereolithography.

Thermal Energy-Based Forming Techniques—Thermoforming

A metal laser sintering/milling hybrid machine, the LUMEX 25C, developed by Matsuura Machinery Corporation in Japan, successfully combines freeform manufacturing and high-speed milling. The integration of laser sintering of metallic powder and high-speed cutting eliminates the finish machining operations (http://www.matsuura.co.jp).

Introduction

Thermal forming (or thermoforming) is a method where thermal energy provided by a heat source "transforms" a material's structure and/or shape. Structural material changes occur, for example, during crystallization, sintering, alloying, annealing, decomposition, and pyrolizing. Shaping in thermoforming may be free form, such as in glass blowing and in selective laser sintering (SLS) (see inset in the heading of this chapter). The latter thermoforming method is a rapid prototyping (RP) technique for solid parts, made by solidifying powder-like materials layer by layer through exposure of the surface of a powder bed to a laser beam. However, thermoforming may also involve a step that combines heat and pressure to conform to a final shape in a mold, such as in vacuum forming, a method for thermally shaping a flat plastic sheet into a three-dimensional (3D) shape by heating the sheet and withdrawing the air between the sheet and the mold.

Thermal and chemical forming techniques are often intertwined because heat (and catalysts) usually aids a chemical reaction. The relative contribution of thermal to chemical in a given process may range from 100% thermal to 100% chemical but falls often somewhere in between. Crystallization (see Volume I, Chapter 4), alloying, and sintering, for example, do not involve a chemical reaction and could be viewed as purely thermal forming techniques, but annealing, decomposition, and pyrolizing all typically involve both heat and a chemical reaction. The predominantly thermal techniques detailed in this chapter are spray pyrolysis, silk screening of ceramics, tape casting, plasma spraying, laser and electron beam deposition, and selective laser sintering (SLS). Spray pyrolysis is a simple form of chemical vapor deposition (CVD) and, together with sol-gel, a chemical forming technique that was covered in Chapter 8, a contender for nanoparticle manufacturing. Silk-screening and tape casting technology constitute two important thermal forming processes often referred to as *hybrid* manufacturing methodologies. Tape casting is also known as *doctor blading* or *knife coating*, and the process is well known under these names in many industries, including paper, plastic, and paint manufacturing. Laser and electron beam deposition can be subtractive or additive, and these two options are typically available in the same laser or electron beam reactor. SLS is a rapid prototyping technique (RP) (see also Chapter 8, Table 8.3) method for solid parts, made by solidifying powder-like materials layer by layer through exposure of the surface of a powder bed to a laser beam. The method might also integrate high-speed computer numerical controlled cutting, effectively combining an additive and a subtractive manufacturing technique, in which case RP and real manufacturing are both options.

Spray Pyrolysis

Introduction

In spray pyrolysis, a precursor reagent dissolved in a carrier liquid is sprayed through a nozzle or set of nozzles to form an aerosol, and the droplets in the aerosol experience thermal decomposition, i.e., pyrolysis in a hot zone. In the case of film formation, the hot zone is simply a hot substrate surface, and in the case of particle formation, the hot zone may be a furnace. Spray pyrolysis is also known as *aerosol decomposition synthesis*, in which a droplet-to-solid particle conversion takes place.

The production of droplets and their dispersion into a gas environment is called *atomization*. There are a number of different kinds of atomizers in use, as listed in Table 9.1. The atomization variables listed here are droplet size, which determines the size of the final solid particle, the atomization rate, which affects the scalability of the process, and the droplet velocity, which affects the residence time of the droplets in the hot zone. One other important parameter, not listed, is the droplet size dispersion, which relates to the homogeneity of the product.

Spray pyrolysis is a gas-phase synthesis method and constitutes a form of chemical vapor deposition (CVD) without the expensive vacuum reactors. During CVD, as we saw in Chapter Seven, the constituents of a vapor phase, often diluted with an inert carrier gas, react at a hot surface (typically higher than 300°C) to deposit a solid thin film. The CVD

Table 9.1 Characteristics of Atomizers Typically Used in Spray Pyrolysis

Atomizer	Droplet Size (μm)	Atomization Rate (cm^3/min)	Droplet Velocity (m/s)
Pressure	10–100	3–no limit	5–20
Nebulizer	0.1–2	0.5–5	0.2–0.4
Ultrasonic	1–100	<2	0.2–0.4
Electrostatic	0.1–10

technologies mostly evolved around the integrated circuit (IC) industry. However, spray pyrolysis, the simplest form of CVD, has never been a contender in that arena. Rather, it is a viable technology for large-area films in solar cells and window panes and, more recently, for the production of nanopowders. Nanoparticle synthesis is a burgeoning field with a broad range of applications. The "holy grail" of research in this field is the ability to generate particles with controlled and narrow size distribution and adequate throughput; thus, the particle size can be tailored as required by the application. In spray pyrolysis when used for nanoparticle synthesis rather than film formation, an organic precursor (liquid or gas) is forced through an orifice at high pressure and burned in a furnace. The resulting ash is air classified to recover the nanoparticles (typically metal oxides).

How Does It Work?

As mentioned above, spray pyrolysis produces films or powders. A simple spray pyrolysis setup for film deposition is shown in Figure 9.1.[2] Metallic salt solutions are sprayed onto a hot substrate where droplets experience thermal decomposition. Spray pyrolysis tends to work best for ceramics [inorganic, nonmetallic materials that are typically crystalline in nature and are compounds formed between metallic and nonmetallic elements, such as aluminum and oxygen (alumina-Al_2O_3)]. All spraying processes display the same significant variables: the substrate temperature, ambient temperature, chemical composition of the carrier gas and/or environment, carrier gas flow rate, nozzle-to-substrate distance, droplet radius, solution concentration, solution flow rate, and—for continuous processes—substrate motion.[2] Because individual droplets

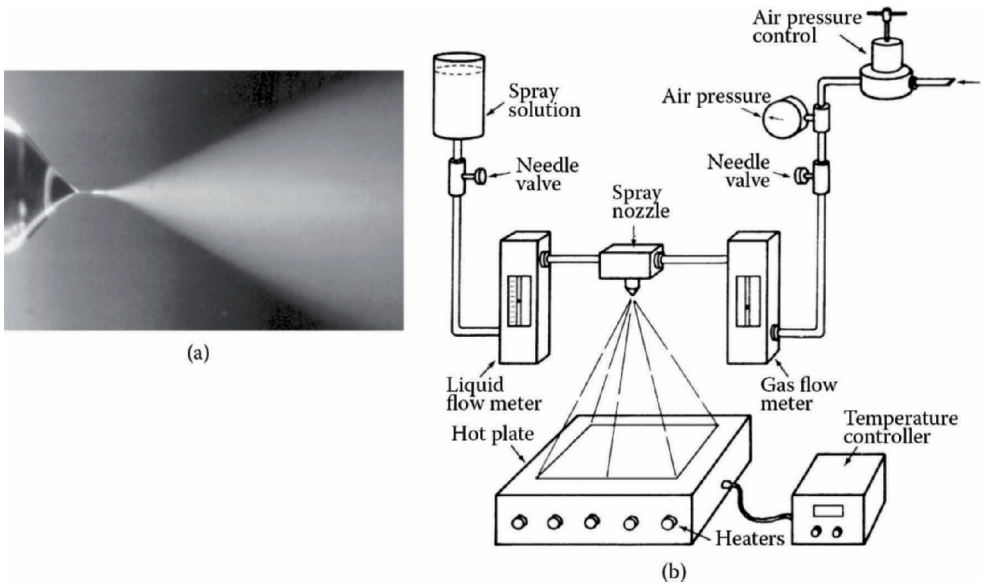

FIGURE 9.1 (a) Atomizer and aerosol. (b) Spray pyrolysis setup. (Mooney, J. B., and S. B. Radding. 1982. Spray pyrolysis processing. *Ann Rev Mater Sci* 12:81–101. Courtesy of Jack Mooney, SRI International, Menlo Park, CA.[2])

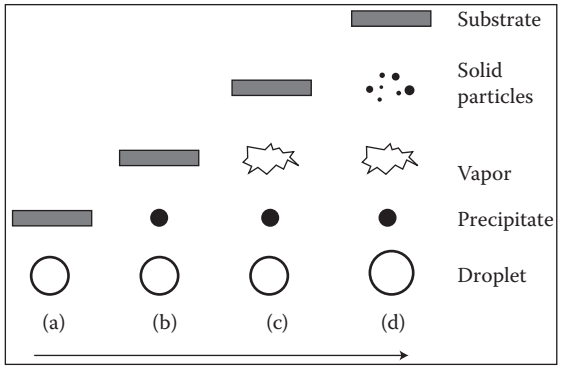

FIGURE 9.2 Steps involved in the decomposition of the dissolved precursors as the temperature of the substrate is ramped up. Steps a to d are explained in the text.

evaporate and react quickly, grain sizes can be very small (e.g., as small as 0.1 µm). The small grains pose a disadvantage for most semiconductor applications but not necessarily for sensor applications; for example, in SnO_2-based gas sensors (Taguchi sensor; see Example 9.1) where sensitivity resides in the intergranular contacts (necks).

In Figure 9.2 we detail the possible scenarios of how droplets laden with solid-particle precursors arrive at a hot substrate as the temperature of the substrate is ramped up. If the temperature is too low, the droplets splash onto substrate and decompose there (Figure 9.2a). At somewhat higher temperature, the solvent evaporates and dry precipitate hits the substrate and decomposes (Figure 9.2b). At higher substrate temperatures, the solvent evaporates and the precipitate melts and vaporizes without decomposition and vapor diffuses to the substrate (Figure 9.2c). At yet higher temperatures, the precursor decomposes to make solid particles before they reach the substrate (Figure 9.2d).

At a fixed substrate temperature, smaller droplets may vaporize before hitting the substrate, and because droplets decrease in size as they approach the substrate, the concentration gradient within the approaching droplet keeps on changing. If the surface concentration of the solute exceeds the solubility limit, precipitation occurs at the surface of the particles, and hollow spheres result, increasing the film roughness.

Spray pyrolysis is a simple, inexpensive, high-throughput technique used to produce several compound semiconductors with utility in various devices, such as solar cells, gas sensors, antireflection coatings, and ion selective electrodes.[3] The technique does not require high-quality targets or substrates and does not need a UHV system. The process produces relatively thick films, is difficult to control, and is not compatible with IC processing. It also tends to form hollow particles (see above) and consumes lots of solvent.

In case spray pyrolysis is used to make a powder instead of a film, a setup as shown in Figure 9.3 may be used. In this apparatus, the precursor solution is atomized into a diffusion dryer, then a thermolysis,

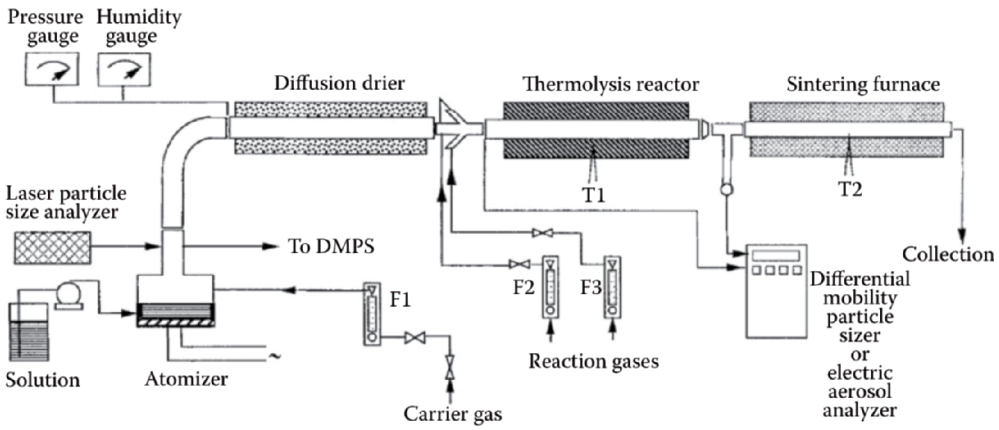

FIGURE 9.3 The diffusion dryer is used to dry and remove water vapor from the aerosol generated by the atomizer. Thermolysis of the precipitate particle at higher temperature to form a microporous particle occurs in the thermolysis furnace and sintering of the microporous particle to form a dense particle in the sintering furnace. The setup is also equipped with a differential mobility particle sizer (DMPS). (From Messing, G. L., S.-C. Zhang, and G. V. Jayanthi. 1993. Ceramic powder synthesis by spray pyrolysis. *J Am Cer Soc* 76:2707–26.[1])

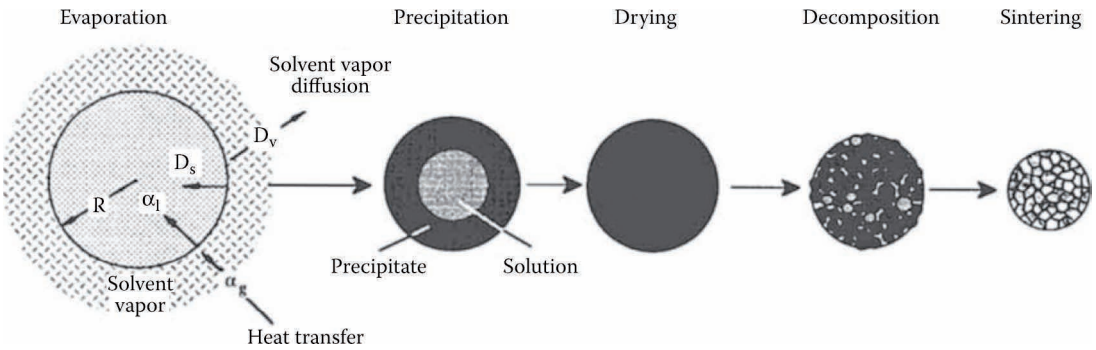

FIGURE 9.4 Droplet evolution in spray pyrolysis. Thermal decomposition or pyrolysis—forms a nanoporous structure and finally sintering—involves the adhesion/solidification of the crystallites. (From Messing, G. L., S.-C. Zhang, and G. V. Jayanthi. 1993. Ceramic powder synthesis by spray pyrolysis. *J Am Cer Soc* 76:2707–26.[1])

and finally a sintering furnace. In this series of reactors, the aerosol droplets undergo evaporation and solute condensation within the droplet, by drying, thermolysis of the precipitate particle at higher temperature to form a microporous particle, and sintering of the microporous particle to form a dense particle. The setup is also equipped with a differential mobility particle sizer (DMPS). Depending on the droplet size and solution concentration, particles sized from some submicrometers to some hundreds of micrometers are available by spray pyrolysis.

The stages the aerosol droplets go through are sketched in Figure 9.4.

During evaporation of solvent from the droplet surface, there is diffusion of solvent vapor away from the droplet (D_v), change in droplet temperature, diffusion of solute toward the center of the droplet (D_S), and change in droplet size (R). Precipitation/drying involves volume precipitation or surface precipitation of the solute, followed by the evaporation of the solvent through the nanoporous crust. If the solute concentration at the center of the drop is less than the equilibrium saturation of the solute at the droplet temperature, then precipitation occurs only in that part of the drop where the concentration is higher than the equilibrium saturation, i.e., surface precipitation (see also Figure 9.5).

It is one of the unique characteristics of spray pyrolysis that chemical reactions occur within micrometer to submicrometer-sized liquid droplets, microcapsule chemical reactors so to speak. Besides controlling the precipitation in these microreactors

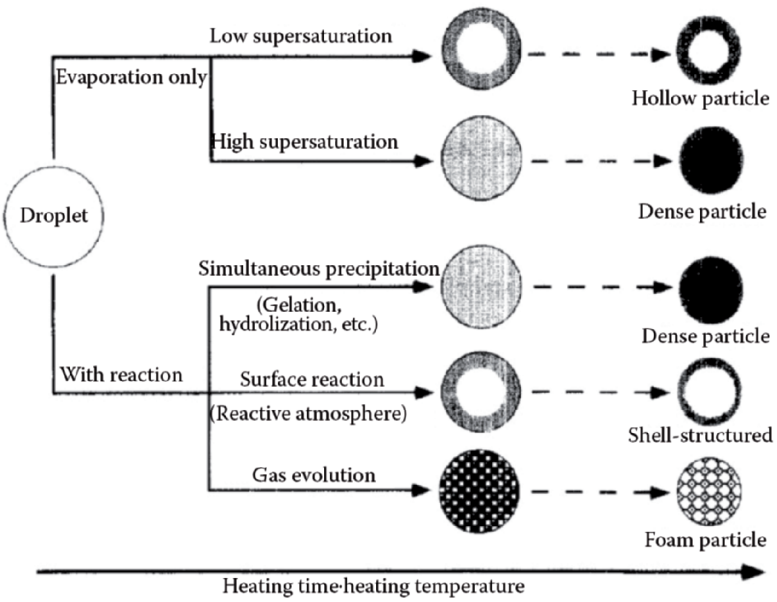

FIGURE 9.5 Droplet pyrolysis with and without chemical reaction.

by simple evaporation, precipitation can also be induced by a chemical reaction, as illustrated in Figure 9.5. Reaction schemes relied on to induce precipitation might involve gelation, hydrolyzation, gas evolution, reacting with a reactive atmosphere, and so on. We encountered another example of microcapsule reactions in Volume I, Chapter 6 where we describe droplet manipulation fluidic platform. In this case, the droplet microreactors are injected in a nonmixing fluid.

Salt-Assisted Spray Pyrolysis

Spray pyrolysis, like sol-gel (see Chapter 8), is a contender for making nanoparticles, used for chemical-mechanical polishing (CMP), magnetic recording tapes, sunscreens, and automotive catalysts. Spray pyrolysis is an attractive method for preparing uniform size and composition of nanoparticles because of its high production rate, continuous unit operation, and simple apparatus. However, with conventional spray pyrolysis the production of submicrometer particles faces some challenges. The concept derives from the principle of one particle from one droplet; thus, very fine droplets are needed to produce nanoparticles. The atomizers most commonly used to generate droplets tend to produce average droplet diameters in the range of several micrometers. For a droplet to dry from a typical initial diameter of 5 μm into a solid particle with a diameter of 0.1 μm, the initial volume fraction of dissolved involatile solute must be less than 0.0008%. In practice, these low solution concentrations lead to a low particle generation rate and make it difficult to maintain a high purity of the final particle product. Conventional spray pyrolysis produces particles that have multiple nanosized crystallites, but these crystallite aggregates are virtually inseparable because of the formation of a 3D network within each drop. The salt-assisted spray pyrolysis (SASP) developed by Dr. K. Okuyama from the Hiroshima University overcomes these limitations associated with conventional spray pyrolysis.[4] In the SASP method, salts such as $NaNO_3$, KNO_3, $LiNO_3$, and KCl are added to the spray precursor solution where the salt promotes nucleation and prevents nanoparticles from agglomerating. As a result, uniform-sized nanoparticles are produced. The diameters of nanoparticles produced by the SASP method range from several nanometers to several tens of nanometers. These sizes are about one-thirtieth to one-eightieth those of fine particles produced by traditional spray pyrolysis. Size distribution of SASP particles appears to be independent of their parent solution droplets; moreover, the SASP process is less energy consuming because it runs at lower temperatures.

In Figure 9.6 SASP is compared with traditional spray pyrolysis (SP).

Flame Spray Pyrolysis

Flame spray synthesis has been established as a state-of-the-art method for the production of high-purity mixed metal oxides for a vast range of applications in catalysis, optics, and electronics (Figure 9.7). It is primarily useful for making oxides. In flame spray pyrolysis, one directly sprays a liquid precursor into a flame, and particle synthesis occurs within the flame by a combustion reaction. This allows for the use of low-vapor-pressure precursors. Products are affected by the flame configuration, process temperature, oxidant composition, and additives. With metalorganic precursors, flame spray pyrolysis constitutes a commercial approach for the manufacture of silica and titania powders. Using heavy residual oils as precursor, carbon black is produced (millions of metric tons per year). The production of TiO_2 powder from the flame spray pyrolysis of $TiCl_4$ (the chloride process) accounts for ~60% of TiO_2 production (Dupont is the world's largest producer with about ~22% of global production). The TiO_2

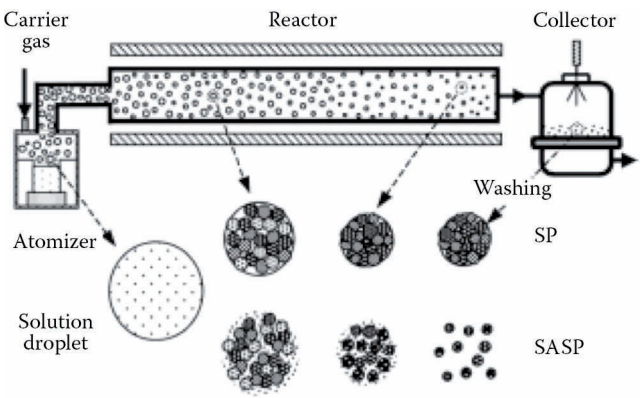

FIGURE 9.6 Comparison of SASP with traditional SP.

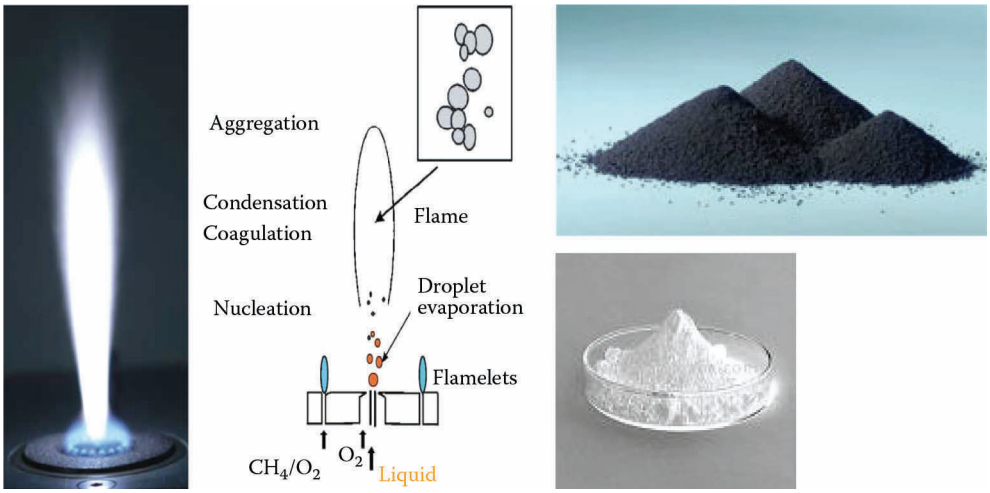

FIGURE 9.7 Flame spray pyrolysis. Using heavy residual oils as precursor, carbon black is produced using flame spray pyrolysis (millions of metric tons per year). The white powder is TiO_2.

powder made this way is the least expensive submicrometer powder available (see bottom right in Figure 9.7). Because of its high index of refraction, it is an ideal opaque dye for paper, paint, pigment, food, and cosmetics. In the chloride process, an electric field can be used to control particle size in the flame.[5] The flame is held between two plates, with one plate connected to a DC source and the other grounded as sketched in Figure 9.8. A flame filled with newly formed TiO_2 particles creates both positive and negative ions. As a result, these charged particles that otherwise would have collided with each other and grown to form larger particles are prevented to do so by the presence of the electrical field. The strength of the E field determines the velocity of the ions and essentially the size of the product particles. This method allows very precise control of the size (within 1 nm) and aggregate structure and crystallinity.

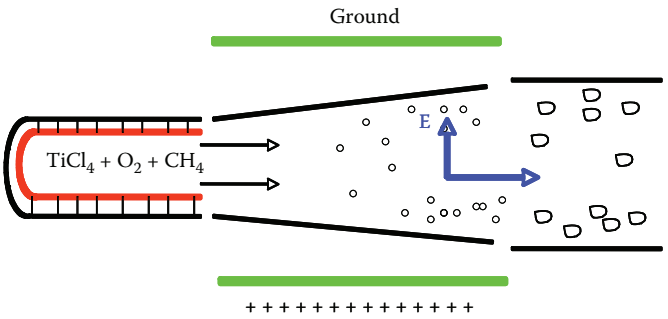

FIGURE 9.8 Electrical field control of particle size in flame spray pyrolysis of TiO_2 nanoparticles.

Pros of this method are its large capacity, proven technique, and high purity of products. Cons include the fact that, unless electrical fields are applied, agglomerates form, and it features a wide particle size distribution.

Electrospray Pyrolysis

Electrospraying is capable of atomizing a liquid into ultrafine droplets and offers yet another option for converting conventional spray pyrolysis into a nanoparticle production means. In this method, the meniscus of a conducting solution supported at the end of a capillary tube becomes conical when charged to a high-enough voltage (several kV) with respect to a counter electrode. When the electrostatic force becomes stronger than the surface tension of the liquid, the solution exits the capillary as a highly charged jet of fluid. As the solvent evaporates from the droplets, particles form and are deposited onto a heated collector. The droplets are stably formed by the continuous breakup of a jet extending from this liquid cone (Figure 9.9).

Electrospray (ES) pyrolysis can produce monodisperse droplets/particles over a wide size range, from a few nanometers to hundreds of micrometers, depending on liquid flow rate, applied voltage, and liquid electric conductivity. Especially in the small size range, the capability of producing monodisperse particles with relative ease is unmatched by any other aerosol generation scheme. Zinc sulfide

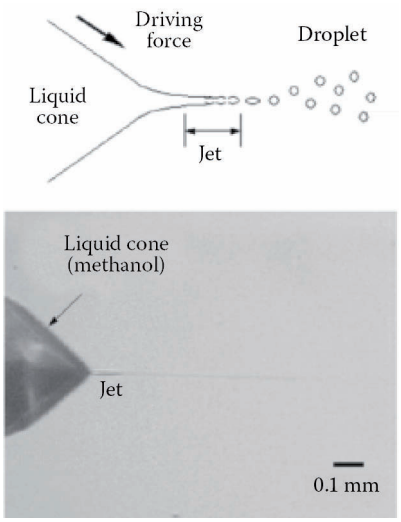

FIGURE 9.9 Droplet formation in the electrospray technique.

FIGURE 9.10 Electrospray from an array of nozzles etched in silicon, with a density of 250 sources/cm^2. (From Deng, W., J. F. Klemic, X. Li, M. A. Reed, and A. Gomez. 2006. Increase of electrospray throughput using multiplexed microfabricated sources for the scalable generation of monodisperse droplets. *Aerosol Sci* 37:696–714.[7])

particles 20–40 nm in diameter were prepared by electrically driven spray pyrolysis from solutions of ethyl alcohol with zinc nitrate [$Zn(NO_3)_2$] and thiourea [$SC(NH_2)_2$] at concentrations from 0.0025–0.2 M and electrical conductivities between 10^{-4} and 10^{-1} Sm^{-1}.[6]

A crucial drawback that has hampered wider ES pyrolysis applications is the low flow rate at which the cone-jet mode is established. Multiplexing the spray source, that is, operating several ESs in parallel is a possible way to address this problem. Deng et al.[7] demonstrated the microfabrication and testing of a compact multiplexed system of ESs as an array of nozzles etched in silicon, with a density of 250 sources/cm^2 (see Figure 9.10).

It is projected that this arrayed ES technology, once optimized, will be applied in various fields, including the synthesis of biological nanoparticles and biomedical coatings for controlled/targeted drug delivery, the synthesis of nanoparticle ceramics, superconductors, quantum dots, and thin films.

The ES method has also had a dramatic technological impact in the field of analytical chemistry. Electrospray ionization (ESI) is a technique used in mass spectrometry to produce ions. It is especially useful in producing ions from macromolecules because it overcomes the propensity of these molecules to fragment when ionized. The development of ESI for the analysis of biological macromolecules was rewarded with the attribution of the Nobel Prize in Chemistry to John Bennett Fenn in 2002. In the same electro-spraying set-up of Figure 9.9 and 9.10, higher molecular weight solutions enable one to produce continuous fibers instead of beads. At low viscosity, the columbic force dominates the elastic force, leading to a rapid breakup of the polymer jet. However, increased viscoelasticity engendered by chain entanglements does not allow the breakup of the jet, resulting in continuous fibers in the so-called electrospinning process. The electrospinning process is indeed a simple, versatile, and widely used method of producing all types of polymer nanofibers.[8–14] As in the case of particle spraying, pyrolysis may further convert the polymer nanofiber precursor to a final desirable product (e.g., carbon nano fibers through the carbonization process, i.e., the high temperature heating in the absence of oxygen; see also C-MEMS in Volume III, Chapter 5).

Among the precursors used in the synthesis of carbon nanofibers by electrospinning, polyacrylonite (PAN)/N,N-dimethylformamide (DMF) solution is the most commonly employed. Carbon nanofibers with diameters in the range of 80–750 nm are typically obtained from this solution by electrospinning. Our team has fabricated carbon nanofibers by electrospinning SU-8 (an epoxy-based negative photoresist) as the polymer precursor and subsequent pyrolysis of that precursor.[15] We have shown that the electrospun material retains its photoresist properties and that it can be directly

patterned in a wide variety of patterns by lithography before pyrolysis. The pyrolysis of SU-8 nanofibers to produce carbon nanofibers will enhance the C-MEMS toolbox considerably and allow for the facile integration of high-surface-area fibers with other photoresist derived carbon structures. This not only will allow for the making of interesting photopatternable carbon composites but also will enable the fabrication of multiscale hierarchal assemblies such as fractal-like electrodes where a high external surface area is coupled with a minimized internal resistance, which is a feature of great utility, in batteries and fuel cells.[16] The biocompatibility of SU-8-derived carbon[17] provides further motivation for the development of multiscale hierarchal scaffolds for tissue engineering and in vivo biosensors.

Example 9.1: Spray Pyrolysis
Application: Taguchi Gas Sensor

The use of a ceramic cylindrical tube in a classical Taguchi sensor (Figure 9.11) maximizes the utilization of heater power; thus, most of the power is used to heat the gas-sensitive tin oxide (SnO_2). A tin oxide paste is applied by dip coating the outside ceramic body to cover the thick film resistance measuring electrodes and is then sintered at high temperature. The resistance of tin oxide at high temperature gives a measure for the amount of reducing gases in the contacting atmosphere. Sintering stabilizes the intergranular contacts (necks) where the sensitivity of the gas sensor resides.[18] The design shown in Figure 9.11 is not suited for mass production because it involves excessive hand labor. The problems with the thick film structure mainly reside in the areas of reproducibility:

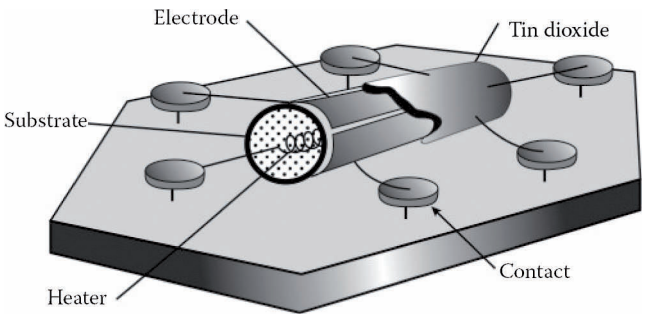

FIGURE 9.11 Classical Taguchi gas sensor.

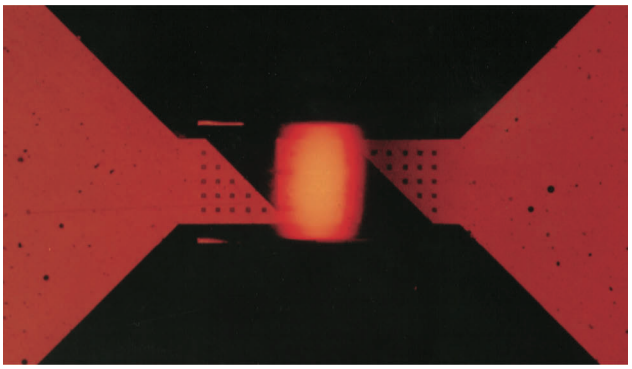

FIGURE 9.12 Heater element.

compressing and sintering a powder, the deposition of the catalyst, and the use of binders and other ceramics (e.g., for filtering). Application of IC techniques could improve the state of the art dramatically if a thin semiconductor oxide film (e.g., tin oxide) with the same sensitivity as the traditional thick sintered film could be made. Micromachined heater elements, as shown in Figure 9.12, improve the reproducibility and the absolute power budget needed to bring the sensor to the required temperature. Thermal efficiency and low power budget are obtained by thermally isolating the heater element on a thin, suspended membrane. Whereas low power budget sensors have proven feasible, it has been more difficult to make a compatible thin film as sensitive as the ceramic-type, thick film devices. When making thin films with physical vapor deposition (PVD) methods, the films have a lower surface area and buried intergranular contacts (see Figure 9.13). The buried intergranular contacts cannot be reached by the contacting gas as easily as in the powder case, making not only for lower sensitivity but also slower responding gas sensors. The slower response of the thin film sensors is because oxygen diffusion in the grain boundaries between compacted grains involves long time constants. When the grain boundaries are blocked on purpose, the sensor reacts faster but displays even less sensitivity.[18]

Using silk screening of thick films (see following section) on a thin membrane would seem to provide the solution—a low-energy heater combined with a fast and sensitive thick tin oxide film. Unfortunately, during our attempts to deposit thick films this way, usually the thin Si membrane broke as a result of the pushing action of the squeegee (see Figure 9.14).[19] Spray pyrolysis

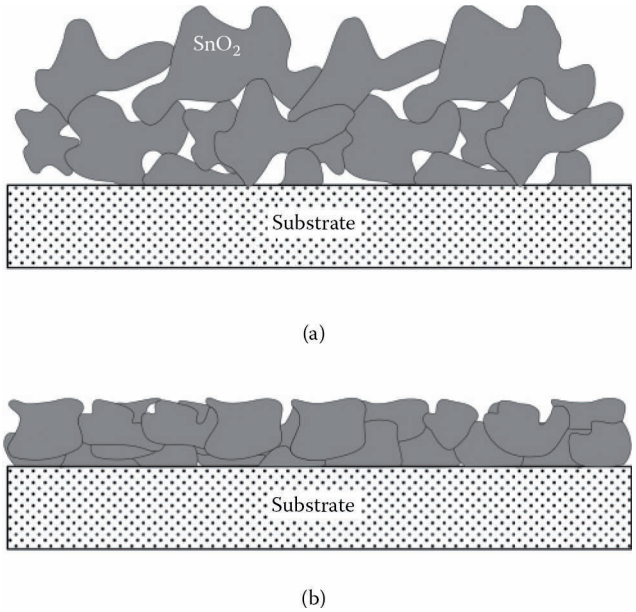

FIGURE 9.13 Grain structure in a sintered powder, thick SnO_2 film (a) and a PVD, SnO_2 thin film (b).

provides the possible answer here because its deposition does not involve mechanical pressure on the silicon membrane. Fast-responding, planar Taguchi SnO_2 gas sensors were made by spraying, with oxygen as the carrier gas, an organic solution of $(CH_3COO)_2SnCl_2$ in ethyl acetate onto quartz, glass, and Al_2O_3 ceramic substrates, heated to 300°C.[3] This result carries significance; other micromachining attempts based on thin PVD SnO_2 film fail to reach the sensitivity attained with the classical thick films and sintered SnO_2 films. Spray pyrolysis, with its very small grain-size deposits, holds the promise of reaching the objective of providing films with freely accessible polycrystalline grains. As a planar technology, it is also suited for large substrates and considered a viable alternative to the dip-coating process.

Screen Printing/Silk Screening

Introduction

Screen printing presents a more cost-effective means of depositing a wide variety of films on planar substrates than does IC technology, especially when fabricating devices at relatively low production volumes. The technique constitutes one of several thick film or hybrid technologies used for selective coating of flat surfaces (e.g., a ceramic substrate). The technology was originally developed for the production of miniature, robust, and (above all) cheap electronic circuits. The up-front investment in a thick film facility is low compared with that of IC manufacturing. For disposable chemical sensors, recent industrial experience indicates that screen printing thick films is a viable alternative to Si thin film technologies. Materials based on low-temperature organic polymers, to be cured at low temperatures or using UV radiation, as well as high-temperature enamel coatings with ceramic paints are coated in screen printing; the latter need sintering at high temperatures. Typical film thicknesses are in the range from several 10 to several 100 µm. Therefore, the coefficients of thermal expansion of the coat have to be matched well to that of the substrate.

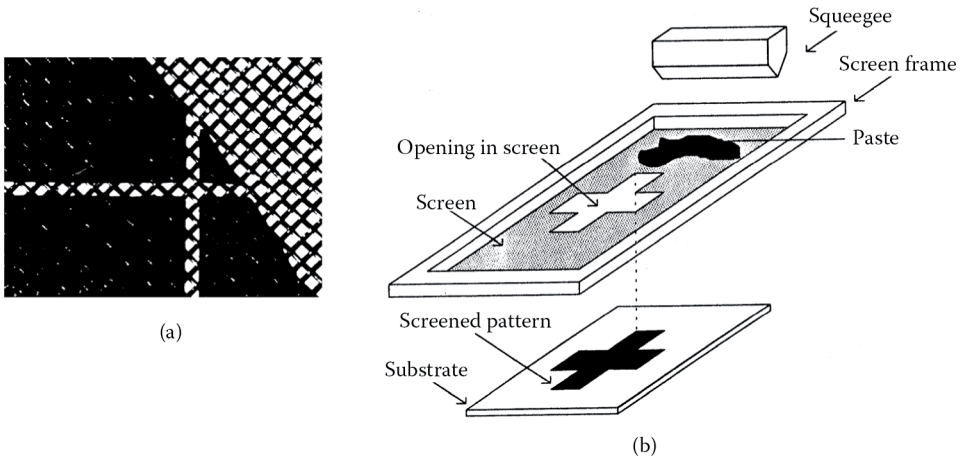

FIGURE 9.14 Screen-printing. (a) Screen with a 0.002-in. line opening oriented at 45° to the mesh weave. (b) Schematic representation of the screen-printing process. (From Lambrechts, M., and W. Sansen. 1992. *Biosensors: microelectrical devices.* Philadelphia: Institute of Physics Publishing. With permission.[20])

How Does It Work?

The elements of screen printing are the screen with openings defining the pattern to be printed, the screen frame, a squeegee, the ink material, and the substrate. A paste or ink is pressed onto the substrate through the openings in the photoemulsion fashioned on the stainless steel screen (see Figure 9.14a).[20] The mesh openings are created using photolithography on the photoemulsion in the screen frame. The paste consists of a mixture of the material of interest, an organic binder, and a solvent. The organic vehicle determines the flow properties (rheology) of the paste. The bonding agent provides adhesion of particles to one another and to the substrate. The choice of active particles makes the ink a conductor, a resistor, or an insulator. The lithographic pattern in the screen emulsion is transferred onto a substrate by forcing the paste through the mask openings with a squeegee (Figure 9.14b). This process depends on the mesh opening size and the viscosity of the ink. The squeegee further keeps the mesh in contact with the substrate, a process that depends on the screen tension and the off-contact distance. Squeegees are made from a stiff material like polyurethane to avoid deformation during printing. Relatively hard squeegees are required to withstand the high pressure needed to print at high speed, for example, high-viscosity materials on glass plates. However, the harder the material, the lower the ability to print an even layer of ink on an uneven surface. The squeegee edge must be sharp. The angle of the squeegee to the mesh defines the amount of material to be printed. Pulling the squeegee at 15–20° off vertical ensures an even deposit of material. The setting of the exact angle depends in part on the squeegee's profile and its hardness. The possible speed of the squeegee depends on the hardness of the squeegee and the viscosity of the printed material.

In a first step, paste is put down on the screen (Figure 9.15Aa); then the squeegee lowers and pushes the screen onto the substrate, forcing the paste through openings in the screen during its horizontal motion (Figure 9.15Ab).[20] During the last step, the screen snaps back; the thick film paste that adheres between the screen and the substrate shears; and the printed pattern is formed on the substrate (Figure 9.15Ac). Heavier frames cause the screen to be less deflected and minimize distortions and achieve a better resolution of the printed pattern. Throughput and resolution depend on the dimensions of the mesh openings (holes in the screen) and the nature of the pastes/inks. This leads to compromises in selecting the mesh size: a coarse mesh enables fast processing and high throughput but at low resolution, whereas a fine mesh enables better resolution but causes problems when pressing highly viscous materials through the screen. With a 325-mesh screen (i.e., 325 wires/in. or 40-μm

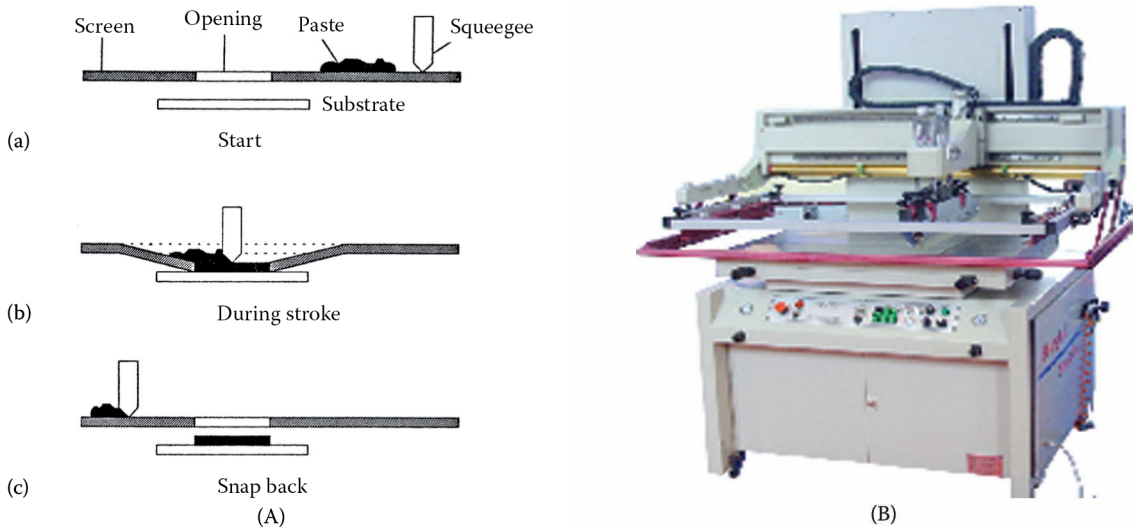

FIGURE 9.15 (A) The three different steps of the silk screening process. (From Lambrechts, M., and W. Sansen. 1992. *Biosensors: microelectrical devices.* Philadelphia: Institute of Physics Publishing. With permission.[20]) (B) Shanghai Shuoxing Screen Printing Equipment Co., Ltd.

holes) and a typical paste, a lateral resolution of 100 µm can be obtained. For difficult-to-print pastes, a stencil mask may be used, such as a thin metal foil with cut openings. However, the resolution of this method is inferior (>500 µm). Lower-cost and high-throughput printing techniques, such as screen printing, have a great promise in the fabrication of organic light-emitting devices (OLEDs). Jabbour et al. demonstrated, for the first time, the use of screen printing to deposit ultrathin layers in OLEDs of less than 15 nm with root mean square surface roughness of less than 1.5 nm.[21] After printing, the wet films are allowed to settle for 15 min to flatten the surface while drying. This removes the solvents from the paste. Subsequent firing burns off the organic binder; metallic particles are reduced or oxidized; and glass particles are sintered. Typical temperatures range from 500–1000°C. After firing, the thickness of the film ranges from 10–50 µm.

A typical silk screening setup is the one from Universal Instruments Corporation (http://www4.uic.com), the DEK 4265 Horizon Screen (see also The Shanghai Shuoxing screen printing machine in Figure 9.15B). Dupont provides technical tips for screen printing at http://www2.dupont.com/MCM/en_US/techinfo/techtips.html, and the Screen Printing Magazine can be found at http://www.screenweb.com/home.php.

Types of Inks/Pastes and Applications

Inks are formulated to exhibit pseudoplastic* behavior, as illustrated in Figure 9.16[22,23] (see also Volume I, Chapter 6 on fluidics), to prevent flowing through the screen until the squeegee applies sufficient pressure. Almost all materials compatible with the high firing temperature and the other ink constituents can be used to screen print. Different pastes—conductive (e.g., Au, Pt, Ag/Pd), resistive (e.g., RuO_2, IrO_2), overglaze, and dielectric (e.g., Al_2O_3, ZrO_2)—are commercially available.

The conductive pastes are based on metal particles, such as Ag, Pd, Au, Pt, or a mixture of these combined with glass. Glass is necessary for the adhesion of the metal conductor to the ceramic (Al_2O_3) substrate. The following conductive pastes can be distinguished by the bonding mechanism used.

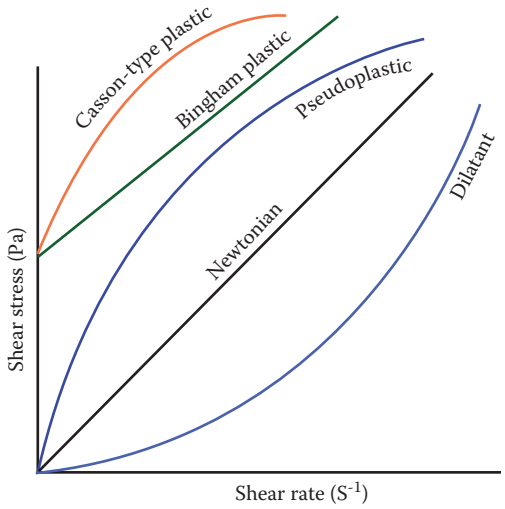

FIGURE 9.16 Pseudoplastic behavior of inks for silk screening (see also Volume I, Chapter 6).

- Glass-bonded or fritted pastes are inks where adhesion of the metal is achieved with the addition of a glass mixture (30%) (a typical glass composition is 65% PbO, 25% SiO_2, and 10% Bi_2O_3). A fritted ink contains powdered glass that binds the ink to the substrate material when fired at a temperature of 850°C. Thus, a fritted ink will generally consist of the glass frit, a material defining the desired ink property, and an organic vehicle that renders the ink printable. Vehicles typically consist of solvents mixed with slightly more viscous materials, such as resins, in a ratio designed to give the optimum overall viscosity to the ink.
- Oxides or fritless-bonded inks adhere to the metal via the addition of copper oxide (3%).
- Mixed-bonded pastes are inks for which adhesion is achieved by use of both glass and copper oxide.

Resistive pastes are based on RuO_2 or $Bi_2Ru_2O_7$ mixed with glass (65% PbO, 25% SiO_2, 10% Bi_2O_3). The resistivity is determined by the mixing ratio. Overglaze and dielectric pastes are based on glass mixtures. According to composition, different melting temperatures can be achieved.

Thick film technology with the above type of traditional inks has application in the construction of

* In pseudo-plastic fluids viscosity diminishes as the applied velocity gradient increases (see also Volume I, Chapter 6).

a wide variety of hybrid sensors, such as sensors for radiant signals, pressure sensors, strain gauges, displacement sensors, humidity sensors, thermocouples, capacitive thick-film temperature sensors, and pH sensors (see Middlehoek et al.[23] and references therein). Also, with silicon-based sensors (e.g., pressure sensors and accelerometers) die-mounted on a ceramic substrate, thick film resistors are used for calibration by trimming resistors on the ceramic substrate.

New inks, specifically developed for chemical and biological sensor applications, are available or under development. For example, SnO_2 pastes incorporating Pt, Pd, and Sb dopants have been developed for the construction of high-temperature (>300°C) semiconductor gas sensors for reducing gases (so-called *Taguchi sensors*) (see Example 9.1).[18] Thick metal phthalocyanine films have been deposited on alumina to form the active material in relatively low-temperature (<180°C) gas sensors.[24]

In Chapter 8 we saw that for biosensor applications, thick film technology based on pastes (polymer-based inks) that can be deposited at room temperature have been developed.

Doctor's Blade or Tape Casting

Silk screening and tape casting technology constitute two important thermal forming processes, often referred to as *hybrid* manufacturing methodologies. Here we detail tape casting as yet another example of thermal forming. Tape casting is also known as *doctor blading* or *knife coating*, and the process is well known under these names in many industries, including paper, plastic, and paint manufacturing. The "doctor's blade" is a scraping blade for the removal of excess substance from a moving surface being coated. Howatt was the first to obtain a patent to use the technique for "forming ceramic materials into flat plates, especially useful in the electric and radio fields."[25] This is still the principal application of tape casting today, although its use extends far beyond the field envisioned in 1952 (http://www.drblade.com). Since then, tape casting has been used to manufacture a variety of multilayer ceramic package products, such as low-temperature cofired ceramics, solid oxide fuel cells, and piezoelectric smart devices.

The ceramic application of doctor blading, also referred to as *green tape* technology, is a thermal forming process well suited for fabrication of mesoscale devices (layers with a thickness between several micrometers and millimeters). In green tape technology, a ceramic slurry, either aqueous or organic solvent-based, is continuously dispensed onto a moving substrate from a hopper or other appropriate plumbing. An important requirement of the slurry is that its viscosity is in the 100–130-Poise (10^{-13} Ns/m^2) range. The substrate and dispensed product then move under the doctor's blade, an adjustable gate with a precisely controlled height on a smooth casting/coating surface. The purpose of the doctor's blade is to allow a known thickness of material to pass under the blade. In today's technology, very thin ceramic layers are defined in micrometers, with tapes as thin as 5 μm reported by equipment manufacturers (http://www.drblade.com). Standard tape casting machines come with thickness ranges from 12 μm to more than 3 mm. Precise, smooth control of the carrier or web speed is also essential to ensure uniform films. Next, the substrate and bladed ceramic slurry are moved through a precision oven for partial drying. The result is a flexible green ceramic tape that can be easily machined before final drying and sintering. Ceramic in green tape form may be cut, for example, with lasers or razor blades into any desired shape. Tape stacks are produced by lamination of several single green tapes under heat and pressure. The optimum dried thickness range for tape casting is generally accepted as being from 0.025–1.27 mm. The green tape process flow is summarized in Figure 9.17. In Figure 9.18 we show a photo of a typical tape caster.

Tape casting is the best method for forming large-area, thin, flat ceramic parts and even for certain thin metal foils. Such thin parts are virtually impossible to press and are very difficult to extrude. The difficulties are compounded in dry pressing when the plate is to be pierced with numerous holes because of the increased possibility of nonuniform die fill. On the other hand, punching via holes and slots of various sizes and shapes into green tape is relatively easy and essential to the many types of multilayered ceramic packages designed and manufactured today. Tape casting has been

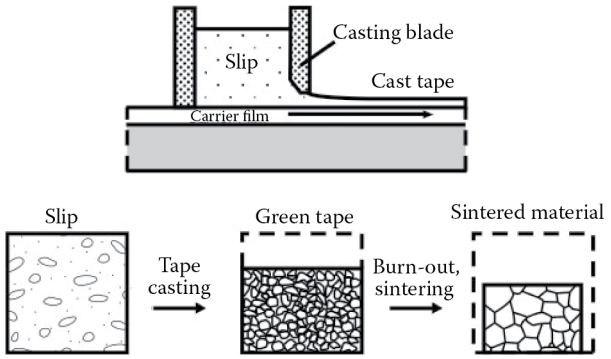

FIGURE 9.17 Tape casting. The top schematic drawing illustrates tape casting. The bottom sketch shows the different stages during the processing: the slip consisting of water, ceramic particles and binder; the cast, dried green sheet; and finally, the microstructure of the sintered material.

expanded to nonceramic, polymer, and metal applications, such as polyvinylidene fluoride (PVDF) battery separator films and tape automated bonding (TAB) semiconductor adhesive-metals. Tape casting is often the preferred choice in manufacturing these products because of its relative simplicity and low implementation cost compared with other available methods, such as dry pressing, slip casting, or injection molding. Tape casting is a straightforward method of forming uniformly thin sheets of film that is inexpensive, scaleable, and may be used with any ceramics, metals, or polymers that are readily mixed in a liquid suspension or slip.

An industrial green tape setup costs between $100,000 and $120,000. Dupont Microcircuit Materials is a typical supplier of green tape materials for a wide variety of electronic and electrical applications in the wireless and wired telecommunications, automotive, military, medical, instrumentation, industrial, data processing, components, and consumer industry segments (Green Tape™; http://www.mcm.dupont.com).

FIGURE 9.18 A typical tape caster. HED Lab-Cast 7-ft. tape caster.

An excellent recent review of tape casting can be found in *Tape Casting: Theory and Practice* by Richard E. Mistler and Eric R. Twiname.[26] More background information on tape casting is also available at http://www.drblade.com.

Example 9.2: Green Tape Technology: Multilayer Planar Oxygen Sensor

Green tape methodology is of special interest in the fabrication of high-temperature gas sensors. As an example, we show Figure 9.19, a multilayer planar oxygen sensor manufactured by NGK Spark Plug Co., Ltd. Also known as a *wide range air-to-fuel ratio* sensor, it incorporates two oxygen-pumping cells and one potentiometric gauge. The operating principle of the NGK sensor is as follows. The potentiometric cell—a lambda sensor—measures EMF between the exhaust in the gap and the atmospheric air. The measured voltage V_{EMF} is compared with V_o (corresponding to EMF of the stoichiometric point). The amplifier applies an appropriate pumping voltage to the pumping cell after comparing V_{EMF} and V_o (if $V_{EMF} > V_o$ then the exhaust is rich; if $V_{EMF} < V_o$ then the exhaust is lean). It is fabricated by laminating and cofiring, at high temperatures, several layers of ceramic green tape, some of which are metal coated and have openings through them.[27] Because both metal and ceramic layers constitute the sensor, the materials should be carefully prepared, and the cofiring process must be tightly controlled to avoid metal diffusion or reaction with the ceramic. Because of the process complexities, this sensor turned out too expensive for common use.

Plasma Spray Deposition

Introduction

Because of the need to incorporate more and different materials in a thickness ranging anywhere from monolayers to a few hundred micrometers,

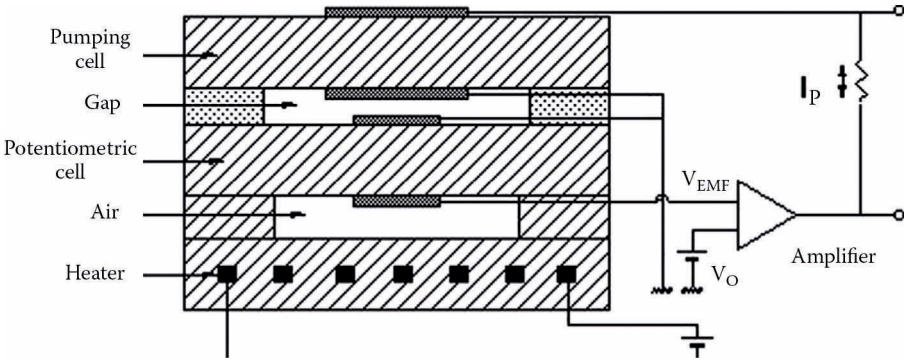

FIGURE 9.19 Planar Oxygen Sensor from NGK, Spark Plug Co., Ltd.

micromachinists are broadening their horizon beyond IC deposition techniques and increasingly are incorporating hybrid thick film methodology in their tool box. Microstructures can be crafted economically with non-IC equipment and materials, and thick film silk screening, spray pyrolysis, sol-gel, and tape casting are all attractive additive techniques in this regard. Spray pyrolysis (see earlier), drop delivery systems (see Chapter 8), and pick-and-place technology (see Volume III, Chapter 4) are but a few examples. Here we review plasma spraying as another example of a non-IC thermal forming tool. With plasma spraying almost any material can be coated on many types of substrates. Applications include corrosion- and temperature-protective coatings, superconductive materials, and abrasion resistance coatings.[28] Today, turbine blades and other components of aircraft engines are plasma coated with corrosion- and temperature-resistant coatings. In this section, we propose that the technique be expanded to the mass manufacture of ceramic-based sensors.

How Does It Work?

The CVD and PVD techniques discussed in Chapter 7, except for the cluster deposition method, rely on atomistic deposition, that is, atoms or molecules are individually deposited onto a surface to form a coating. Plasma spraying, like spray pyrolysis, is a typical particle deposition method; particles a few micrometers to 100 µm in diameter are transported from source to substrate. The basic configuration of a plasma-arc torch setup for layer deposition and a plasma spray nozzle are shown in Figures 9.20 and 9.21, respectively.

In plasma spraying, a high-intensity plasma arc is operated between a stick-type cathode and a nozzle-shaped, water-cooled anode as illustrated in Figure 9.21. For atmospheric spraying, one typically works at power levels from 10–100 kW. Plasma gas, pneumatically fed along the cathode, is heated by the arc to plasma temperatures and leaves the anode nozzle as a plasma jet or plasma flame. Argon and mixtures of argon with other noble (He) or molecular gases (e.g., H_2, N_2, O_2) are frequently used for plasma spraying. Fine powder suspended in a carrier gas is injected into the plasma jet where the particles are accelerated and heated. The plasma jet may reach temperatures of 20,000 K and velocities up to 1,000 ms^{-1}. The temperature of the particle surface is lower than the plasma temperature, and the dwelling time in the plasma gas is very short. The lower surface temperature and short duration prevent the spray particles from being vaporized in the gas

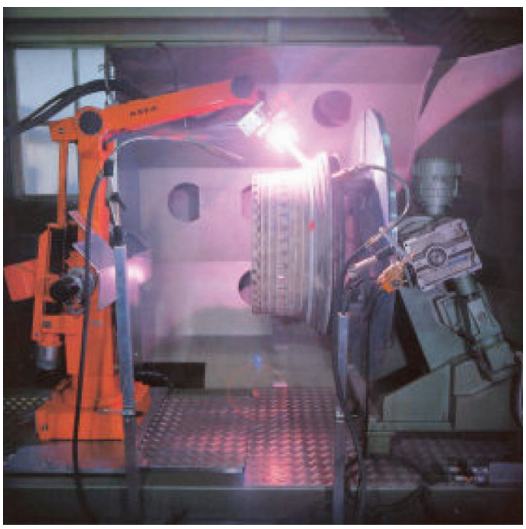

FIGURE 9.20 Setup for plasma spray. With a robot arm and a sound-proof spraying booth.

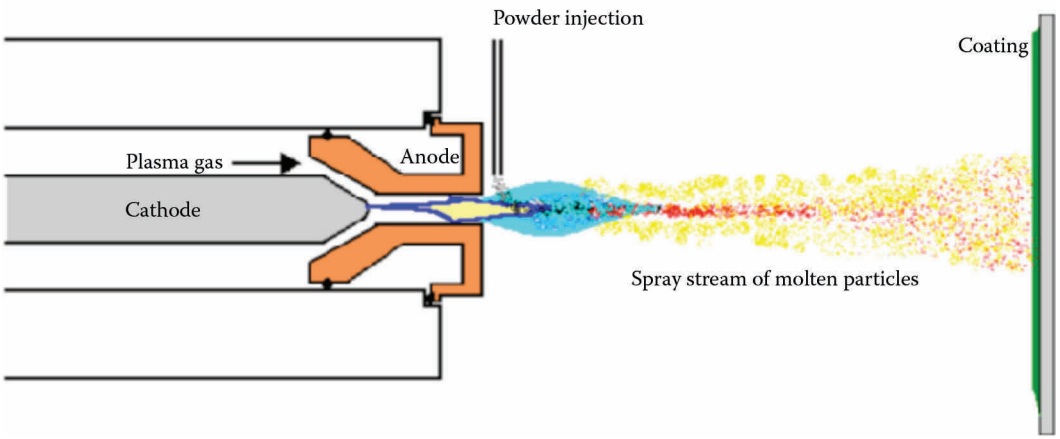

FIGURE 9.21 Plasma spray nozzle.

plasma. The particles in the plasma assume a negative charge, owing to the different thermal velocities of electrons and ions. As the molten particles splatter with high velocities onto a substrate, they spread, freeze, and form a more or less dense coating, typically forming a good bond with the substrate. The resulting coating is a layered structure (lamellae), as shown in Figure 9.22. Typical coatings for high-temperature applications involve an oxidation-resistant coating and a thermal barrier coating (TBC). The role of TBCs is, as their name suggests, to provide thermal insulation of the blade. A coating of about 1–200 μm can reduce the temperature by up to 200°C. The oxidation-resistant coating is also called *bond coat* because it provides a layer on which the ceramic TBC can adhere.

As shown in Figure 9.23, a particle leaving the spray nozzle goes through different regions of temperature and flow velocity. Ideally, the particles should arrive at the substrate at high velocities in a completely molten state to form the densest coating with little porosity. To produce porous films for the fabrication of oxygen sensors in our own work,[19] we positioned the substrate somewhere between regions 4 and 5. To produce dense films, we positioned the substrate in region 4. With this technique, a minimum thickness is about 25 μm, and very thick coats up to a few millimeters thick are possible. When attempting to deposit gas-sensitive layers, such as ZrO_2, on thermally isolated, thin Si membranes to make a power-efficient gas sensor, we found that the kinetic energy of the plasma was too high, and it broke the thin suspended Si membranes. The high temperature and kinetic energy preclude the potential for integrating Si with high-temperature plasma spraying. In Example 9.3 below we demonstrate how plasma spraying of yttria-stabilized zirconia may be used in the batch fabrication of all solid-state oxygen sensors.

Plasma spray deposition is perhaps the most flexible of all the thermal spray processes because it can develop sufficient energy to melt any material. Because it uses powder as the coating feedstock, the number of coating materials that can be used in the plasma spray process is almost unlimited. Plasma spraying equipment may be purchased, for example, from Sulzer Metco (http://www.sulzermetco.com/index.html).

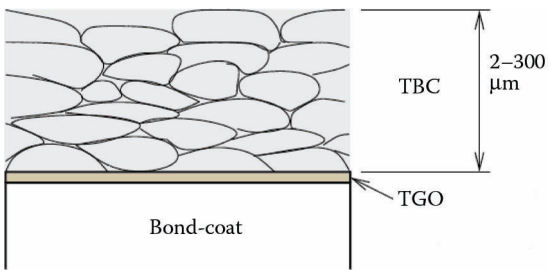

FIGURE 9.22 Schematic microstructure of a TBC obtained by APS on a TGO.

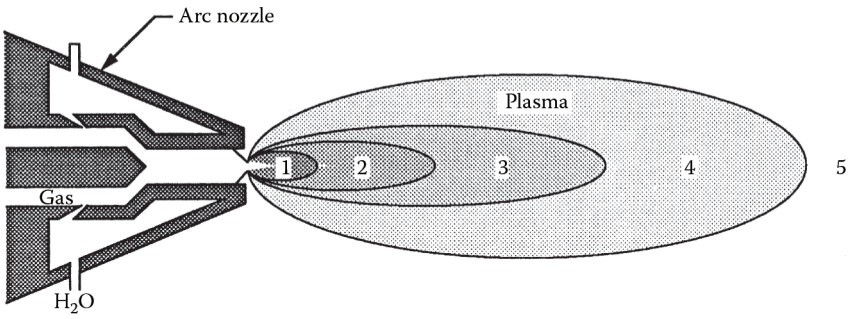
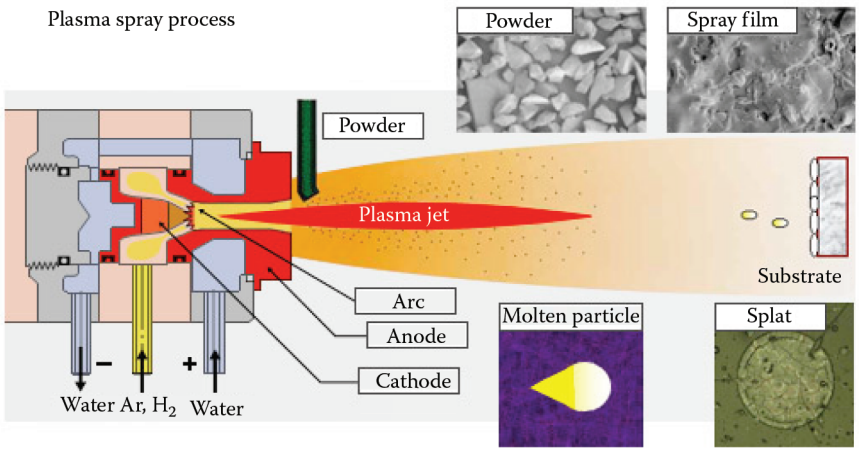
Example 9.3: Plasma Spraying: Multilayer Planar Oxygen Sensor

Here we present an example of how to use plasma spray technology to batch produce solid-state oxygen sensors based on yttria-stabilized ZrO_2 (YSZ) solid electrolyte films.[29] Plasma spraying is a particulate method geared toward



Region	Distance from nozzle	Temperature range (K)	Linear flow velocity (m/s)
1	< 1 cm	1.5×10^4 — 1×10^4	~ 400
2	1 < d < 5 cm	1×10^4 — 5×10^3	~ 400 — 200
3	5 < d < 10 cm	5×10^3 — 2×10^3	~ 200 — 100
4	10 < d < 20	2×10^3 — 1×10^3	< 100
5	20 < d	< 500	

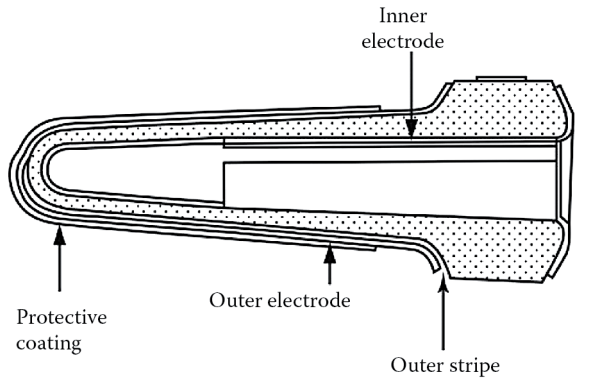
(a)



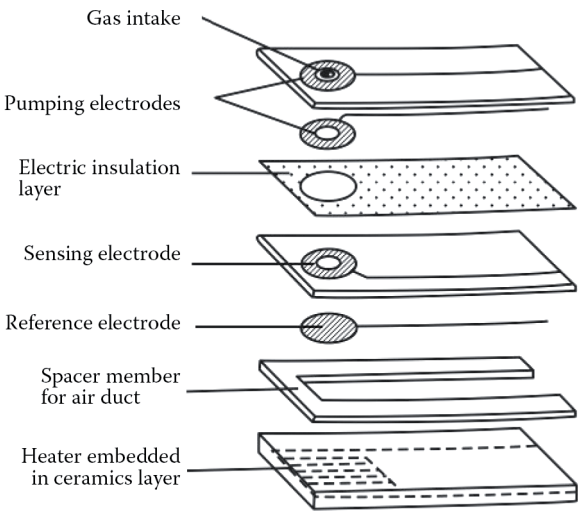
(b)

FIGURE 9.23 (a) Typical ranges of temperature and flow velocity with distance from the nozzle. (b) Plasma spray nozzle.

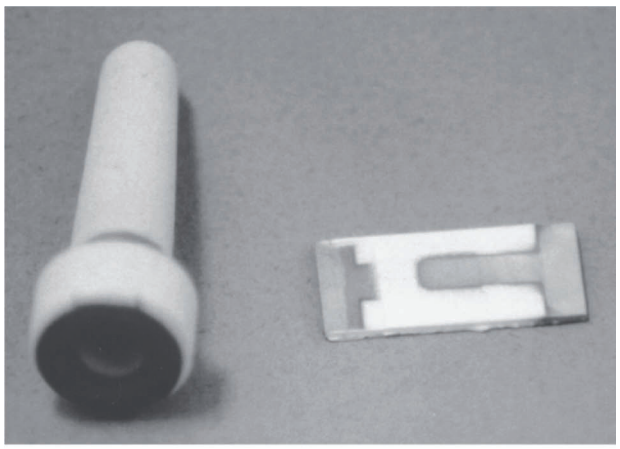
fast deposition of thicker films (>30 μm), and it might enable the batch fabrication of solid-state oxygen sensors at a fraction of the current cost ($2 vs. $12 and up). Traditional automotive solid-state oxygen sensors for combustion control (so-called *lambda probes*) are nose-shaped, 3D structures fabricated by sintering a molded green tape zirconia body (see Figure 9.24a). A plasma-sprayed, porous, gas-diffusion barrier, typically a spinel structure oxide, protects the resulting dense ceramic YSZ solid electrolyte and the silk-screened oxygen-sensing Pt electrode contacting it. Newer designs for oxygen sensors, called *wide range air-to-fuel ratio sensors*, incorporate two oxygen pumping cells and one potentiometric gauge. As we saw in Example 9.2, these sensors are planar and fabricated by laminating and cofiring at high temperatures several layers of ceramic green tape, some of which are metal coated and have openings through them (see Figures 9.19 and 9.24b).[27] Because both metal and ceramic layers constitute the sensor, the materials should be well prepared, and the cofiring process must be tightly controlled to avoid metal diffusion or reaction with the ceramic. Because of the process complexities, this sensor is too expensive. In Figure 9.24c, an alternative planar oxygen sensor fabricated using plasma-spray deposition is compared with the traditional cone-shaped oxygen sensor.[29,30] In this planar oxygen sensor, the metal electrodes are deposited by sputtering,



(a)



(b)



(c)

FIGURE 9.24 Solid-state oxygen sensors. (a) Traditional oxygen probe only protective, gas diffusion barrier is applied by plasma spray. (b) Wide-range air-to-fuel ratio sensor. (c) Planar oxygen probe, sensor, and gas diffusion layer made by plasma spray and compared with a classical oxygen probe. [(b) from Suzuki, S., T. Sasayama, M. Miki, M. Ohsuga, S. Tanake, S. Ueno, and N. Ichikawa. 1986. SAE Paper 860408. With permission.[27]]

and the plasma-sprayed YSZ film acts both as a gas-diffusion layer and as an oxygen-conducting electrolyte. The ionic conductivity of the plasma-deposited YSZ films does not reach the same level as YSZ electrolytes sintered at high temperatures because the films are not as dense. However, the relatively thin film geometry of the present sensor allows for using the plasma-sprayed YSZ film as an oxygen-pumping cell for the wide-range, air-to-fuel ratio sensor. The major challenge in the manufacture is the control of the porosity gradient in the gas diffusion barrier and electrolyte material, which is accomplished by controlling the size of the spraying powder and spraying conditions.[30] To change the temperature and flow velocity of the particles, we changed the distance between the nozzle and the substrate. With reference to Figure 9.23, to produce porous YSZ, we positioned the substrate somewhere between regions 4 and 5; to produce dense films, we positioned the substrate in region 4. The plasma-sprayed films adhere very well to the substrates and have exceptionally high integrity. The plasma method produces almost fully activated YSZ films onto a substrate carrying the thin film sputter-deposited Pt electrodes, and there is no need for additional sintering. This straightforward manufacture of solid-state oxygen sensors can be performed in large batches by using simple shadow masks and laser cutting the separate sensor elements.

We believe that this approach—a combination of thin and thick film methods—opens up the potential for planarization of many types of gas sensor devices. In the manufacture of chemical sensors, thick film technology on hybrid substrates is more prevalent than in the IC industry, and plasma deposition of all types of chemical sensor materials is, in the author's opinion, fertile ground for research. Plasma deposition of sensor materials such as ZrO_2, SnO_2, and ZnO on large inert carrier substrates could provide wafers coated with chemical sensor material very quickly and inexpensively.

Plasma Arc Deposition

In the plasma reactors discussed above, the energy necessary for evaporation and reaction is provided by an electric arc that forms between a stick-type cathode and a nozzle-shaped, water-cooled anode

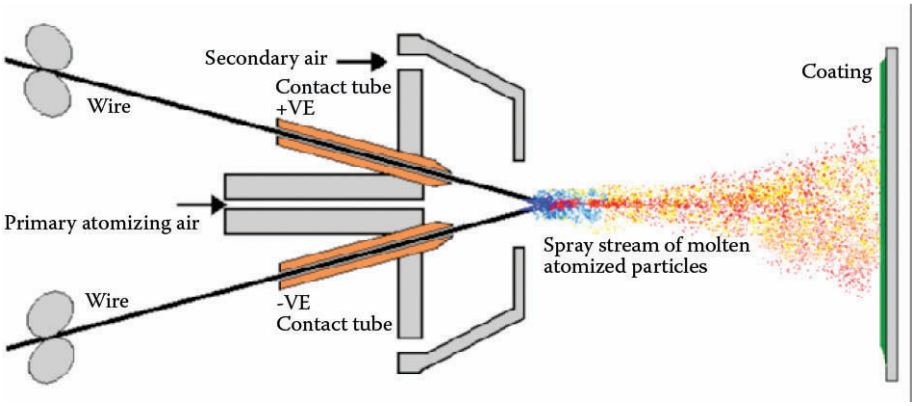


FIGURE 9.25 Plasma arc spray deposition process.

as illustrated in Figure 9.21. The material to be deposited is a fine powder suspended in a carrier gas and is injected into the plasma jet where the particles are accelerated and heated. The electrodes themselves do not participate in the reaction itself; in contrast, in the arc spray deposition process, illustrated in Figure 9.25, the electrodes are made of the metal to be vaporized. The electrodes are polarized in the presence of an inert background gas until the breakdown voltage is reached, and an arc is formed across the electrodes that vaporizes them. The molten material is propelled by compressed air toward the substrate surface. The impacting molten particles on the substrate rapidly solidify to form a coating. High spray rates and efficiency make plasma arc deposition a good tool for spraying large areas and high production rates. Disadvantages of the electric arc spray process are that only electrically conductive electrodes can be sprayed. The main traditional applications of the arc spray process are anticorrosion coatings of zinc and aluminum.

Plasmas and Nanoparticles

In the section above on spray pyrolysis, we discovered that this technique can be used for either film formation or for nanopowder generation. The same is true for the plasma equipment discussed above. Plasma temperatures are in the order of 10,000 K; thus, precursors injected in those plasmas are generally decomposed fully into atoms. To form nanoparticles from these, the atoms must then react or condense to form small solid particulates when cooled by mixing with a cool gas or by expansion through a nozzle. We saw an example of that in the ion cluster beam technology discussed in Chapter 7. In ion cluster beam technology the cooling occurs when the vapor exits a special evaporation cell. As shown in Figure 7.14, the heating of the evaporant in an evaporation cell with a small opening causes an adiabatic expansion of more than 100–10^{-5} or 10^{-7} mbar on exiting that cell. The expansion causes a sudden cooling, inducing the formation of atom clusters.

A very prominent application of arc deposition is that of fullerenes. The first large-scale synthesis of fullerenes was discovered in 1989 by Huffman and Kratschmer; their technique consisted of the arc evaporation of graphite electrodes via resistive heating within an atmosphere of approximately 100 atm of helium (see Volume III, Chapter 3). Spark discharge deposition was also the very technique that led to the discovery of carbon nanotubes in 1991. Carbon nanotubes were found in the carbon soot of graphite electrodes during arc discharge by using a current of 100 amps. In this process, the negative electrode sublimates because of the high temperatures caused by the discharge. Because nanotubes were initially discovered using this technique, it is still the most widely used method for nanotube synthesis. The yield for this method is up to 30% by weight, and it produces both single- and multiwalled nanotubes with lengths of up to 50 μm. The method is also used, for example, to produce fused silica. Silica sand is first vaporized in arc plasma at atmospheric pressure, and the resulting mixture of plasma gas and silica vapor is rapidly cooled by quenching with oxygen, thus ensuring the quality of the fumed silica produced.

In an RF induction plasma, energy coupling to the plasma is accomplished through the electromagnetic field generated by an induction coil. The plasma gas does not come in contact with electrodes, thus eliminating possible sources of contamination and allowing the operation of such plasmas with a wide range of gases, including inert, reducing, oxidizing, and other corrosive atmospheres. The working frequency is typically between 200 kHz and 40 MHz. Because the residence time of the injected feed droplets in the plasma is very short, it is important that the droplet sizes are small enough to obtain complete evaporation. The RF plasma method has been used to synthesize different nanoparticle materials, for example, various ceramic nanoparticles such as oxides and nitrides of Ti and Si.

Laser and Electron Beam Deposition

Introduction

Laser and electron beam machining are thermal techniques that are used as either subtractive tools in laser and electron beam etching (see Chapter 5) or as additive tools such as in the applications covered in this section, i.e., laser-assisted CVD (LCVD), SLS (a RP technique), and electron-assisted CVD (ECVD). Lasers also are used in stereolithography to make polymeric microstructures; this additive photochemical technology was reviewed in Chapter 8 and will not be repeated here. Pulsed laser deposition (Chapter 5) is also not covered here; although it uses intense laser radiation (thermal) to erode a target, it deposits the eroded material onto the adjacent substrate mechanically, not thermally.

Forming Processes with Laser Machining

Laser-Assisted Chemical Vapor Deposition

Laser-assisted chemical vapor deposition (LCVD) is an additive technique that involves the deposition of solids by localized chemical reaction using a laser beam (see Figure 9.26). The method has been used for growing 3D microstructures and thin films in elemental or compound form, and at least 17 elements of the periodic chart have been deposited (e.g., W, Ni, Ti).[31] The reactions are either pyrolytic,

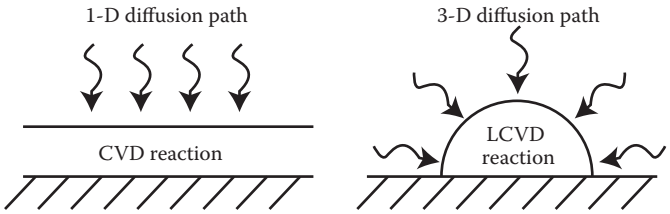

FIGURE 9.26 Comparison of a CVD and an LCVD reaction.

i.e., thermally activated, or photolytic, i.e., nonthermally activated. The latter method fills the need for a low-temperature deposition process. Because this chapter is about thermal forming, we will emphasize the former types of reactions.

The setup shown in Figure 5.25 is used to both laser etch and to laser deposit materials. Lasers and electron and ion beams add another important capability to materials processing, namely, the ability to process selected materials at specific sites and at low bulk temperatures. Of the different techniques, the laser is the more versatile. It can be operated in air, is not affected by surface charging, and can more easily be incorporated in a manufacturing assembly line.[32] With a laser source, it is possible to write a pattern on a surface directly by scanning the microsized light beam over the substrate in the presence of the suitable reactive gases. The species to be deposited is usually chemically encapsulated in a precursor gas with carbonyls or alkyl "backbones." Typical laser-driven deposition reactions are:

- Tungsten deposited by:

$$WF_6 + 3H_2 \rightarrow W + 6HF \quad \text{Reaction 9.1}$$

- Nickel deposited by:

$$Ni(CO)_4 \rightarrow Ni + 4CO \quad \text{Reaction 9.2}$$

- Silicon deposited by:

$$SiH_4 \rightarrow Si + 2H_2 \quad \text{Reaction 9.3}$$

Doped polysilicon lines with conductivities as low as 10^{-2}–10^{-3} Ω-cm may be obtained by adding PH_3 to the silane. Typical deposition rates are in the order of micrometers per second. By optimizing the process, very high deposition rates have been obtained in LCVD. For example, in the case

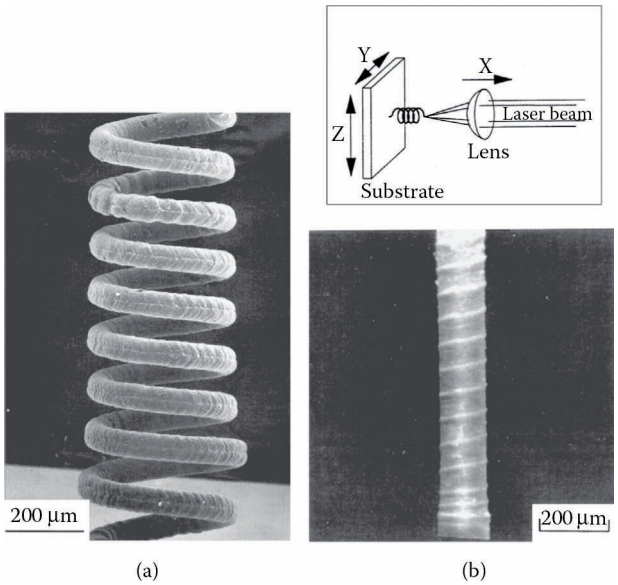

FIGURE 9.27 Examples of LCVD microfabricated shapes made by adjusting the focal point of a laser (tungsten helix) (a) and rotating goniometer (Si microsolenoid with tungsten helix) (b). [From Boman, M., H. Westberg, S. Johansson, and J.-Å. Schweitz. 1992. *Proceedings: IEEE micro electro mechanical systems (MEMS '92).* Travemunde, Germany: IEEE. With permission.[33]]

of silicon, deposition rates of 500 µm/s have been reported by using 100% SiH_4 at 1 atm, and the writing speed of tungsten on silicon substrates can exceed several centimeters per second.[33]

Not only "flat" lines but also more complex 3D structures such as fibers and springs can be grown by LCVD (Figure 9.27). This is accomplished by adjusting the focal point of the laser continuously by moving the substrate using a 3D linear micro-positioning system.[33] Microscale Si and boron rods and helical structures, freestanding tungsten coils, and a tungsten helix on a cylindrical silicon substrate (for a microsolenoid) have been demonstrated this way. For deposition of the tungsten helix on the Si rod, a rotating goniometer is used.

Table 9.2 lists examples of localized, electroless, and maskless laser depositions. Besides 2D and 3D writing patterns, there are two other site-specific actions that are possible by the laser irradiation technique: 1) the driving of dopants into semiconductor materials, and 2) the inducing of oxidation at a surface. Examples of the latter two laser machining applications are listed in Table 9.2 as well.

Selective Laser Sintering

Selective laser sintering (SLS®, registered trademark by DTM™ of Austin, TX) is a process that was patented in 1989 by Carl Deckard, a University of Texas graduate student.

SLS is an additive layered rapid manufacturing method that creates solid, 3D objects by using a high-power laser (for example, a carbon dioxide laser) to fuse small particles of plastic, metal, or ceramic powders into a mass representing a desired 3D object. A thin layer of powder material is laid down, and the laser "draws" on the layer, sintering together the particles hit by the laser. The layer is then lowered a small amount, and a new layer of powder is placed on top. This process is repeated one layer at a time until the part is complete. As shown

TABLE 9.2 Examples of Localized Laser Deposition, Doping, and Oxidation

Material Deposition		
Deposit	Precursor	Laser
Ti	$TiCl_4$	Ar^+
Ti/Al	$TiCl_4$, $Al(CH_3)_3$	Ar^+
Cr	$Cr(CO)_6$	Ar^+
Laser-induced doping		
Dopant/substrate or film	Precursor	Laser
B in Si	Evaporated B	Ruby
P in polysilicon	P-doped glass	N_2 dye
As in Si	AsH_3	XeCl
Laser oxidation of substrates		
Substrate	Oxide species	Laser
Ti	TiO_2	Nd:YAG
Zr	ZrO_2	CO_2

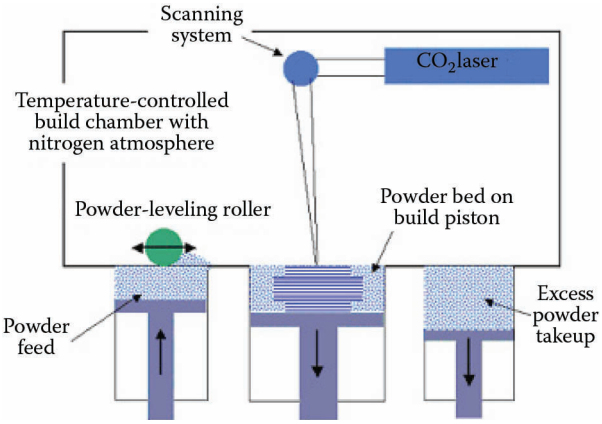

FIGURE 9.28 Selective laser sintering.

in Figure 9.28, an SLS machine consists of two powder magazines on either side of the work area. A leveling roller moves powder over from one magazine, crossing over the work area to the other magazine. The laser selectively fuses powdered material by scanning cross-sections generated from a 3D digital description of the part (for example, from a CAD file or scan data) on the surface of a powder bed. After each cross-section is scanned, the powder bed is lowered by one layer thickness; a new layer of material is applied on top; and the process is repeated until the part is completed.

The chief advantage of SLS over other RP methods such as stereolithography (SLA) revolves around material properties. Many materials are possible, and these materials can approximate the properties of thermoplastics such as polycarbonate, nylon, or glass-filled nylon.

A new RP method combines additive and subtractive techniques. The laser sintering/milling hybrid machine, the LUMEX 25C, developed by Matsuura Machinery Corporation, successfully combines free-form manufacturing and high-speed milling (see inset in the heading of this chapter). This is the world's first "metal laser modeling hybrid machining unit." The integration of laser sintering of metallic powder and high-speed cutting eliminates the finish machining operations. It layers a powder mixture (90% steel and 10% copper) over the part and then sinters it with a 300-W (500 W maximum) CO_2 laser. The edges of the part are milled after sintering five layers, with tolerances in the 25-µm range. For the generated part, a surface roughness of 15 µm can be obtained.

Conclusions

Additive laser machining presents several application opportunities in micromachining because of its versatility, site-specific operation, and RP capability. Ultrafast laser machining, when lasers become less expensive, will make laser micromachining yet more attractive. There are some obvious drawbacks with these direct write techniques; they are serial processes, and the deposition rate limits the speed of the micromanufacture. However, for RP, mold fabrication, and site-specific manufacturing, laser machining has a very bright future, and, as we have remarked before, some microsystems might carry a bigger price tag than an IC, making more expensive manufacturing technology acceptable.

Electron Beam Forming Processes: Electron Beam-Assisted CVD

Electron beam-induced metal deposition is a slow but flexible and versatile process for the fabrication of microstructures with high lateral accuracies. For example, using a precursor gas at a pressure of 2×10^{-2} mbar, W/C needles 0.2 µm in diameter have been deposited. The diameter of the needles is bigger than the electron beam diameter, which is less than 100 nm, because of electron scattering. To increase the growth rate, directing the precursor gas through a small nozzle onto the surface increases the local gas flow. The total gas flow needs to be kept below a maximum value to maintain the base pressure less than 10^{-5} mbar. For the deposition of other metals, numerous gases have been reported in the literature as precursors (mainly, for ion beam-induced deposition): $Al(CH_3)_3$ for Al, $C_7H_7O_2F_6Au$ for Au, and (methylcyclopentadienyl)trimethyl platinum for Pt.[34] A schematic of an electron beam fabrication setup is shown in Figure 9.29, along with an SEM photograph of W/C needles produced in this type of setup.[34] The deposition time of the needles shown was 1–2 min. Using the same type of technology, Matsui[35,36] demonstrated tips with a diameter of 15 nm for use in a tunneling microscope.

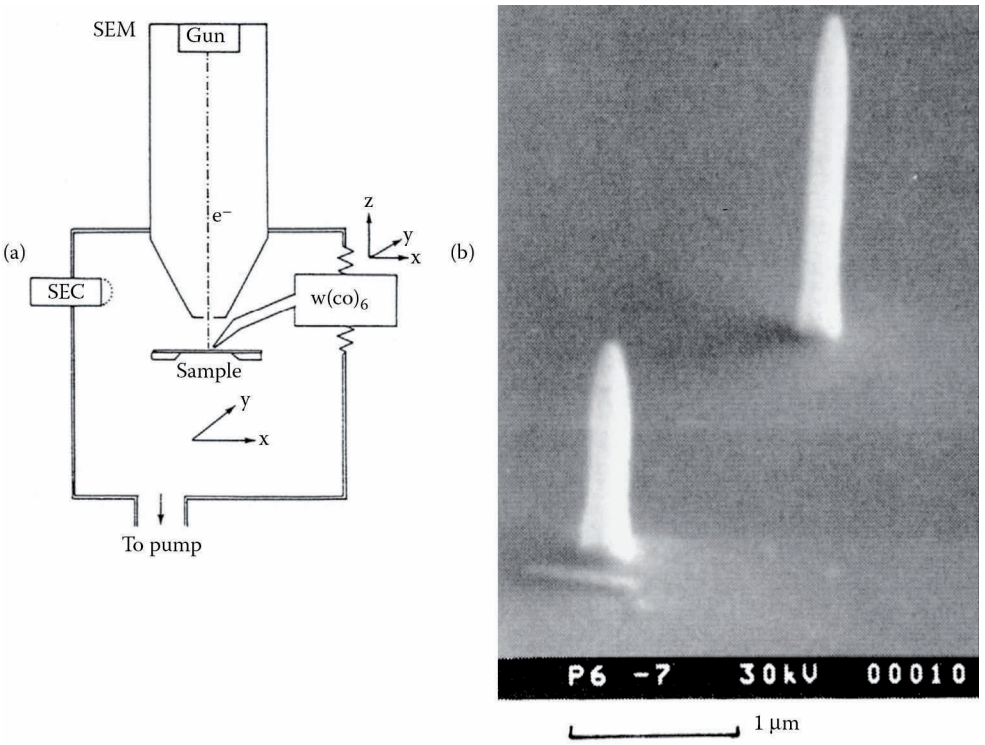

FIGURE 9.29 Electron beam machining setup (a) and example of an electron beam-formed W/C microstructure (b). [From Brunger, W. H., and K. T. Kohlmann. 1992. *Proceedings: IEEE micro electro mechanical systems (MEMS '92).* Travemunde, Germany: IEEE. With permission.[34]]

For processes such as controlled submicrometer repair of masks, focused ion beam-induced deposition appears to be the preferred technique, although both lasers[37,38] and electron beams[39] have been used as well.

Questions

Questions by Dr. Madou assisted by Mr. Omid Rohani, UC Irvine

9.1: Explain how salt-assisted spray pyrolysis (SASP) overcomes some of the limitations of traditional spray pyrolysis.

9.2: Explain the flame spray pyrolysis process. What are the advantages and disadvantages of using this method?

9.3: What are typical applications of thick film technology?

9.4: Suppose that you want to form a thin flat ceramic part with a large surface area and various holes and shapes cut into it. Which manufacturing method do you suggest for this purpose? Why?

9.5: Sketch a multilayer ceramic planar oxygen sensor. Explain how this sensor works.

9.6: What might the possible advantages be of plasma depositing (plasma spraying) sensor materials in the manufacture of chemical sensors?

9.7: Explain the plasma spray deposition manufacturing process briefly.

9.8: How do we get nanoparticles from plasma atoms?

9.9: Explain the selective laser sintering (SLS) process.

9.10: How do you convert your chemical vapor deposition (CVD) reactor into a reactor that produces nanoparticles?

9.11: Why does one need a pseudoplastic material to function as an ink in silk screening?

9.12: What is a doctor's blade, and where is it used?

9.13: Compare laser-assisted CVD (LCVD) with E-beam assisted CVD (ECVD).

9.14: Name some of the applications of TiO_2 powders.

Micromolding Techniques—LIGA

The Graduate, starring Dustin Hoffman, was released by Embassy Pictures in 1967. A memorable poolside scene from the movie:

Mr. McGuire:	*Come with me for a minute. I want to talk to you. I just want to say one word to you. Just one word.*
Ben:	*Yes, sir.*
Mr. McGuire:	*Are you listening?*
Ben:	*Yes sir, I am.*
Mr. McGuire:	**PLASTICS.**
Ben:	*Exactly how do you mean?*
Mr. McGuire:	*There is a great future in plastics. Think about it. Will you think about it?*
Ben:	*Yes I will.*

Introduction

A wide variety of micro- and nanofabrication techniques such as x-ray lithography (Chapter 2), computer numerical control (CNC) machining (Chapter 6), laser machining (Chapter 5), and many others are either too slow or too expensive for the mass production of inexpensive devices. This is where micromolding/replication technology comes into play because of its capacity for very large volume and inexpensive manufacture.[1]

A key example involving micromolding is LIGA, which, we learned in Chapter 2, is the German acronym for x-ray lithography (*x-ray lithographie*), electrodeposition (*galvanoformung*), and molding (*abformtechnik*). The process involves a thick layer of x-ray resist (from micrometers to centimeters), high-energy x-ray radiation exposure, and development to

arrive at a three-dimensional (3D) resist structure. Subsequent metal deposition fills the resist mold with a metal, and, after resist removal, a freestanding metal structure results.[2] The metal shape may be a final product or serve as a mold insert for precision plastic molding. Molded plastic parts may in turn be final products or lost molds (see Figure 2.9). The plastic mold retains the same shape, size, and form as the original resist structure but is produced quickly and inexpensively as part of an infinite loop. The plastic lost mold may generate metal parts in a second electroforming process or generate ceramic parts in a slip casting process.

The bandwidth of possible sizes in all three dimensions renders LIGA useful for manufacture of microstructures (micrometer and submicrometer dimensions) and packages for these microstructures (millimeter and centimeter dimensions), and even for the connectors from those packages to the "macro world" (e.g., electrical, through-vias or physical and gas, in- and outlets). Once LIGA was established in the research community, interest in other micro- and nanomolding/replication methods became more pronounced. Given the cost of the LIGA equipment, various LIGA-like (pseudo-LIGA) processes took center stage. These pseudo-LIGA methods involve micromolding/replication of masters created by alternate means such as deep reactive ion etching (DRIE) and novel deep ultraviolet (UV) thick photoresists (e.g., SU-8). This more generalized lithography and replication procedure is illustrated in Figure 10.1.

Micro- and nanofabrication of molds is reshaping manufacturing approaches for a wide variety of mass-produced small parts. Frequently, integrated circuit (IC)-based batch microfabrication methods are considered together with more traditional, serial machining methods. In this evolution, LIGA and pseudo-LIGA processes constitute "handshake-technologies," bridging IC and classical manufacturing technologies. The capacity of LIGA and pseudo-LIGA for creating a wide variety of shapes from different materials makes these methods akin to classical machining with the added benefit of unprecedented aspect ratios and absolute tolerances rendered possible by lithography or other high-precision mold fabrication techniques.

LIGA and LIGA-like processes can be used directly to fabricate prototype microdevices, but, for commercial-scale manufacture of microdevices, replication by molding from a LIGA or LIGA-like mold is required. If the feature sizes are larger than

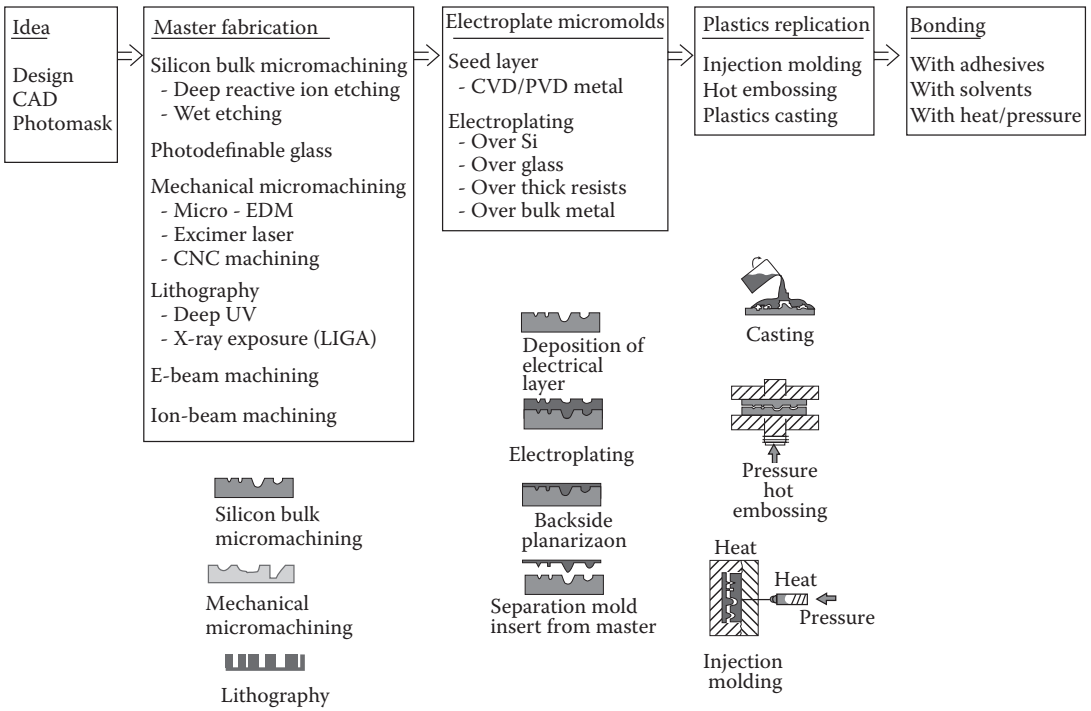

FIGURE 10.1 Process flow for plastic microfabrication.

50 μm and several levels of feature depths are involved, even CNC machining may be used to manufacture a prototype device. For example, in Figure 10.2, we show a CNC-machined plastic (polycarbonate) fluidic compact disc (CD) platform prototype. Compared with LIGA or LIGA-like processes, CNC machining does not provide as good a surface finish or dimensional control (see Chapter 6). However, it does not have any material limitation; various metals and plastics can be used. For feature sizes smaller than 50 μm (but larger than several micrometers), ultraprecision milling or laser ablation can be used. These prototype processes, just like LIGA and LIGA-like processes, are all intensive, slow, and costly, and for these microfabrication techniques to become economically viable, microstructures must be able to be replicated/micromolded successively, in an "infinite loop," without remaking the master mold. For example, in the plastic molding process, a metal structure produced by metal deposition serves as a mold insert and is used over and over without remaking the metal master. For mass-produced plastic devices, one of the following molding techniques is suitable: liquid resin molding, thermoplastic injection molding (IM), and compression (embossing/imprinting) molding. Our results of IM of a plastic fluidic platform, as shown in Figure 10.2, from a micromachined mold using pseudo-LIGA is shown in Figure 10.6.

In this chapter, we first review the most popular industrially available polymer molding techniques, and then, as examples that push the technology to its extremes, we detail LIGA and LIGA-like processes.

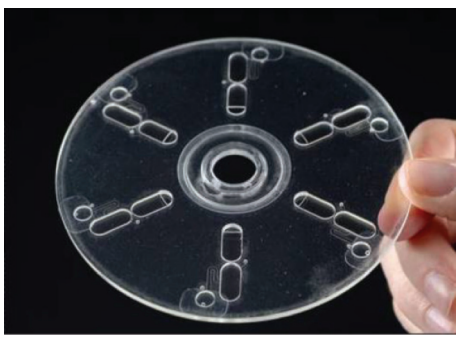

FIGURE 10.2 CNC-machined plastic lab CD platform: prototype cell disrupter disk, made from machined plastic disks and cut transfer adhesive films. (UCI and RotaPrep, Drs. Madou and Kido.)

The miniature features and the high-aspect ratios of the mold inserts generated from LIGA and LIGA-like methods present new problems compared with the molding and demolding processes of macrocomponents and compared with the production of small but low-aspect-ratio products such as CDs. A variety of the special processes developed to accommodate these new needs are reviewed. We start with a historical introduction to LIGA and analyze the process steps. The different applications and technical characteristics of x-rays from a synchrotron are discussed, and then we present an introduction to the crucial issues involved in making x-ray masks and their alignment for LIGA. This is followed by a treatise on LIGA substrate choice, resist requirements, exposure, development, electroplating, and finally molding. The electroplating and molding sections apply to LIGA and pseudo-LIGA approaches. The section on LIGA is followed by a review of competing mold fabrication techniques and a short treatise on ceramic molding.

Micromolding with an elastomeric mold (e.g., polydimethylsiloxane), or soft lithography, was reviewed in Chapter 2, where we stressed its low cost and convenience in research. Compared with other micromolding techniques reviewed in the current chapter, soft lithography is especially useful for thin microstructure fabrication.

Bonding of plastic molded microparts, including plastic welding, organic solvent bonding, and bonding with thermoset adhesives, is covered in Volume III, Chapter 4 in its discussion of packaging techniques.

Plastic Molding

Liquid Resin Molding Techniques

Introduction

Because mold inserts made by photolithography techniques are typically limited to rather soft metals like nickel or brittle materials such as silicon and glass, micromolding based on low-viscosity liquid resins (instead of high-viscosity polymer melts) is a very attractive approach. During liquid resin molding, the low-viscosity reactive polymer components are mixed shortly before injection into the mold

cavity, and polymerization takes place during the molding process. Under liquid resin molding techniques, we distinguish between reaction IM (RIM) and transfer molding.

Reaction Injection Molding and Transfer Molding

Two typical setups for RIM and transfer molding are shown in Figure 10.3a and b, respectively.[3] In the RIM setup shown in Figure 10.3a, two or more highly reactive liquid resins impinge and mix inside a mixer and are injected into the mold. In RIM, the polymerization is usually mixing activated; therefore, it can quickly react at room temperature or slightly above and convert from liquid to solid. The transfer molding setup in Figure 10.3b, for a thermally activated system, is simpler and less expensive. Here, the reactive species have been premixed at room temperature, and the mixture is poured into the "transfer pot." A plunger squeezes the mixture through the sprue into the mold cavity. To cure the mixture, the mold is heated or radiated, depending on the resin system. With the lowest viscosity resins, vacuum-assisted transfer molding is used, which is even less expensive than mechanical transfer molding.

Two complications associated with RIM are 1) an internal mold release agent must be used and 2) polymer shrinkage during polymerization. Release agents are added to the bulk polymer and tend to reduce the thermomechanical properties of the molded polymer. External mold release agents, coating the surfaces of the mold insert, are unsuitable because they are difficult to introduce into all the microfeatures of the mold insert. Because the resin must be fully cured at high temperatures, the cycle time is typically more than 10 min. Hanemann et al.[4] developed a photoinitiated RIM process by using the methylmethacrylate (MMA) resin. They found that the cycle time can be greatly reduced (to 2–3 min), but other disadvantages, such as internal mold release agent and polymerization shrinkage, still exist.

Summary: Pros and Cons of Liquid Resin Molding

The pros and cons of RIM are summarized in Table 10.1. Typical materials are optically clear reactive liquid resins, e.g., epoxies, urethanes, silicone rubbers, cross-linkable acrylics, and hydrogels.

Injection Molding

Introduction

Injection molding (IM) is based on heating a thermoplastic material until it melts, thermostatting the mold parts, injecting the melt with a controlled injection pressure into the mold cavity, and cooling the manufactured goods. IM is probably the most widely used technique in macroscopic production of polymer parts. Besides conventional IM, one variant of IM—a good candidate for microfabrication—is

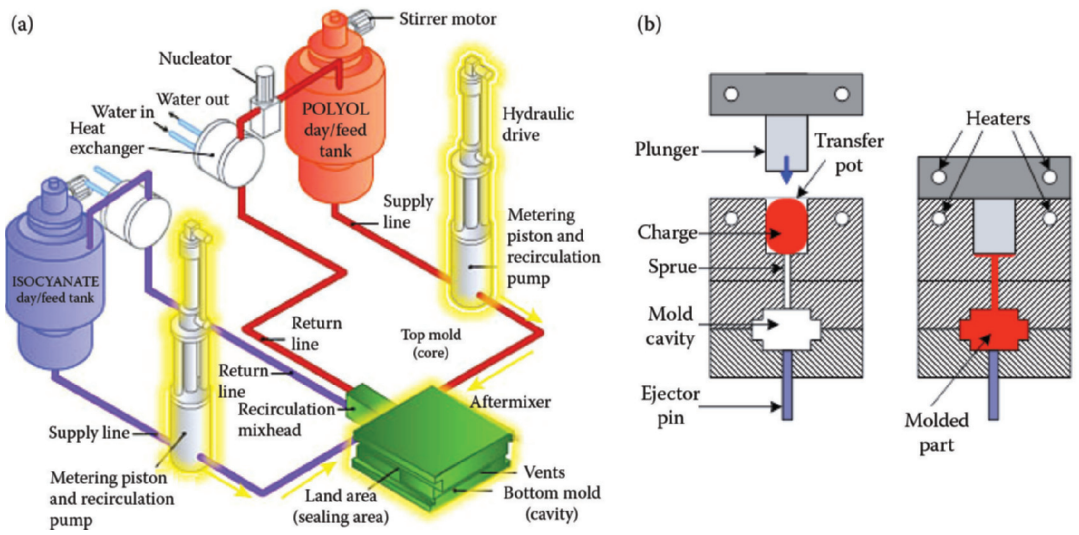

FIGURE 10.3 Two typical setups for RIM (a) and transfer molding or TM (b).

TABLE 10.1 Pros and Cons of Liquid Resin Molding

Pros	Cons
Ease of mold filling (low η)	Long cycle time (minutes, sometimes even hours)
Low stress on master (low η)	Polymerization shrinkage
High chemical and thermal resistance (because of the cross-linking)	Contamination (resin residue if the reaction is not 100%)
Replication extremely good for small, high-aspect ratio, and 3D features	Production cost medium to high

detailed here[3]: thin-wall IM. A typical injection compression molding setup is shown in Figure 10.4. The mold insert in IM, as in RIM, must have extremely smooth walls to be able to demold the plastic structures. Such smooth walls cannot be produced with a classical mold-making technique such as spark erosion. For some polymers, such as polymethylmethacrylate (PMMA), the polymer pellets need to be dried for 4–6 h at 70°C before use in IM because PMMA absorbs water in air (up to 0.3%), leading to poorer wall quality.

Conventional Injection Molding

In conventional IM of microparts, the mold remains closed, and the walls are kept at a uniform temperature above the glass transition temperature (T_g) of the polymer; thus, the injected molten plastic mass does not harden prematurely. To be able to fill very small mold features with aspect ratios higher than 10, the temperature of the tool holding the insertion mold should be higher than what is typically used in IM applications of parts with lower aspect ratios. However, one should stay well below the melting temperature (e.g., 170°C for PMMA with a melting temperature of 240°C) because the microstructure might show temperature-induced defects if one works at a temperature closer to the melting temperature.[5]

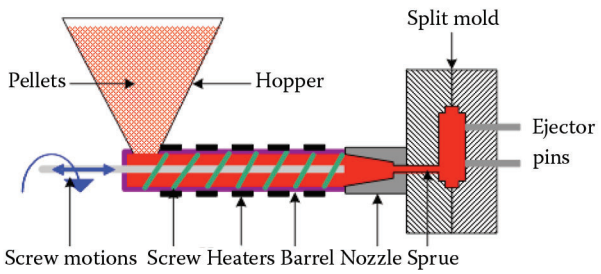

FIGURE 10.4 Typical injection molding setup.

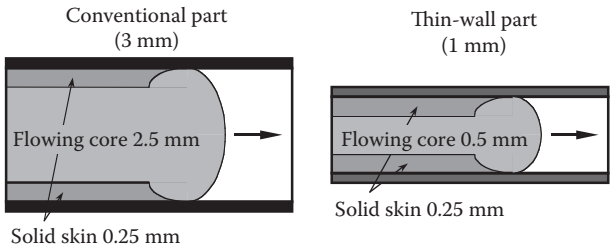

FIGURE 10.5 Schematics of solid skin buildup in conventional and thin-wall injection molding. (OSU, Drs. Madou and Lee.)

One of the most important factors for replication fidelity in IM is the thickness of the skin, which forms on the mold surface during filling of the cavity (see Figure 10.5).[3]

The injection pressure must penetrate this skin to replicate the shape of the master accurately. The faster the injection, the thinner this skin on the insert mold surfaces. The upper shapes of the master forming the bottom of the parts are usually perfectly formed. It is the bottom of the master and especially inner corners that cause problems. Because in conventional IM the mold is kept closed during the entire mold-filling process, high clamping forces on the mold parts are required, and the method is used for relatively thick substrates with high replication demands and low cost. Parts made this way often end up having high molded-in stresses.

Conventional thermoplastic IM is the technique used, for example, to make compact discs (CDs), involving features about 0.1 μm in depth and minimum lateral dimensions of 0.6 μm; that is, an aspect ratio of 0.16. CDs are made by IM of polycarbonate in a cavity formed between a mirror surface block and a stamper (i.e., mold or master). Conventionally, electroforming from a glass master generates nickel stampers. The principal attributes required of a stamper substrate are toughness, thermal shock resistance, thermal conductivity, and hardness. For IM in particular, toughness, thermal shock resistance, and thermal conductivity are critical. Thermal shock resistance is the product of a material's modulus of rupture or tensile strength and its thermal conductivity, divided by the product of its coefficient of thermal expansion and its modulus of elasticity. In Table 10.2, we compare some materials for their merit as stamper substrates. Ion machining is one of the methods that can be used to make mold

Table 10.2 Materials Selection for Stamper/Insert Mold Substrates

Substrate	Knoop Hardness (kg/mm^2)	Fracture Toughness ($MPa\ m^{1/2}$)	Thermal Shock Resistance (W/m)	Thermal Conductivity (W/m K)	Ion Machinability (Surface Quality)
Nickel	100	~100	7,138	80	Poor
Al_2O_3	2,100	4	3,225	30	Very good
SiC	2,500	3	19,149	90	Excellent
Glassy carbon	500	2	135,517	120	Excellent
Corning 9647 (glass)	450	1.3	546	2.5	Excellent

Source: Bifano, T. G., H. E. Fawcett, and P. A. Bierden. 1997. Precision manufacture of optical disc master stampers. *Precision Eng* 20: 53–62.[6]

inserts (see Figure 10.1 under Master fabrication), and surface quality after ion etching is also listed (ion machinability).

Nickel CD stampers are normally 138 mm in diameter and 0.3 mm thick with an average roughness less than 10 nm. For ceramic stampers, a thickness of 0.9 mm is chosen to avoid fracture in IM. Typical conditions for IM are summarized in Table 10.3.

IM of parts with small features and low-aspect ratios (e.g., CDs) have been widely applied. The main challenge in microelectromechanical system (MEMS) and nanoelectromechanical system (NEMS) replication attempts is to extend this technique to the fabrication of components with the same small feature size but much larger aspect ratios, as needed in many medical and biochemical applications (see later discussions of LIGA and pseudo-LIGA).

Thin-Wall Injection Molding

Thin-wall IM is basically high-speed IM.[3,7] Speeds can be 10 times faster than in conventional IM, reducing the thickness of the polymer skin on the mold (see Figure 10.5). The polymer melt can quickly be injected into the mold to fill all the detail structure of the cavity before solidification occurs.

In our own thin-wall IM experiments for replication of BioMEMS devices, such as the fluidic CD (about 1 mm thick)[3,8] shown in Figure 10.6, we have used a Sumitomo 200-ton high-pressure and high-speed machine.[7] Only at injection speeds of 50 mm/s or higher does the quality of the replication become adequate. A birefringence technique was used to qualitatively examine the stress in the polymer parts as demonstrated in Figure 10.7. Samples showing sharp color contrast have large molded-in stresses. At the lower flow rates the residual stress is higher because, during the flow, the polymer has been stretched and solidified, meaning that there is a lot of flow-induced stress. Increasing the flow

rate decreases the amount of residual stress because the polymer can quickly fill in the mold and relax before solidification occurs. Nevertheless, there is some remaining stress that may cause warpage or less chemical resistance. By comparison, in casting there is essentially no flow: it is stress free.

A comparison of sample birefringence from different replication methods is given in Figure 10.8.[3] One observes that reactive casting with an epoxy resin causes the least amount of residual stress (least sharp color contrasts).

Another example of thin-walled structures made with thin-wall IM is shown in Figure 10.9. High injection speed is needed to completely fill the mold cavities for a thin-wall relay case (0.45 mm thick, flow length is 50.4 mm).

Injection Molding Equipment

For manufacturing MEMS structures, conventional IM machines used for CD fabrication are expanded with special features for the molding of microsized parts or parts with high-aspect ratio. The IM machine periphery then includes a vacuum unit for the evacuation of the split mold cavity and a precise temperature control unit. It is desirable to use one temperature control cycle on each surface of the split mold (see Figure 10.4). The flow temperatures are adapted to the respective half of the tool or to the molding and demolding process cycle to achieve a relatively short overall cycle time and a homogeneous tool temperature. To keep the cycle time as short as possible, the thermal mass of the tool sections to be heated is minimized and

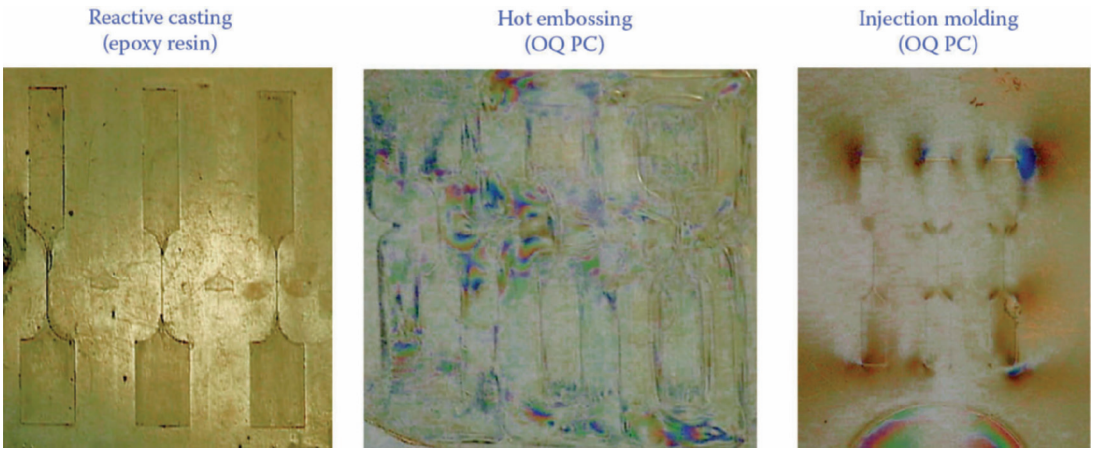

FIGURE 10.8 Comparison of birefringence patterns of microfluidic platforms made by different replication methods. (From Lee, L. J., C.-H. Shih, Y.-J. Juang, J. Garcia, M. J. Madou, and K. W. thermally insulated from the adjacent assemblies. The guiding mechanisms of the tool halves and the ejector system may not be fitted too loosely because small transverse movements might damage the microstructures during demolding. The machines and tools to be evacuated have to comply with tolerances in the micrometer range.[9] Demolding of the microstructures takes place by means of ejector pins, which are located on the sole of the mold tool, the guiding mechanism, or directly at extremities of the microstructure.[9] Under laboratory conditions, the microstructures are removed manually. In small series production, a handling robot is used. It may be equipped with a feed picker. In addition, the machines used for small series and mass production are provided with a granulate drying, supply, and metering system such that fully automatic molding in personnel-free shifts is possible.[10]

Commercial IM machines designed for microsized parts or parts with microsized features are available from Battenfeld (http://www.battenfeld.de), Boy Machines (http://www.dr-boy.de/rightmachine.htm), Engel (http://www.engel.at), Ferromatik Milacron (http://www.ferromatik.com), Murray (http://www.murrayeng.com), and Nissei (http://www.nisseiamerica.com). Figure 10.10 shows a photograph of Battenfeld's Microsystem 50.

Summary: Pros and Cons of Injection Molding

Pros and cons of IM are summarized in Table 10.4. Example materials in IM include polycarbonate (PC), polymethylmethacrylate (PMMA), polystyrene (PS), polyvinylchloride (PVC), polypropylene (PP), polyethylene (PE), and polyacrylnitrilbutadienstyrol (ABS).

Compression Molding (Also Relief Imprinting or Hot Embossing)

Introduction

The basic principle of compression molding (also *hot embossing* and *relief imprinting*) is that a polymer substrate is first heated above its glass transition temperature, T_g (or softening temperature). A mold (or master) is then pressed against the substrate, fully transferring the pattern onto it (embossing). After a certain time of contact between the mold and the substrate, the system is cooled down below T_g, followed by separation of the mold and the substrate (de-embossing). Importantly, the hot embossing process can be achieved in either a cyclic process or a continuous process. Compression molding[11,12] provides several advantages compared with IM, such as relatively low costs for embossing tools, simple process, and high replication accuracy for small features.

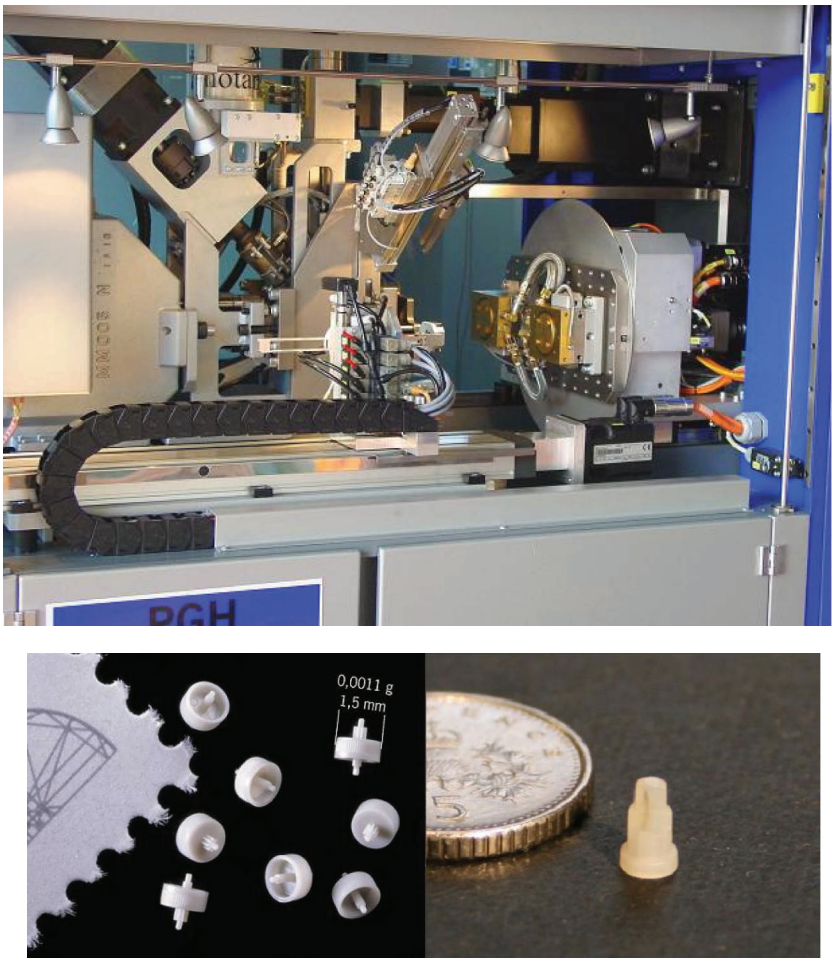

FIGURE 10.10 (a) Detail of the Battenfeld Microsystem 50 IM machine. (b) Examples of micromolded components with microfeatures.

A typical setup for cyclic and continuous embossing is shown in Figure 10.11a and Figure 10.11b, respectively.[3] In a cyclic process (Figure 10.11a), a metal master is put in a hydraulic press, and applying the appropriate force, thus replicating the structure from the master to the polymer, stamps a heated polymer sheet. This constitutes a low-cost method for making prototypes. For mass production, a continuous process is preferred (Figure 10.11b). Here, a polymer sheet stretches through a temperature chamber, and several masters, mounted on a conveyor belt, continuously produce parts. The process also may incorporate a lamination station to enclose certain features. This continuous-type process is very much in keeping with a vision for continuous manufacture of MEMS and NEMS devices.

TABLE 10.4 Pros and Cons of Injection Molding

Pros	Cons
Good for small structures with low aspect ratio, e.g., CD and DVD	Only low-molecular-weight polymers (may reduce mechanical and thermal strength)
Good for large, high-aspect ratio, and 3D features	More expensive equipment
Excellent dimensional control	Cyclic process only
Short cycle time (as low as 10 s)	High stress on master
High productivity	High residual stresses on molded parts
Closed mold process enables packing pressure application	

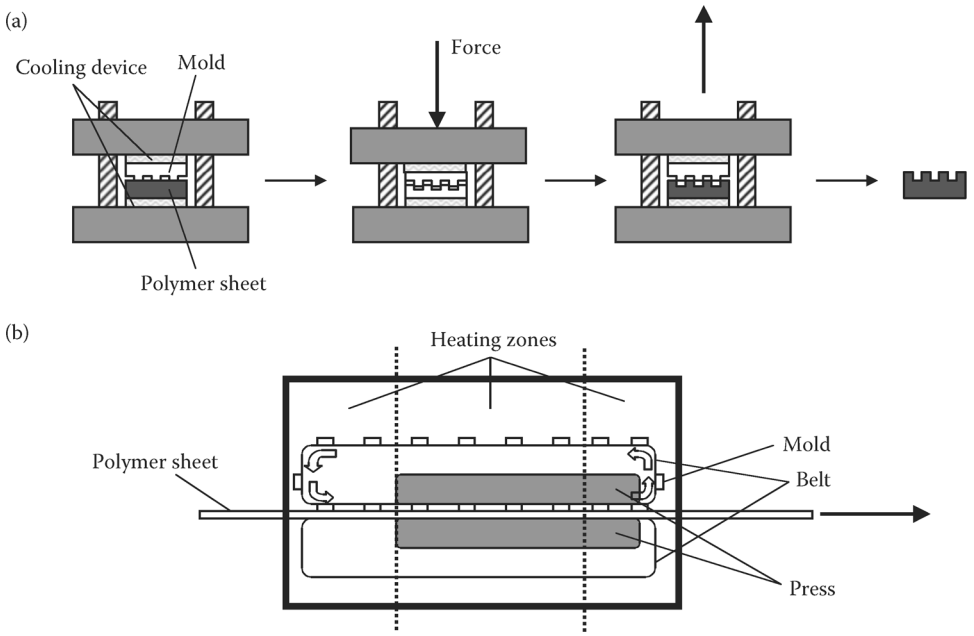

FIGURE 10.11 Schematic of cyclic (a) and continuous (b) embossing processes. (From Lee, L. J., C.-H. Shih, Y.-J. Juang, J. Garcia, M. J. Madou, and K. W. Koelling. 1999. *Novel microfabrication options for BioMEMS conference.* San Francisco: The Knowledge Foundation.[3])

Hot Embossing

As seen from Figure 10.11a, hot embossing takes place in a machine frame similar to that of a press. The force frame delivers the embossing force—on the order of 5–20 tons. An upper boss holds the molding tool, and the lower boss holds the substrate. Processing parameters include thermal cycle, compression force, and compression speed. The temperature difference between embossing and de-embossing determines the thermal cycle time, typically from 25–40°C. In principle, one could, after hot embossing, cool down the whole device to room temperature before de-embossing, or, at the other extreme, one could de-emboss just below or at the glass-transition temperature. A compromise is needed; the quality of the replication may not be good if one tries to remove the master when the polymer is still soft, whereas cooling all the way down to room temperature takes too long. A small temperature cycle leads to smaller induced thermal stress. Such a smaller temperature cycle also reduces replication errors as a result of different thermal expansion coefficients of tool and substrate. By actively heating and cooling the upper and lower bosses, one gets cycle times of about 5 min. A vacuum for hot embossing ensures longer lifetime for the mold, absorbs any water released during the embossing process from the polymer material, and prevents bubbles from entrapped gases. A Jenoptik hot embossing machine is shown in Figure 10.12.

Replication of micro- and nanosized structures has been successfully achieved using hot embossing.[12–18] Adding an antiadhesive film to reduce the interaction between the mold and the replica during embossing

FIGURE 10.12 JENOPTIK HEX 04 hot embossing system manufactured by Jenoptik Mikrotechnik GmbH (http://www.jenoptik.com).

Table 10.5 Pros and Cons of Compression Molding (Imprinting or Hot Embossing)

Pros	Cons
Low polymer flow	More difficult for structures with high-aspect ratio (near T_g processing)
High-molecular-weight polymers (with better mechanical and thermal properties)	Less dimensional control (open mold process)
Simple process	Planar features only
Continuous or cyclic (see Figure 10.7)	High residual stresses on molded parts
Good for small structures	Difficult for large parts and multiple feature depth (too high a pressure and temperature are required)

has also been studied.[19,20] Instead of the conventional nickel molds, the possibility of using silicon molds because of their excellent surface quality and easy mold release has been demonstrated.[21,22] Also, the use of a plastic mold in the embossing process was recently illustrated.[23]

At the Kernforschungszentrum Karlsruhe, or KfK, hot embossing is mainly used for small series production, whereas IM is applied to mass production.

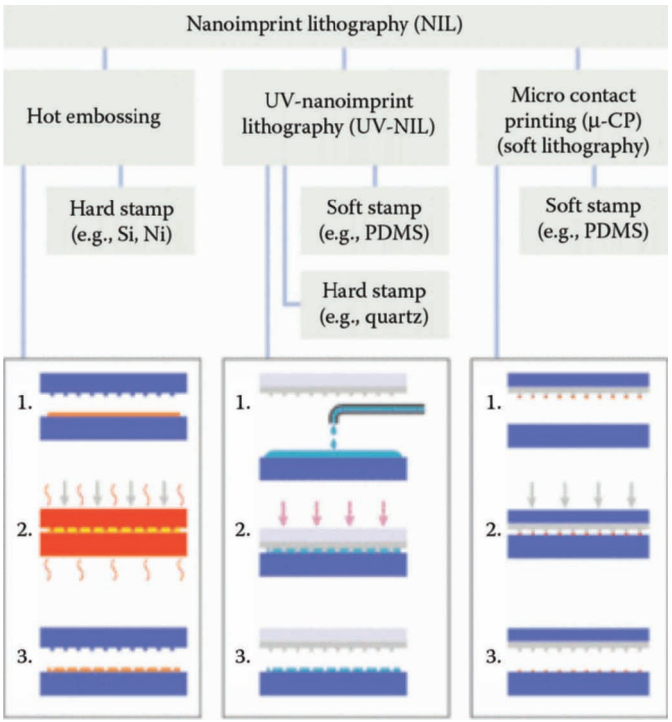

FIGURE 10.13 Nanoimprint lithography (NIL). Comparison of hot embossing with UV-nanoimprint lithography and microcontact printing.

Both techniques are applied to amorphous (PMMA, PC, PSU) and semicrystalline thermoplastics (POM, PA, PVDF, PFA). RIM is used for molding of thermoplastics (PMMA, PA), duroplastics (PMMA, epoxide), or elastomers (silicones).[24]

Summary: Pros and Cons of Compression Molding

Pros and cons of compression molding are summarized in Table 10.5. In Figure 10.13 we compare hot embossing with UV-nanoimprint lithography (see Chapter 2) and microcontact printing (soft lithography, Chapter 2). These techniques can all be grouped under nanoimprint lithography (NIL).

LIGA—Background

History

LIGA combines the sacrificial wax molding method, known since the time of the Egyptians, with x-ray lithography and electrodeposition. Combining electrodeposition and x-ray lithography was first carried out by Romankiw and coworkers at IBM as early as 1975.[25] These authors made high-aspect-ratio metal structures by plating gold in x-ray-defined resist patterns of up to 20 μm thick. They had, in other words, already invented "LIG"; that is, LIGA without the *abformung* (molding).[25] This IBM work was an extension of through-mask plating, also pioneered by Romankiw et al. in 1969, and was geared toward the fabrication of thin film magnetic recording heads (see Figure 2.4a).[26] The addition of plastic molding to the lithography and plating process was realized by Ehrfeld et al.[27] at the Kernforschungszentrum Karlsruhe (KfK) in 1982. By adding molding, these pioneers recognized the broader implications of LIGA as a new means of low-cost manufacturing of a wide variety of microparts with unprecedented accuracies from various materials previously impossible to batch fabricate.[27] In Germany, LIGA originally developed almost completely outside of the semiconductor industry. In the United States, it was the late Henry Guckel who, starting in 1988, repositioned the field in light of semiconductor process capabilities and brought it closer to standard manufacturing processes.

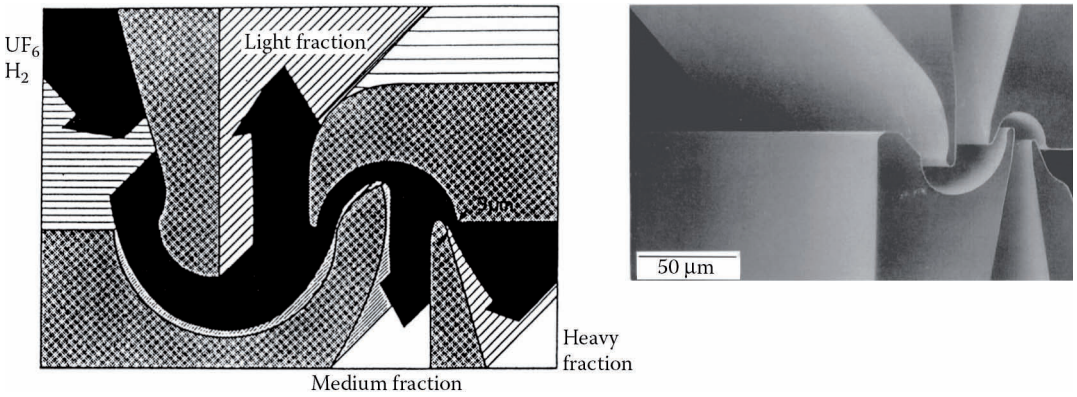

FIGURE 10.14 Schematic and scanning electron micrograph of a separation nozzle structure produced by electroforming with nickel using a micromolded PMMA template. This nozzle represents the first product ever made by LIGA. (From Hagmann, P., W. Ehrfeld, and H. Vollmer. 1987. *First meeting of the European Polymer Federation, European symposium on polymeric materials.* Lyon, France. http://opac.fzk.de:81/de/oai_frm.html?titlenr=24694&server=//127.0.0.1&port=81; Archiv *KAROLA–OA–Volltextserver_des_Forschungszentrums Karlsruhe* (Germany). With permission.[28])

The development of the LIGA process initiated at KfK was intended for the mass production of micrometer-sized nozzles for uranium-235 enrichment (see Figure 10.14).[27] The German group used synchrotron radiation from a 2.5-GeV storage ring for the exposure of the poly(methylmethacrylate) (PMMA) resist.

Today LIGA and especially LIGA-like processes are researched in many laboratories around the world, and developing the ideal means for fabricating micromolds for the large-scale production of precise micromachines remains an elusive holy grail. In LIGA, mold inserts are made via x-ray lithography, but, depending on the dimensions of the microparts, the accuracy requirements, and the fabrication costs, mold inserts may also be realized by electron beam (e-beam) writing, computer numerically controlled (CNC) machining, wet Si bulk micromachining, deep UV resists, deep reactive ion etching (DRIE), ultrasonic cutting, excimer laser ablation, electrical discharge machining (EDM), and laser cutting (see Figure 10.1).

Synchrotron Orbital Radiation

Introduction

Lithography based on synchrotron radiation, also called *synchrotron orbital radiation* (SOR), is primarily pursued with the aim of adopting the technology as an industrial tool for the large-scale manufacture of microelectronic circuits with characteristic dimensions in the submicrometer range (see Chapter 2).[29,30] Synchrotron radiation sources "outshine" electron impact and plasmas sources for generating x-rays. They emit a much higher flux of usable collimated x-rays, thereby allowing shorter exposure times and larger throughputs. Pros and cons of x-ray radiation for lithography in IC manufacture are summarized in Table 10.6.

Despite the many promising features of x-ray lithography, the technique today lacks mainstream acceptance in the IC industry, and continued improvements in optical lithography outpace the industrial use of x-ray lithography for IC applications. However, its use for prototype development on small product runs will no doubt continue its course. In 1991, experts projected that x-ray lithography would be in use by 1995 for 64-Mb dynamic random

TABLE 10.6 Pros and Cons of SOR X-Ray Lithography for IC Manufacture

Pros	Cons
Lithography process insensitive to resist thickness, exposure time, development time (large DOF)	Resist not very sensitive (not too important because of the intense light source)
Absence of backscattering results in insensitivity to substrate type, reflectivity and topography, pattern geometry and proximity, dust and contamination	Masks very difficult and expensive to make
High resolution, <0.2 µm	Very high start-up investment
Some have suggested high throughput	Not proven as a system Radiation effects on SiO_2

access memory (DRAM) manufacture with critical dimensions around 0.3–0.4 μm. With more certainty, they projected that the transition to x-rays would occur with the 0.2–0.3-μm critical dimensions of 256-Mb DRAMs, which came online by 1998.[29] Both dates obviously passed without materialization of the wide-scale industrial use of x-rays.

In addition to being an option for the next-generation IC lithography as discussed in more detail in Chapter 2, x-rays are also used in the fabrication of 3D microstructures. In LIGA, synchrotron radiation is used in the lithography step only. However, other micromachining applications for SOR exist. Urisu and his colleagues, for example, explored the use of synchrotron radiation for radiation-excited chemical vapor deposition and etching.[31] Micromachinists are hoping to piggyback x-ray lithography research and development efforts for the fabrication of micromachines onto major IC projects. Today the use of x-ray lithography for fabricating microdevices, other than ICs, does not present a large business opportunity by itself. Not having a major IC product line associated with x-ray lithography makes it extra hard to justify the use of x-ray lithography for micromachining, especially because other, less-expensive micromachining technologies are only very recently starting to open up the type of mass markets one is used to in the IC world. The fact that the x-rays used in LIGA are shorter wavelength than in the IC application (2–10 Å vs. 20–50 Å) also puts micromachinists at a disadvantage. For example, soft x-rays in the IC industry may eventually be generated from a much less-expensive source, such as a transition radiation source.[32] Also, nontraditional IC materials are frequently used in LIGA. The fabrication of x-ray masks poses more difficulties than masks for IC applications. Rotation and slanting of the x-ray masks to craft nonvertical walls further differentiate LIGA exposure stations. All these factors make exploring LIGA a challenge. However, given sufficient research and development money, large markets are likely to emerge in the next 10 years. These markets could be in the manufacture of devices with stringent requirements imposed on resolution, aspect ratio, structural height, and parallelism of structural walls. Optical applications for the information technology field seem particularly attractive early product targets.

Thus far, it is the research community that has primarily benefited from the availability of SOR photon sources. With its continuously tunable radiation across a very wide photon range, highly polarized, and directed into a narrow beam, SOR provides a powerful probe of atomic and molecular resonances. Other types of photon sources prove unsatisfactory for these applications in terms of intensity or energy spread. As can be concluded from Table 10.7, applications of SOR beyond lithography range from structural and chemical analysis to microscopy, angiography, and even to the preparation of new materials.

Table 10.7 SOR Applications

Synchrotron Radiation: Technical Aspects

Some important concepts associated with synchrotron radiation (such as the bending radius of the synchrotron magnet, magnetic field strength, beam current, critical wavelength, and total radiated power) require introduction. Figure 10.15 presents a schematic of an x-ray exposure station. Electrons are injected into the ring, where they are maintained at energies anywhere from 10^6–10^9 eV. The cone of radiation shown in this figure is the electromagnetic radiation emitted by the circling electrons as a result of the radial acceleration that keeps them in the orbit of the electron synchrotron or storage ring. For high-energy particle studies, this radiation, emitted tangentially to the circular electron path (*Bremsstrahlung*[*]), limits the maximum energy the electrons can attain. Bremsstrahlung is a nuisance for studies of the composition of the atomic nucleus in which high-energy particles are smashed into the nucleus. To minimize the Bremsstrahlung, physicists desire ever bigger synchrotrons.[†] The energy lost in the emission process is made up in a radiofrequency (RF) cavity, where electrons are accelerated back up to the storage ring energy. Injection of electrons must be repeated a few times a day because the electron current slowly decays as a result of leakage. For x-ray lithography applications, electrical engineers want to maximize the x-ray emission and build small synchrotrons instead (e.g., the radius of curvature for a compact, superconducting synchrotron is 2 m). The operating cost of these magnets is primarily that of the liquid helium refrigeration. Once high-T_c (critical temperature, the temperature at which the resistance falls to zero) superconducting materials can be made in bulk, compact storage rings will become very attractive. The angular opening of the radiation cone in Figure 10.15 is determined by the electron energy, E, and is given by:

$$\theta \approx \frac{mc^2}{E} = \frac{0.5}{E(\text{GeV})}(\text{mrad}) \qquad (10.1)$$

The x-ray light bundle with the cone opening, θ, describes a horizontal line on an intersecting substrate because the x-ray bundle is tangent to the circular electron path. In the vertical direction, the intensity of the beam exhibits a Gaussian distribution, and the vertical exposed height on the intersecting substrate can be calculated knowing θ and R, the distance from the radiation point, P, to the substrate. With E = 1 GeV, θ = 1 mrad, and R = 10 m, the exposed area in the vertical direction measures about 0.5 cm. To expose a substrate homogeneously over a wider vertical range, the sample is moved vertically through the irradiation band with a precision scanner, for example, at a speed of 10 mm/s over a

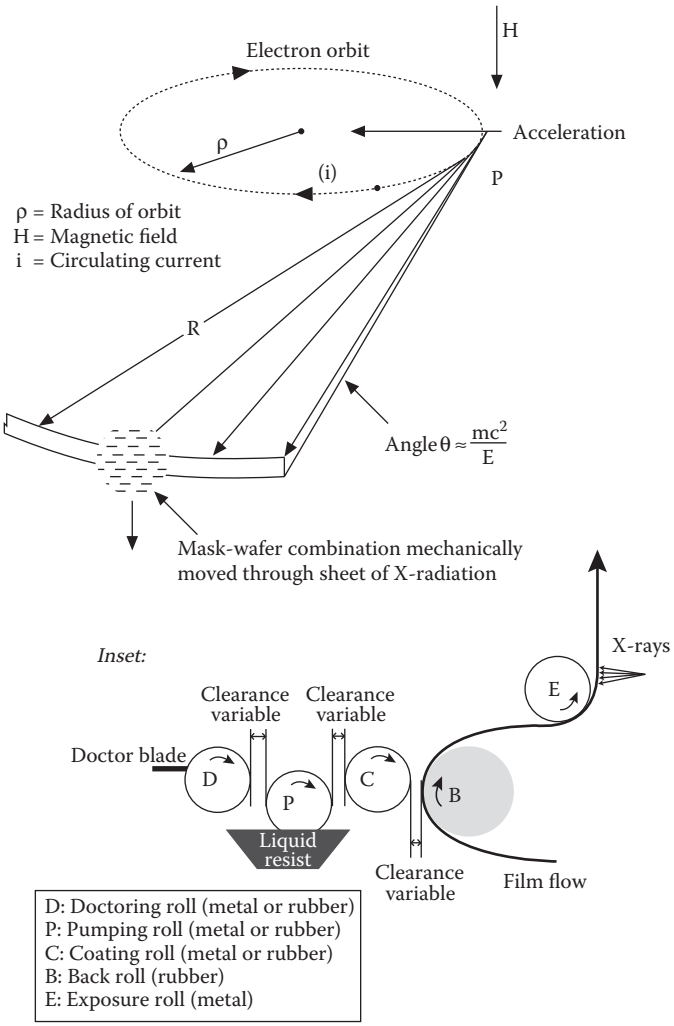

FIGURE 10.15 Schematic of an x-ray exposure station with a synchrotron radiation source. The x-ray radiation cone (opening θ) is tangential to the electron's path, describing a line on an intersecting substrate. Inset, a vision for the future of x-ray lithography: continuous micromanufacturing.

[*] German for "braking radiation."

[†] The Superconducting Super Collider Laboratory (SSCL or SSC for short), which was never finished, was to be an oval-shaped accelerator, the circumference of which would have been 54 miles. The collider oval was to be located about 200 ft. underground and would have surrounded the city of Waxahachie, Texas.

100-mm scanning distance. Usually, the substrate is stepped up and down repeatedly until the desired x-ray dose is obtained. It is interesting to note that an SOR setup affords continuous lithography, a prospect, this author believes, that will make disposable ICs and MEMS and NEMS a possibility. Rolls of dry x-ray photoresist or x-ray photoresist covered metal foils could pass through the exposure beam, resulting in a continuous lithography process, that is, a "beyond batch" type of approach (see Figure 10.15, inset).

The electron energy E in Equation 10.1 is given by:

$$E(GeV) = 0.29979\ B(Tesla)\ \rho\ (meters) \quad (10.2)$$

with B the magnetic field and ρ the radius of the circular path of the electrons in the synchrotron.

The total radiated power can be calculated from the energy loss of the electrons per turn and is given by:

$$P(kW) = \frac{88.47E^4 i}{\rho} \quad (10.3)$$

with i the beam current.

The emission of the synchrotron electrons is a broad spectrum without characteristic peaks or line enhancements, and its distribution extends from the microwave region through the infrared, visible, ultraviolet (UV), and into the x-ray region. The critical wavelength, λ_c, is defined so that the total radiated power at lower wavelengths equals the radiated power at higher wavelengths, and is given by:

$$\lambda_c = \frac{5.59\rho(m)}{E^3(GeV)} \quad (10.4)$$

Equation 10.3 shows that the total radiated power increases with the fourth power of the electron energy. From Equation 10.4, we appreciate that the spectrum shifts toward shorter wavelengths with the third power of the electron energy.

The dose variation absorbed in the top versus the bottom of an x-ray resist should be kept small so that the top layer does not deteriorate before the bottom layers are sufficiently exposed. Because the depth of penetration increases with decreasing wavelength, synchrotron radiation of very short wavelengths is needed to pattern thick resist layers. To obtain good aspect ratios in LIGA structures, the critical wavelength ideally should be 2 Å. Bley et al.,[34] at KfK, designed a new synchrotron optimized for LIGA. They proposed a magnetic flux density, B, of 1.6285 T; a nominal energy, E, of 2.3923 GeV; and a bending radius, ρ, of 4.9 m. With those parameters, Equation 10.4 results in the desired λ_c of 2 Å and an opening angle of radiation, based on Equation 10.1, of 0.2 mrad (in practice this angle will be closer to 0.3 mrad because of e-beam emittance).

The x-rays traveling from the ring to the sample site are held in a high vacuum. The sample itself is either kept in air or in a helium atmosphere. The inert atmosphere prevents corrosion of the exposure chamber, mask, and sample by reactive oxygen species, and removal of heat is much faster than in air (the heat conductivity of He is high compared with air). In He, the x-ray intensity loss is also 500 times less than in air. A Be window separates the high vacuum from the inert atmosphere. For wavelengths shorter than 1 nm, Be is very transparent—that is, an excellent x-ray window. A 25-µm-thick Be window can withstand a 1-atm pressure differential across a small diameter (<1 in.). For large area exposures, windows up to 6-cm diameter have been developed. Be windows age with x-ray exposure and must be replaced periodically.

Access to the Technology

Today, the construction cost for a typical synchrotron totals more than $30 million, restricting the access to LIGA. Obviously, a less-expensive alternative for generating intense x-rays is preferred. Along this line, in Japan, Ishikawajima-Harima Heavy Industries (IHI) is building compact synchrotron x-ray sources (e.g., an 800-MeV synchrotron of about 30 ft./side) (http://www.ihi.co.jp).

By the end of 1993, eight nonprivately owned synchrotrons were in use in the United States. The first privately owned synchrotron was put into service in 1991 at IBM's Advanced Semiconductor Technology Center (East Fishkill, NY). Table 10.8 lists the eight US synchrotron facilities.

Most of the facilities listed in Table 10.8 allow LIGA work to continue. For example, Cronos Integrated Microsystems, Inc., a JDS Uniphase Company and a spinoff from MCNC (Research Triangle Park, NC),

Table 10.8 Access to Synchrotron Radiation Is or Will Soon Be Available at the Following Facilities in the United States

Facility	Institute	URL
Advanced Photon Source (APS)	Argonne National Laboratory	http://www.aps.anl.gov

Synchrotron Radiation Center (SRC)	University of Wisconsin, Madison	http://www.src.wisc.edu
Center for Advanced Microstructures and Devices (CAMD)	Louisiana State University	http://www.camd.lsu.edu
Advanced Light Source (ALS)	Lawrence Berkeley Laboratory	http://www-als.lbl.gov

in collaboration with the University of Wisconsin, Madison, announced its first multiuser LIGA process sponsored by Advanced Research Projects Agency in September 1993 (http://www.memsrus.com). CAMD, at Louisiana State University, has three beam lines exclusively dedicated to micromachining work, and the Advanced Light Source at Berkeley has one beam line available for micromachining.

Like Cronos, Forschungszentrum Karlsruhe GmbH offers a multiuser LIGA service (LEMA, or LIGA experiment for multiple applications). The commercial exploitation of LIGA is pursued by at least three German organizations: microParts GmbH STEAG (http://www.microparts.de), IMM (http://www.imm.uni-mainz.de), and Forschungszentrum Karlsruhe, or KfK (http://www.fzk.de). In the United States, Louisiana State University's CAMD (http://www.camd.lsu.edu; Baton Rouge, LA) with its spinoff Mezzo Systems, Inc., founded in 2000, (http://www.mezzosystems.com) is leading the way.

LIGA and LIGA-Like Process Steps

X-Ray Masks

Introduction

With reference to Figure 10.16 we now detail each of the steps in the LIGA process.

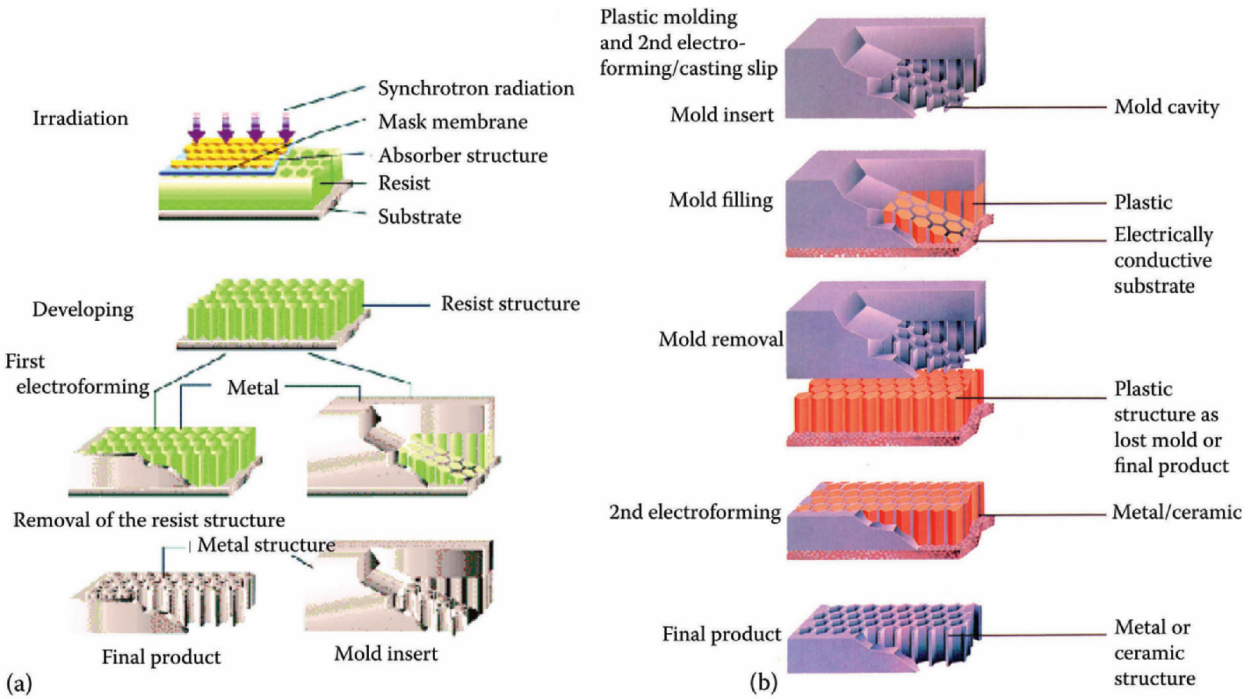

FIGURE 10.16 (a) Basic LIGA process step: x-ray deep-etch lithography and first electroforming. (b) Plastic molding and second electroforming/slip casting.

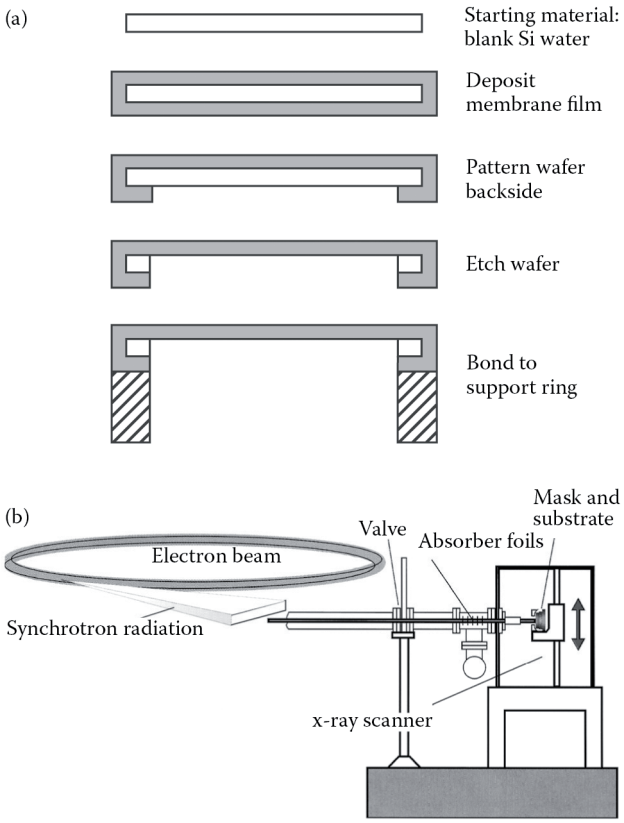

FIGURE 10.17 Schematic of a typical x-ray mask (a) and mask and substrate assembly in an x-ray scanner (b). [(b) from IMM, http://www.imm-mainz.de/. 1995. Commercial brochure. With permission.[2]]

X-ray mask production is one of the most difficult aspects of x-ray lithography. To be highly transmissive to x-rays, the mask substrate by necessity must be a low Z (atomic number) thin membrane. X-ray masks should withstand many exposures without distortion, be alignable with respect to the sample, and be rugged. A possible x-ray mask architecture and its assembly with a substrate in an x-ray scanner are shown in Figure 10.17. The mask shown here has three major components: an absorber, a membrane or mask blank, and a frame. The absorber contains the information to be imaged onto the resist. It is made up of a material with a high atomic number (Z), often Au, patterned onto a membrane material with a low Z. The high-Z material absorbs x-rays, whereas the low-Z material transmits x-rays. The frame lends robustness to the membrane/absorber assembly so that the whole can be handled confidently.

The requirements for x-ray masks in LIGA differ substantially from those for the IC industry. A comparison is presented in Table 10.9.[35] The main difference lies in the absorber thickness. To achieve a high contrast (>200), very thick absorbers (>10 μm vs. 1 μm) and highly transparent mask blanks (transparency >80%) must be used because of the low x-ray resist sensitivity and the great depth of the resist. Another difference focuses on the radiation stability of membrane and absorber. For conventional optical lithography, the supporting substrate is a relatively thick, optically flat piece of glass or quartz highly transparent to optical wavelengths. It provides a highly stable (>10^6 μm) basis for the thin (0.1 μm) chrome absorber pattern. In contrast, the x-ray mask consists of a very thin membrane (2–4 μm) of low-Z material carrying a high-Z thick absorber pattern.[36] A single exposure in LIGA results in an exposure dose 100 times higher than in the IC case.

We will look into these different mask aspects separately before detailing a process with the potential of obviating the need for a separate x-ray mask altogether, that is, through the use of conformal or transfer masks.

TABLE 10.9 Comparison of Masks in LIGA and the IC Industry

	Semiconductor Lithography	LIGA Process
Transparency	≥50%	≥80%
Absorber thickness	±1 μm	±10 μm
Field size	50 × 50 mm^2	100 × 100 mm^2
Radiation resistance	= 1	= 100
Surface roughness	<0.1 μm	<0.5 μm
Waviness	<±1 μm	<±1 μm
Dimensional stability	<0.05 μm	<0.1–0.3 μm
Residual membrane stress	~10^8 Pa	~10^8 Pa

X-Ray Membrane (Mask Blank)

The low-Z membrane material in an x-ray mask must have a transparency for rays with a critical wavelength, λ_c, from 0.2–0.6 nm of at least 80% and should not induce scattering of those rays. To avoid pattern distortion, the residual stress, σ_r, in the membrane should be less than 10^8 dyn/cm^2. Mechanical stress in the absorber pattern can cause in-plane distortion of the supporting thin membrane, necessitating a high Young's modulus for the membrane material. Humidity or high deposited doses of x-ray might also distort the membrane directly. During one typical lithography step, the mask may be exposed to 1 MJ/cm^2 of x-rays. Because most membranes must be very thin for optimum transparency, a compromise has to be found between transparency, strength, and form stability. Important x-ray membrane materials are listed in Table 10.10. The higher radiation dose in LIGA prevents the use of boron nitride (BN) and compound mask blanks, which incorporate a polyimide layer. Those mask blanks are perfectly appropriate for classical IC lithography work but will not do for LIGA work. Mask blanks of metals such as Ti and Be were specifically developed for LIGA applications because of their radiation hardness.[35,37] In comparing titanium and beryllium membranes, beryllium can have a much greater membrane thickness, d, and still be adequately transparent. For example, a membrane transparency of 80%, essential for adequate exposure of a 500-µm-thick PMMA resist layer, is obtained with a thin 2-µm titanium film, whereas with beryllium, a thick 300-µm membrane achieves the same result. The thicker beryllium membrane permits easier processing and handling. In addition, beryllium has a greater Young's modulus E than titanium (330 vs. 140 kN/mm^2), and because it is the product of $E \times d$ that determines the amount of mask distortion, distortions resulting from absorber stress should be much smaller for beryllium blanks.[37,38] Thus, beryllium comes forward as an excellent membrane material for LIGA because of its high transparency and excellent damage resistance. Such a mask should be good for up to 10,000 exposures and may cost $20,000–30,000 ($10,000–15,000 in quantity). Stoichiometric silicon nitride (Si_3N_4) used in x-ray mask membranes may contain numerous oxygen impurities, absorbing x-rays and thus producing

Table 10.10 Comparison of Membrane Materials for X-Ray Masks

Material	X-Ray Transparency	Nontoxicity	Dimensional Stability	Remark
Si	0 (50% transmission at 5.5-µm thickness)	++	0 (thermal exp coefficient 2.6°C^{-1} 10^{-6}) Young's modulus = 1.3	Single-crystal Si, well developed, rad hard, stacking faults cause scattering, material is brittle
SiN_x	(50% transmission at 2.3-µm thickness)	++	(thermal exp coefficient 2.7°C^{-1} 10^{-6}) Young's modulus = 3.36	Amorphous, well developed, rad hard if free of oxygen, resistant to breakage
SiC	(50% transmission at 3.6-µm thickness)	++	(thermal exp coefficient 4.7°C^{-1} 10^{-6}) Young's modulus = 3.8	Poly and amorphous, rad hard, some resistance to breakage
Diamond	+(50% transmission at 4.6-µm thickness)	++	++(thermal exp coefficient 1.0°C^{-1} 10^{-6}) Young's modulus = 11.2	Poly, research only, highest stiffness
BN	(50% transmission at 3.8-µm thickness)		(thermal exp coefficient 1.0°C^{-1} 10^{-6}) Young's modulus = 1.8	Not rad hard, i.e., not applicable for LIGA
Be	++	—	++	Research, especially suited for LIGA, even at 100 µm the transparency is good, 30 µm typical, difficult to electroplate, toxic material
Ti	—		0	Research, used for LIGA, not very transparent, films must not be more than 2–3 µm thick

heat. This heat often suffices to prevent the use of nitride as a good LIGA mask. Single-crystal silicon masks have been made (1 cm^2 and 0.4 µm thick and 10 cm^2 and 2.5 µm thick) by electrochemical etching techniques. Nanostructures, Inc. (http://www.nanostructures.com) is one of the companies that make such thin Si masks. For Si and Si_3N_4, the Young's modulus is low compared with CVD-grown diamond, and for SiC films, the Young's modulus is as much as three times higher. These higher stiffness materials are more desirable because the internal stresses of the absorbers, which can distort mask patterns, are less of an issue. Unfortunately, diamond and SiC membranes are also the most difficult to produce.

Absorber Materials

The requirements on the absorber are high attenuation (>10 db), stability under radiation for extended periods, negligible distortion (stress <10^8 dyn/cm^2), ease of patterning, repairability, and low defect density. Typical absorber materials are listed in Table 10.11. Gold is used most commonly, and some research groups are looking at the viability of tungsten and other materials. In the IC industry, an absorber thickness of 0.5 µm might suffice, whereas LIGA deals with thicker layers of resist requiring a thicker absorber to maintain the same resolution.

Figure 10.18 illustrates how x-rays, with a characteristic wavelength of 0.55 nm, are absorbed along their trajectory through a Kapton preabsorber filter, an x-ray mask, and resist.[39] As we saw in Volume I,

TABLE 10.11 Comparison of Absorber Materials for X-Ray Masks

Material	Remark
Gold	Not the best stability (grain growth), low stress, electroplating only, defects repairable (thermal exp coefficient 14.2°C^{-1} 10^{-6}) (0.7 µm for 10 dB)
Tungsten	Refractory and stable, special care is needed for stress control, dry etchable, repairable (thermal exp coefficient 4.5°C^{-1} 10^{-6}) (0.8 µm for 10 dB)
Tantalum	Refractory and stable, special care is needed for stress control, dry etchable, repairable
Alloys	Easier stress control, greater thickness needed to obtain 10 dB

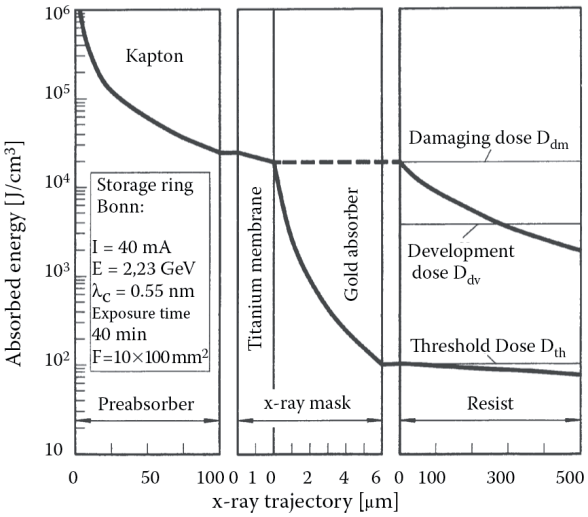

FIGURE 10.18 Absorbed energy along the x-ray trajectory including a 500-µm-thick PMMA specimen, x-ray mask, and a Kapton preabsorber. (From Bley, P., W. Menz, W. Bacher, K. Feit, M. Harmening, H. Hein, J. Mohr, W. K. Schomburg, and W. Stark. 1991. Proc. 1991 Int. MicroProcess Conf. *J. Appl. Phys.* JJAP Series 5, p. 384, Japan, Tokyo. With permission.[39])

Chapter 5, photon absorption by a solid in the visible region of the spectrum depends on the atomic arrangement of the atoms and their bonding (for example, pure silicon is strongly absorbing, but silicon combined with oxygen is transparent). For the energetic photons in the x-ray regime, photon absorption is much easier to predict and is independent of the details of atomic arrangement. It depends primarily on the electron concentration per unit volume. Because the concentration of atoms per unit volume only differs by factors of two or three from each other, the electron concentration in two materials can be estimated from the atomic number, Z. Lead ($Z = 82$) absorbs x-rays much more efficiently than aluminum ($Z = 13$) and consequently is used in shielding around x-ray apparatus. X-ray absorption depends on the energy of the x-rays and decreases with increasing x-ray energy, E. Absorption decreases nearly proportionally to the cube of the energy (i.e., absorption proportional to $1/E^3$; Equation 10.4). Thus, the low energy portion of the synchrotron radiation is absorbed mainly in the top portion of the resist layer because absorption increases with increasing wavelength. The Kapton preabsorber filters out much of the low energy radiation to prevent overexposure of the top surface of the resist. The x-ray dose at which the resist gets damaged, D_{dm},

the dose required for development of the resist, D_{dv}, and the "threshold dose" at which the resist starts dissolving in a developer, D_{th}, are all indicated in Figure 10.18. In the areas under the absorber pattern of the x-ray mask, the absorbed dose must stay below the threshold dose, D_{th}. Otherwise, the structures partly dissolve, resulting in poor feature definition. From Figure 10.18, we can deduce that the height of the gold absorbers must exceed 6 µm to reduce the absorbed radiation dose of the resist under the gold pattern to below the threshold dose, D_{th}. In Figure 10.19, the necessary thickness of the gold absorber patterns of an x-ray mask is plotted as a function of the thickness of the resist to be patterned; the Au must be thicker for thicker resist layers and for shorter characteristic wavelengths, λ_c, of the x-ray radiation. To pattern a 500-mm-high structure with a λ_c of 0.225 nm, the gold absorber must be more than 11 µm high.

Exposure of yet more extreme photoresist thicknesses is possible if proper x-ray photon energies are used. At 3,000 eV, the absorption length in PMMA roughly measures 100 µm, which enables the above-mentioned 500-µm exposure depth.[40] Using 20,000-eV photons results in absorption lengths of 1 cm. PMMA structures up to 10 cm (!) thick have been exposed this way.[41] A high-energy mask used by Guckel for these high-energy exposures has an Au absorber 50 µm thick and a blank membrane of 400-µm-thick Si. Guckel obtained an absorption contrast of 400 when exposing a 1000-µm-thick PMMA sheet with this mask. An advantage of using such thick Si blank membranes is that larger resist areas can be exposed because one does not depend on a fragile membrane/absorber combination.[42]

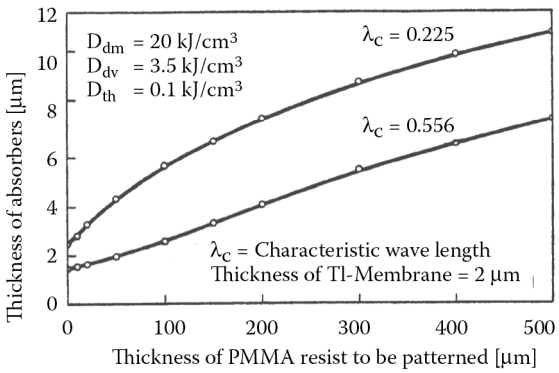

FIGURE 10.19 Necessary thickness of the gold absorbers of an x-ray mask. (From Bley, P., W. Menz, W. Bacher, K. Feit, M. Harmening, H. Hein, J. Mohr, W. K. Schomburg, and W. Stark. 1991. Proc. 1991 Int. MicroProcess Conf. *J. Appl. Phys*. JJAP Series 5, p. 384, Japan, Tokyo. With permission.[39])

Absorber Fabrication

Single-Layer Absorbers To make a mask with gold absorber structures of a height more than 10 µm, one must first succeed in structuring a resist of that thickness. The height of the resist should be a bit higher (e.g., 20%) than the absorber itself to accommodate the electrodeposited metal fully between the resist features. Currently, no means to structure a resist of that height with sufficient accuracy and perfect verticality of the walls exist unless x-rays are used. Different procedures for producing x-ray masks with thicker absorber layers using a two-stage lithography process have been developed.

The KfK solution calls for first making an intermediate mask with photo or e-beam lithography. This intermediate mask starts with a 3-µm-thick resist layer, in which case the needed line-width accuracy and photoresist wall steepness of printed features are achievable. After gold plating between the resist features and stripping the resist, this intermediate mask is used to write a pattern with x-rays in a thicker resist, e.g., 20 µm thick. After electrodepositing and resist stripping, the x-ray mask, that is, the master mask, is obtained.

Because hardly any accuracy is lost in the copying of the intermediate mask with x-rays to obtain the master mask, it is the intermediate mask quality that determines the ultimate quality of the LIGA-produced microstructures. The structuring of the resist in the intermediate mask is handled with optical techniques when the requirements on the LIGA structures are less stringent. The minimal lateral dimensions for optical lithography in a 3-µm-thick resist typically measure about 2.5 µm. Under optimum conditions, a wall angle of 88° is achievable. With e-beam lithography, a minimum lateral dimension of less than 1 µm is feasible. The most accurate pattern transfer is achieved through reactive ion etching of a trilevel resist system. In this approach, a 3–4-µm-thick polyimide resist is first coated onto the titanium or beryllium membrane, followed by a coat of 10–15-nm titanium deposited

with magnetron sputtering. The thin layer of titanium is an excellent etch mask for the polyimide; in optimized oxygen plasma, the titanium etches 300 times slower than the polyimide. To structure the thin titanium layer itself, a 0.1-µm-thick optical resist is used. Because this top resist layer is so thin, excellent lateral tolerances result. The thin Ti layer is patterned with optical photolithography and etched in argon plasma. After etching the thin titanium layer, exposing the polyimide locally, oxygen plasma helps to structure the polyimide down to the titanium or beryllium membrane. Lateral dimensions of 0.3 µm can be obtained in this fashion. Patterning the top resist layer with an e-beam increases the accuracy of the three-level resist method even further. Electrodeposition of gold on the titanium or beryllium membrane and stripping of the resist finish the process of making the intermediate LIGA mask. To make a master mask, this intermediate mask is printed by x-ray radiation onto a PMMA resist-coated master mask. The PMMA thickness corresponds to a bit more than the desired absorber thickness. Because the resist layer thickness is in the 10–20-µm range, a synchrotron x-ray wavelength of 10 Å is adequate for making the master mask. A further improvement in LIGA mask making is to fabricate intermediate and master mask on the same substrate, greatly reducing the risk for deviations in dimensions caused, for example, by temperature variations during printing.[43] The ultimate achievement would be to create a one-step process to make the master mask. Along this line, Hein et al.[38] investigated the direct patterning of 10-µm-high resist layers with a 100-kV e-beam.

Stepped Absorber In principle, stepped absorber structures may result in stepped LIGA structures by means of x-ray lithography with a single mask. In this manner, variable dose depositions can be achieved at the same resist heights. The variable dose results in different molecular weights and hence in a different developing behavior. This technique unfortunately leads to rounded features and poor step-height control. Further below under "Stepped and Slanted Microstructures" we will learn how to make better resolved stepped features.

CNC Machined Absorbers A rather unexpected approach to pattern absorber layers for x-ray masking is pursued by Friedrich et al. from the Michigan Technological University (http://www.me.mtu.edu/~microweb). Friedrich et al. are exploring x-ray mask fabrication by traditional machining methods, such as micromilling, micro-EDM, and lasers.[44] Using micromilling, this group succeeded in making mask features up to 62 µm deep and walls down to 4 µm thick and 10 µm high. The milling is carried out with a 22-µm end mill, fabricated itself by using a 20-keV gallium ion beam. The advantages of this approach are rapid turnaround (less than 1 day/mask), low cost, and flexibility (almost any type of material can be machined) because no intermediate steps interfere. Disadvantages are less dimensional edge acuity and nonsharp interior corners, as well as much lower absolute tolerance.

Alignment of X-Ray Mask to Substrate

The mask and resist-coated substrate must be properly registered to each other before they are put in an x-ray scanner. Alignment of an x-ray mask to the substrate is problematic because no visible light can pass through most x-ray membranes. To solve this problem, Schomburg et al.[37] etched windows in their Ti x-ray membrane. Diamond membranes have a potential advantage here because they are optically transparent and enable easy alignment for multiple irradiations without a need for etched holes.

Figure 10.20 illustrates an alternative, x-ray alignment system involving capacitive pickup between conductive metal fingers on the mask and ridges on a small substrate area; Si, in this case [US Patent 4,607,213 (1986) and 4,654,581 (1987)]. When using

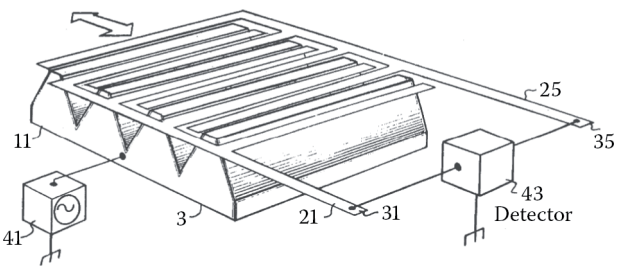

FIGURE 10.20 Mask alignment system in x-ray lithography. Conductive fingers on the mask and ridges on the Si are used for alignment. [From US Patents 4,654,581 (1987) and 4,607,213 (1986).]

multiple groups of ridges and fingers, two-axis lateral and rotational alignment become possible.

Another alternative may involve liquid nitrogen-cooled Si (Li) x-ray diodes as alignment detectors, eliminating the need for observation with visible light.[45]

Conformal, Transfer, or Self-Aligned Mask for High-Aspect-Ratio Microlithography

Vladimirsky et al.[46,47] developed a procedure to eliminate the need for an x-ray mask membrane. Unlike conventional masks, the so-called *x-ray transfer mask* does not treat a mask as an independent unit. The technique is based on forming an absorber pattern directly on the resist surface forming a conformal, self-aligned, or transfer mask. An example process is shown in Figure 10.21. In this sequence, a transfer mask plating base is first prepared on the PMMA substrate plate by evaporating 70 Å of chromium (as adhesion layer) followed by 500 Å of gold using an e-beam evaporator. A 3-µm-thick layer of standard Novolak-based AZ-type resist S1400-37 (Shipley Co., Marlborough, MA) is then applied over the plating base and exposed in contact mode through an optical mask using an UV exposure station. Three micrometers of electroplated gold on the exposed plating base further completes the transfer mask. A blanket exposure and subsequent development remove the remaining resist. The 500 Å of gold plating base is dissolved by a dip of 20–30 s in a solution of KI (5%) and I (1.25%) in water; the Cr adhesion layer is removed by a standard chromium etch (from KTI, Chemicals Inc., Sunnyvale, CA). Thus, fabrication of the transfer mask can be performed using standard lithography equipment available at almost any lithography shop. Depending on the resolution required, the x-ray transfer mask can be fabricated using known photon, e-beam, or x-ray lithography techniques. The patterning of the PMMA resist with a self-aligned mask is accomplished in multiple steps of exposure and development. An example of a cylindrical resonator made this way is shown in Figure 10.22. Each exposure/development step involves an exposure dose of about 8–12 J/cm^2. Subsequent 5-min development steps remove ~30 µm of PMMA. In seven steps, a self-supporting, 1.5-mm-thick PMMA resist is patterned to a depth

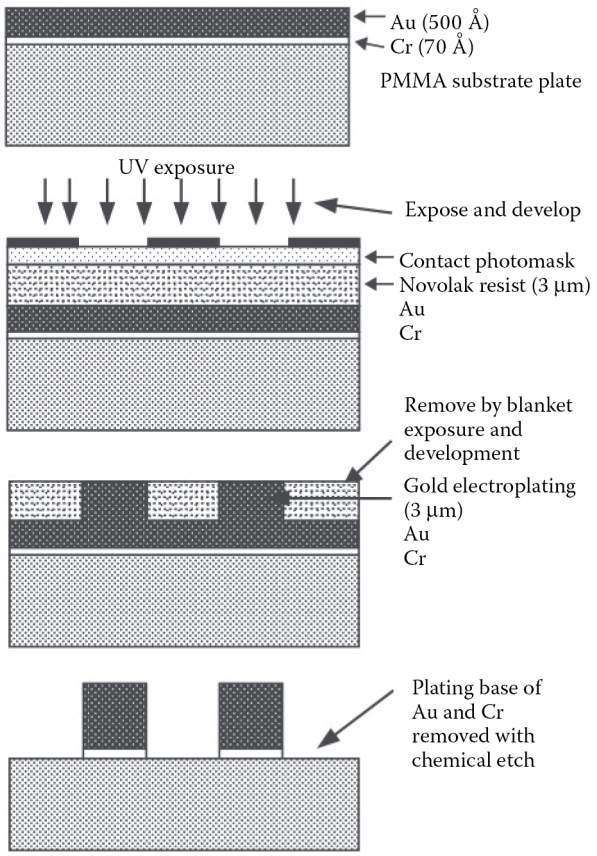

FIGURE 10.21 Sample transfer mask formation. [From Vladimirsky, Y., O. Vladimirsky, V. Saile, K. Morris, and J. M. Klopf. 1995. *Microlithography '95 (Proceedings of the SPIE).* Santa Clara, CA: SPIE.[46]]

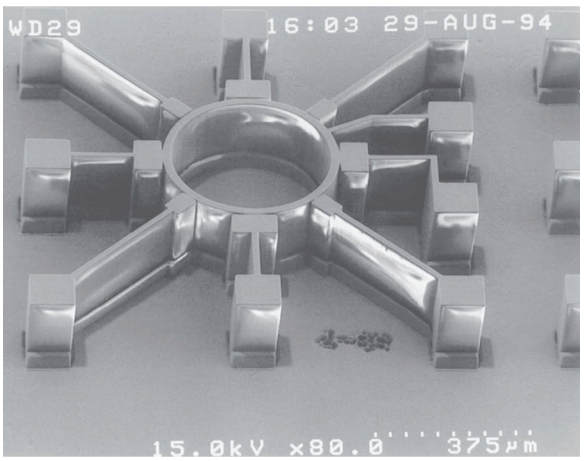

FIGURE 10.22 SEM micrograph of a cylindrical PMMA resonator made by the transfer mask method and multiple exposure/development steps. [From Vladimirsky, Y., O. Vladimirsky, V. Saile, K. Morris, and J. M. Klopf. 1995. *Microlithography '95 (Proceedings of the SPIE).* Santa Clara, CA: SPIE. With permission.[46]] (Courtesy of Dr. V. Saile.)

of more than 200 µm. The resist pattern shown in Figure 10.22 is 230 µm thick and exhibits a 2-µm gap between the inner cylinder and the pickup electrodes (aspect ratio is 100:1). The resonator pattern was produced using soft x-rays (=10 Å) and a 3-µm-thick Au absorber only.

Vladimirsky et al.[46] suggest that the forming of the transfer mask directly on the sample surface creates several additional new opportunities; besides in situ development, etching, and deposition, these include exposure of samples with curved surfaces and dynamic deformation of a sample surface during the exposure (hemispherical structures for lenses are possible this way). Elegant and cost-saving innovations like these could help mainstream LIGA.

Shih et al.[48] further developed and fine-tuned the conformal mask method for LIGA. In one very attractive embodiment of the technology, a PMMA layer on an Al substrate is coated with a Cu foil (17.5 µm) by cold pressing. The copper foil is further laminated with a dry photoresist foil (48-µm Hitachi H-N650). After exposure and development of the dry resist, gold or tin/lead absorber patterns are electroplated on the exposed Cu foil. After stripping the dry resist in a 3 wt% NaOH solution at around 50°C and the underlying copper foil in a $Cu(NH_3)_4Cl_2$ solution at 45°C, the conformal mask is ready for use. Using this approach, 1000-µm-high structures with an aspect ratio of 6.25 were fabricated with a double-exposure development cycle only. Using yet another transfer mask approach, this same research group made LIGA dies for spinnerets (see Example 10.1).[49] The authors summarize the advantages of the transfer mask method as follows:

- Alleviates the difficulty in fabricating fragile mask membranes
- Avoids alignment requirements during successive exposure steps
- Reduces exposure time and absorber thickness for the same exposure source
- Enhances pattern transfer fidelity because there is almost no proximity gap
- Avoids thermal deformation caused by exposure heat
- Increases photoresist development rate by stepwise elevated exposure dose

Choice of Primary Substrate

In the LIGA process, the primary substrate, or base plate, must be a conductor or an insulator coated with a conductive top layer. A conductor is required for subsequent electrodeposition. Some examples of primary substrates that have been used successfully are Al,[48] austenite steel plate, Si wafers with a thin Ti or Ag/Cr top layer,[50] and copper plated with gold, titanium, or nickel.[43] Other metal substrates and metal-plated ceramic, plastic, and glass plates have been used.[51] It is important that the plating base provide good adhesion for the resist. For that purpose, before applying the x-ray resist on copper or steel, the surface sometimes is mechanically roughened by microgrit blasting with corundum. Microgrit blasting may lead to an average roughness, R_a, of 0.5 µm, resulting in better physical anchoring of the microstructures to the substrate.[52] In the case of a polished metal base, chemical preconditioning may be used to improve adhesion of the resist microstructures. During chemical preconditioning, a titanium layer, sputter-deposited onto the polished metal base plate (e.g., a Cu plate), is oxidized for a few minutes in a solution of 0.5 M NaOH and 0.2 M H_2O_2 at 65°C. The oxide produced typically measures 30 nm thick and exhibits a microrough surface instrumental to securing resist to the base plate. The Ti adhesion layer may further be covered with a thin nickel seed layer (~150 Å) for electroless or electroplating of nickel. When using a highly polished Si surface, adhesion promoters need to be added to the resist resin (see "Resist Adhesion" further below). A substrate of special interest is a processed silicon wafer with integrated circuits (ICs). Integrating the LIGA process with IC circuitry on the same wafer will open up additional LIGA applications (see text below and Figure 10.39).

The back of electrodeposited microdevices is attached to the primary substrate but can be removed from the substrate if necessary. In the latter case, the substrate may be treated chemically or electrochemically to induce poor adhesion. Ideally, excellent adhesion exists between substrate and resist, and poor adhesion exists between the electroplated structure and plating base. Achieving these two contradictory demands is one of the main challenges in LIGA.

Thick resist plates can act as plastic substrates themselves. For example, using 20,000-eV rather than the more typical 3,000-eV radiation, Guckel et al.[40,41] exposed plates of PMMA up to 10 cm thick.

Resist Requirements

An x-ray resist ideally should have high sensitivity to x-rays, high resolution, resistance to dry and wet etching, thermal stability of greater than 140°C, and a matrix or resin absorption of less than 0.35 μm^{-1} at the wavelength of interest.[53] These requirements are only those for IC production with x-ray lithography.[54] To produce high-aspect-ratio microstructures with very tight lateral tolerances demands an additional set of requirements. The unexposed resist must be absolutely insoluble during development. This means that a high contrast (γ) is required. The resist must also exhibit very good adhesion to the substrate and be compatible with the electroforming process. The latter imposes a resist glass transition temperature (T_g) greater than the temperature of the electrolyte bath used to electrodeposit metals between the resist features remaining after development (e.g., at 60°C). To avoid mechanical damage to the microstructures induced by stress during development, the resist layers should exhibit low internal stresses.[55] If the resist structure is the end product of the fabrication process, further specifications depend on the application itself, for example, optical transparency and refractive index for optical components or large mechanical yield strength for load-bearing applications. For example, PMMA exhibits good optical properties in the visible and near-infrared range and lends itself to the making of all types of optical components.[56] Because of excellent contrast and good process stability known from e-beam lithography, PMMA is the preferred resist for deep-etch synchrotron radiation lithography. Two major concerns with PMMA as a LIGA resist are a rather low lithographic sensitivity of about 2 J/cm^2 at a wavelength λ_c of 8.34 Å and susceptibility to stress cracking. For example, even at shorter wavelengths, λ_c = 5 Å, more than 90 min of irradiation are required to structure a 500-µm-thick resist layer with an average ring storage current of 40 mA and a power consumption of 2 MW at the 2.3-GeV ELSA synchrotron (Bonn, Germany) (see Figure 10.18).[57] The internal stress arising from the combination of a polymer and a metallic substrate can cause cracking in the microstructures during development, a phenomenon PMMA is especially prone to, as illustrated in the scanning electron microscope (SEM) in Figure 10.23.

To make throughput for deep-etch lithography more acceptable to industry, several avenues to more sensitive x-ray resists have been pursued. For example, copolymers of PMMA were investigated: methylmethacrylate (MMA) combined with methacrylates with longer ester side chains show sensitivity increases of up to 32% (with tertiary butylmethacrylate). Unfortunately, a deterioration in structure quality was observed.[59] Among the other possible approaches for making PMMA more x-ray sensitive, we can count on the incorporation of x-ray-absorbing high-atomic-number atoms or the use of chemically amplified photoresists. X-ray resists explored more recently for LIGA applications are poly(lactides), for example, poly(lactide-co-glycolide) (PLG), polymethacrylimide (PMI), polyoxymethylene (POM), and polyalkensulfone (PAS). PLG is a new positive resist developed by BASF AG, more sensitive to x-rays by a factor of two to three compared with PMMA. From the comparison of different resists for deep x-ray lithography in Table 10.12, PLG emerges as the most promising LIGA

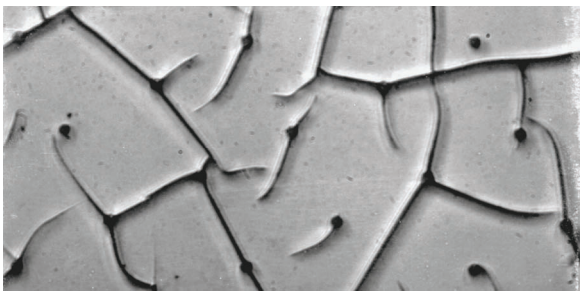

FIGURE 10.23 Cracking of PMMA resist. Method to test stress in thick resist layers. The onset of cracks in a pattern of holes with varying size (e.g., 1–4 µm) in a resist is shifted toward smaller hole diameter the lower the stress in the film. The SEM picture displays extensive cracking incurred during development of the image in a 5-µm-thick PMMA layer on an Au-covered Si wafer. The 5-µm-thick PMMA layer resulted from five separate spin coats. Annealing pushed the onset of cracking toward smaller holes until the right cycle was reached and no more cracks were visible. (From Madou, M. J., and M. Murphy. 1995. Unpublished results.[58])

resist. POM, a promising mechanical material, may also be suited for medical applications given its biocompatibility. All the resists shown in Table 10.12 exhibit significantly enhanced sensitivity compared with PMMA, and most exhibit a reduced stress corrosion.[57] Negative x-ray resists have inherently higher sensitivities compared with positive x-ray resists, although their resolution is limited by swelling. Poly(glycidyl methacrylate-co-ethyl acrylate) (PGMA), a negative e-beam resist (not shown in Table 10.12), has also been used in x-ray lithography. In general, resist materials sensitive to e-beam exposure also display sensitivity to x-rays and function in the same fashion; materials positive in tone for e-beam radiation typically are also positive in tone for x-ray radiation. A strong correlation exists between the resist sensitivities observed with these two radiation sources, suggesting that the reaction mechanisms might be similar for both types of irradiation. IMM, in Germany, started developing a negative x-ray resist 20 times more sensitive than PMMA, but the exact chemistry has not yet been disclosed.[2] More common x-ray resists from the IC industry are reviewed in Table 10.13.

Methods of X-Ray Resist Application

Multiple Spin Coats

Different methods to apply ultrathick layers of x-ray resists such as PMMA have been studied. In the case of multilayer spin coating, high interfacial stresses between the layers can lead to extensive crack propagation on developing the exposed resist. For example, in Figure 10.23, we present an SEM picture of a

5-µm-thick PMMA layer deposited in five sequential spin coatings. Development results in the cracked riverbed mud appearance, with the most intensive cracking propagating from the smallest resist features. The test pattern used to expose the resist consisted of arrays of holes ranging in size from 1–4 µm. Annealing the PMMA films shifted the cracking toward holes with smaller diameter compared with the unannealed film shown in Figure 10.23.[58] CAMD (see Table 10.8) has demonstrated that multiple spin coating of PMMA can be used for up to 15-µm-thick resist layers and that applying the appropriate annealing and developer (see below) eliminates cracking.[62] Below, we will learn that a prerequisite for low stress and small lateral tolerances in PMMA films is a high mean molecular weight. The spin-coated resist films in Figure 10.23 do not have a high-enough molecular weight to lead to good enough selectivity between radiated and nonradiated PMMA during a long development process.

Commercial PMMA Sheets

High-molecular-weight PMMA is commercially available as prefabricated plate (e.g., GS 233, Rohm GmbH, Darmstadt, Germany), and several groups have used freestanding or bonded PMMA resist sheets for producing LIGA structures.[42,52] After overcoming the initial problems encountered when attempting to glue PMMA foils to a metallic base plate with adhesives, this has become the preferred method in several labs.[52] Guckel used commercially available thick PMMA sheets (thickness >3 mm), XY-sized and

solvent-bonded them to a substrate, and, after milling the sheet to the desired thickness, exposed the resist plate without cracking problems.[42]

Casting of PMMA

PMMA also can be purchased in the form of a casting resin, for example, Plexit 60 (PMMA without added cross-linker) and Plexit 74 (PMMA with cross-linker added) from Rohm GmbH. In a typical procedure, PMMA is in situ polymerized from a solution of 35 wt% PMMA of a mean molecular weight of anywhere from 100,000 g/mol up to 106 g/mol in methylmethacrylate (MMA). Polymerization at room temperature takes place with benzoyl peroxide (BPO) catalyst as the hardener (radical builder) and dimethylaniline (DMA) as the starter or initiator.[52,59] The oxygen content in the resin, inhibiting polymerization, and gas bubbles, inducing mechanical defects, are reduced by degassing while mixing the components in a vacuum chamber at room temperature and at a pressure of 100 mbar for 2–3 min.

In a practical application, resin is dispensed on a base plate provided with shims to define pattern and thickness and subsequently covered with a glass plate to avoid oxygen absorption. Because of the hardener, polymerization starts within a few minutes after mixing the components and comes to an end within 5 min. The glass cover plate is coated with an adhesion-preventing layer (e.g., Lusin L39, Firma Lange u. Seidel, Nuremberg, Germany). After polymerization, the antiadhesion material is removed by diamond milling, and a highly polished surface results. In situ polymerization and commercial-cast PMMA sheets top the list of thick resist options in LIGA today.

Plasma polymerization of PMMA in layers (>100 μm) was discussed in Chapters 7 and 8 (see Figure 8.9).

Resist Adhesion

Adhesion promotion by mechanically or chemically modifying the primary substrate was introduced above, under "Choice of Primary Substrate." Smooth surfaces such as Si wafers with an average roughness, R_a, smaller than 20 nm pose additional adhesion challenges often solved by modifying the resist itself. To promote adhesion of resist to polished untreated surfaces, such as metal-coated Si wafers, coupling agents must be used to chemically attach the resist to the substrate. An example of such a coupling agent is methacryloxypropyl trimethoxy silane (MEMO). With 1 wt% of MEMO added to the casting resin, excellent adhesion results. The adherence is brought about by a siloxane bond between the silane and the hydrolyzed oxide layer of the metal. As illustrated in

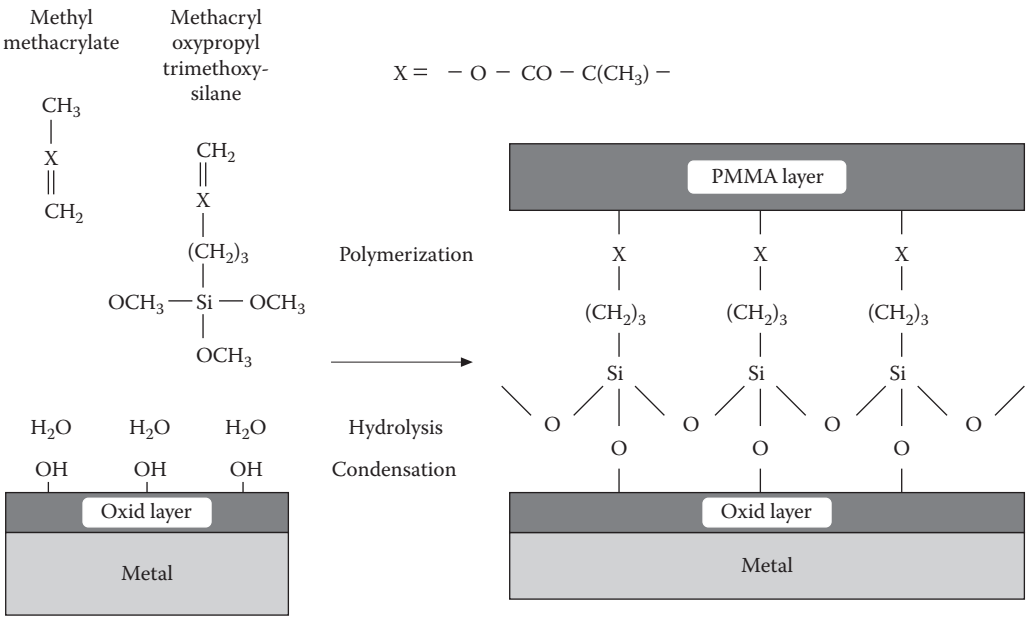

FIGURE 10.24 Schematic presentation of the adherence mechanism of methacryloxypropyl trimethoxy silane (MEMO). (From Mohr, J., W. Ehrfeld, and D. Munchmeyer. 1988. Requirements on resist layers in deep-etch synchrotron radiation lithography. *J Vac Sci Technol* B6:2264–67. With permission.[59])

Figure 10.24, the integration of this coupling agent in the polymer matrix is achieved via the double bond of the methacryl group of MEMO.[59]

Hydroxyethyl methacrylate (HEMA) can improve PMMA adhesion to smooth surfaces, but higher concentrations are needed to obtain the same adhesion improvement. Silanization of polished surfaces before PMMA casting, instead of adding adhesion promoters to the resin, did not seem to improve the PMMA adhesion. In the case of PMMA sheets, as mentioned before, one option is solvent bonding of the layers to a substrate. In another approach, Galhotra et al.[63] simply mechanically clamped the exposed and developed self-supporting PMMA sheet onto a 1.0-mm-thick Ni sheet for subsequent Ni plating. Rogers et al.[64] have shown that cyanoacrylate can be used to bond PMMA resist sheets to a Ni substrate and that it can be lithographically patterned using the same process sequence used to pattern PMMA. For a 300-µm-thick PMMA sheet on a sputtered Ni coating on a silicon wafer, a 10-µm-thick cyanoacrylate bonding layer was used. Such a thick cyanoacrylate layer caused some problems for subsequent uniform electrodeposition of metal. The dissolution rate of the cyanoacrylate is faster than the PMMA resist, resulting in metal posts with a wide profile at the base.

Stress-Induced Cracks in PMMA

The internal stress arising from the combination of a polymer on a metallic substrate can cause cracking in the microstructures during development. To reduce the number of stress-induced cracks (see Figure 10.23), both the PMMA resist and the development process must be optimized. Detailed measurements of the heat of reaction, the thermomechanical properties, the residual monomer content, and the molecular weight distribution during polymerization and soft baking have shown the necessity to produce resist layers with a high molecular weight and with only a very small residual monomer content.[52,59] Figure 10.25 compares the molecular weight distribution determined by gel permeation chromatography of a polymerized PMMA resist (two hardener concentrations were used) with the molecular weight distribution of the casting resin. The casting resin is unimodal, whereas the polymerized resist layer typically shows a bimodal distribution, with peak molecular weights centered around 90,000 and 300,000 g/mol. The first low-molecular-weight peak belongs to the PMMA oligomer dissolved in the casting resin, and the second molecular-weight peak results from the polymerization of the monomer. The molecular weight distribution is constant across the total resist thickness, except for the boundary layer at the base plate, where the average molecular weight can be significantly higher (~450,000 g/mol).[55]

The amount of the high-molecular-weight portion in the polymerized resist depends on the concentration of the hardener. A low hardener content leads to a high-molecular-weight dominance and vice versa (see Figure 10.25).[59] Because high molecular weight is required for low stress, a hardener concentration of

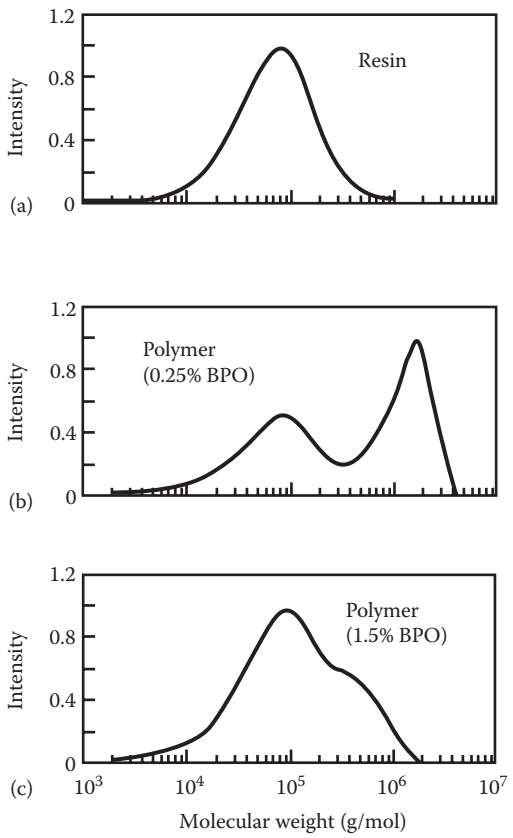

FIGURE 10.25 Molecular weight distribution of the casting resin (a), a resist layer polymerized at low hardener content (b), and a resist layer polymerized at high hardener content (c) determined by gel permeation chromatography. (From Mohr, J., W. Ehrfeld, and D. Munchmeyer. 1988. Requirements on resist layers in deep-etch synchrotron radiation lithography. *J Vac Sci Technol* B6:2264–67. With permission.[59])

less than 1% BPO must be used. Ideally, for a low stress resist, the residual monomer content should be less than 0.5%. The residual monomer content decreases with increasing hardener content, and >1% BPO is needed to reduce the residual monomer content to less than 0.5%. The problem resulting from these opposite needs can be overcome by the addition of 1% of a cross-linking dimethacrylate (triethylene glycol dimethacrylate) to the resin. In such cross-linked PMMA, a smaller amount of BPO suffices to suppress the residual monomer content; crack-free PMMA can be obtained with 0.8% of BPO.[52]

For solvent removal, and to further minimize the defects caused by stress, the polymerized resin is cured at 110°C for 1 h (soft bake). The measurement of the reaction enthalpy shows that postpolymerization reactions occur at room temperature and during heating to the glass transition temperature.[59] The rate of heating up to that temperature is 20°C/h; after curing, the samples are cooled down from 110°C to room temperature at a very low rate of 5–10°C/h.[52, 55] The soft-bake temperature is slightly below the glass transition temperature measured to be 115°C.

Another important factor that reduces stress in thick PMMA resist layers is the optimization of the developer. Stress-induced cracking can be minimized with solvent mixtures whose dissolution parameters lie near the boundary of the PMMA solubility range; that is, a nonaggressive solvent is preferred. This is discussed in more detail below under "Development." Small amounts of additives such as described above for reducing stress or to promote adhesion do not influence the mechanical stability of the microstructures or the sensitivity of the resist.

Exposure

Optimum Wavelength

For a given polymer, the lateral dimension variation in a LIGA microstructure could, in principle, result from the combined influence of several mechanisms. These include Fresnel diffraction, the range of high-energy photoelectrons generated by the x-rays, the finite divergence of synchrotron radiation, and the time evolution of the resist profiles during the development process. The theoretical manufacturing precision obtainable by deep x-ray lithography was investigated by means of computer simulation of both the irradiation step and the development step by Becker et al.[65] and Munchmeyer.[66] Results were further tested experimentally and confirmed by Mohr et al.[52] The theoretical results demonstrate that the effect of Fresnel diffraction (edge diffraction), which increases as the wavelength increases, and the effect of secondary electrons in PMMA, which increases as the wavelength decreases, lead to minimal structural deviations when the characteristic wavelength ranges between 0.2 and 0.3 nm (assuming an ideal development process and no x-ray divergence). To fully use the accuracy potential of a 0.2–0.3-nm wavelength, the local divergence of the synchrotron radiation at the sample site should be less than 0.1 mrad. Under these conditions, the variation in critical lateral dimensions likely to occur between the ends of a 500-µm-high structure as a result of diffraction and secondary electrons is estimated to be 0.2 µm. The estimated Fresnel diffraction and secondary electron scattering effects are shown as a function of characteristic wavelength in Figure 10.26.

Using cross-linked PMMA, or linear PMMA with a unimodal and extremely high-molecular-weight distribution (peak molecular weight greater than 1 million g/mol), the experimentally determined lateral tolerances on a test structure, as shown in Figure 7.27, are 0.055 µm/100-µm resist thickness, in good agreement with the 0.2 µm over 500 µm expected

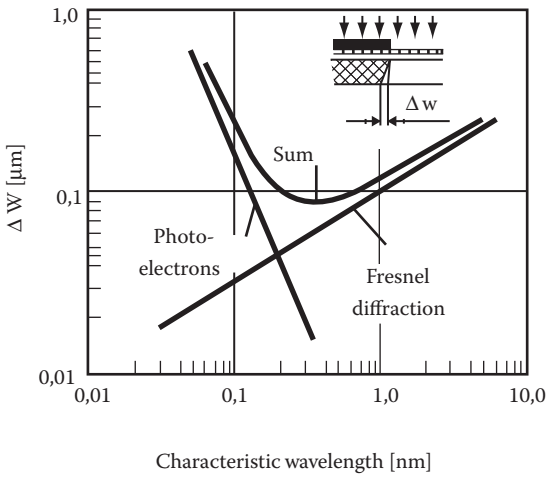

FIGURE 10.26 Fresnel diffraction and photoelectron generation as a function of characteristic wavelength, λ_c, and the resulting lateral dimension variation (ΔW). (From Menz, W., and P. Bley. 1993. *Mikrosystemtechnik fur Ingenieure*. Weinheim, Germany: VCH Publishers.[67])

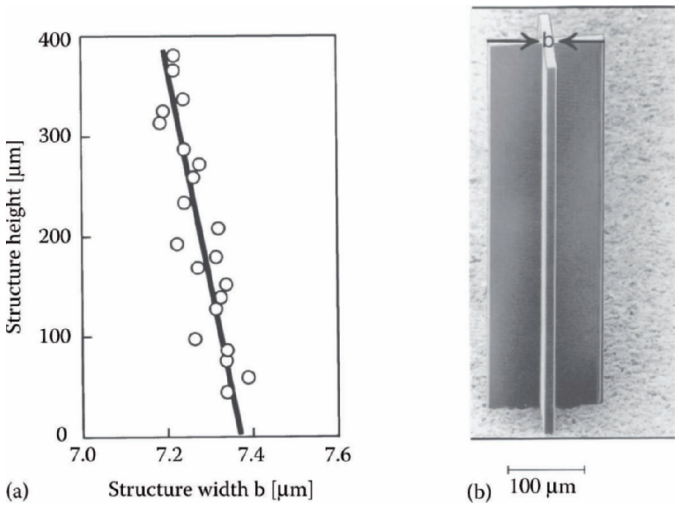

FIGURE 10.27 Structural tolerances. (a) SEM micrograph of a test structure to determine conical shape. (b) Structural dimensions as a function of structure height. The tolerances of the dimensions are within 0.2 mm over the total structure height of 400 mm. (From Mohr, J., W. Ehrfeld, and D. Munchmeyer. 1988. Requirements on resist layers in deep-etch synchrotron radiation lithography. *J Vac Sci Technol* B6:2264–67.[59]) (Courtesy of the Karlsruhe Nuclear Research Center.)

on a theoretical basis.[52] These results are obtained only when a resist/developer system with a ratio of the dissolution rates in the exposed and unexposed areas of approximately 1000 is used.

The use of resist layers, not cross-linked and displaying a relatively low bimodal molecular-weight distribution, as well as the application of excessively strong solvents such as used to develop thin PMMA resist layers in the IC industry, leads to a more pronounced conical shape in the test structure of Figure 10.23. An illustration of the effect of molecular weight distribution on lateral geometric tolerances is that linear PMMA with a peak molecular weight less than 300,000 g/mol shows structure tolerances of up to 0.15 µm/100 µm.[52] To obtain the best tolerances requires a PMMA with a very high molecular weight, also a prerequisite for low stress in the developed resist. Finally, if the synchrotron beam is not parallel to the absorber wall but at an angle greater than 50 mrad, greater coning angles may also result.[52]

Deposited Dose

As shown in Figure 10.28, depicting the average molecular weight of PMMA as a function of radiation

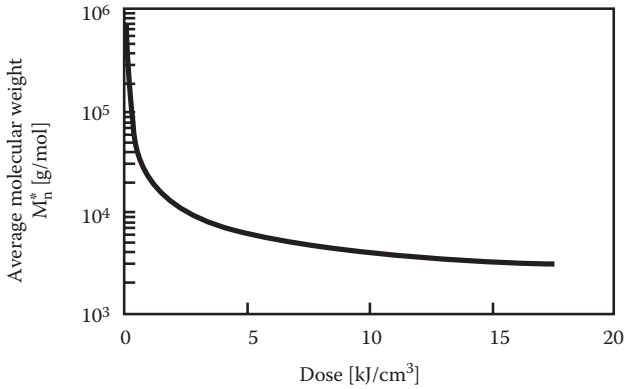

FIGURE 10.28 Average molecular weight M_n^* versus x-ray radiation dose. (From Menz, W., and P. Bley. 1993. *Mikrosystemtechnik fur Ingenieure.* Weinheim, Germany: VCH Publishers. With permission.[67])

dose, the x-ray irradiation of PMMA reduces the average molecular weight (M_n', see Chapter 1, Equation 1.10).[67] For one-component positive resists, this decrease of the average molecular weight causes the solubility of the resist in the developer to increase dramatically. The average molecular weight making dissolution possible is a sensitive function of the type of developer used and the development temperature. It can be observed from Figure 10.28 that above a certain dose (15–20 kJ/cm^3), the average molecular weight does not decrease any further.

The molecular weight distribution, measured after resist exposure, is unimodal with peak molecular weights ranging from 3,000–18,000 g/mol, dependent on the dose deposited during irradiation. The peak molecular weight increases nearly linearly with increasing resist depth; that is, decrease of the absorbed dose.[55] At the bottom of the resist layer, the absorbed dose must be higher than the development dose, D_{dv}, whereas at the top of the resist, the absorbed dose must be lower than the damaging dose, D_{dm}. In Figure 10.18, where the absorption of x-rays along the path from source to sample was illustrated, the exposure time and the preabsorber were chosen so that the bottom of a 500-µm-thick PMMA layer received the necessary development dose D_{dv}, whereas the dose at the top of the layer stayed well below D_{dm}. Exposure of PMMA with longer wavelengths results in correspondingly longer exposure times and can lead to an overexposure of the top surface, where the lower energy radiation is mainly absorbed.

Menz and Bley[67] describe the influence of the radiation dose on the quality of the resulting LIGA structures in a slightly different manner. Following their approach, Figure 10.29a illustrates a typical bimodal molecular weight distribution of PMMA before radiation, exhibiting an average molecular weight of 600,000. The gray region in this figure indicates the molecular weight region where PMMA readily dissolves; that is, less than the 20,000 g/mol level for the temperature and developer used. Because the fraction of PMMA with a 20,000 molecular weight is very small in nonirradiated PMMA, the developer hardly attacks the resist. After irradiation with a dose D_{dv} of 4 kJ/cm^3, the average molecular weight becomes low enough to dissolve almost all the resist (Figure 10.29b). With a dose D_{dm} of 20 kJ/cm^3, all the PMMA dissolves swiftly (Figure 10.29c). At a dose more than D_{dm}, the microstructures are destroyed by the formation of bubbles. It follows that to dissolve PMMA completely and to make defect-free microstructures, the radiation dose for the specific type of PMMA used must lie between 4 and 20 kJ/cm^3. These two numbers also lock in a maximum value of five for the ratio of the radiation dose at the top and bottom of a PMMA structure. To make this ratio as small as possible, the soft portion of the synchrotron radiation spectrum is usually filtered out by a preabsorber [for example, a 100-µm-thick polyimide foil (Kapton)] to reduce differences in dose deposition in the resist.

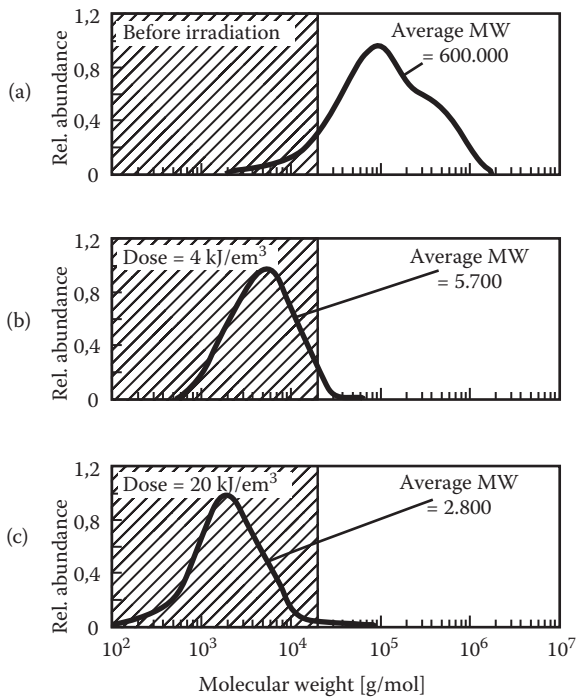

FIGURE 10.29 Molecular weight distribution of PMMA before (a) and after irradiation with 4 (b) to 20 kJ/cm^3 (c). The shaded areas indicate the domain in which PMMA is minimally 50% dissolved (at 38°C in the LIGA developer described in the text). (From Menz, W., and P. Bley. 1993. *Mikrosystemtechnik fur Ingenieure*. Weinheim, Germany: VCH Publishers. With permission.[67])

X-ray exposure equipment developed by KfK has vibration-free bedding; the exposure chamber is under thermostatic control (±0.2°C) and includes a precision scanner for the periodic movement of the sample through the irradiation plane. The polyimide window isolates the vacuum of the accelerator from the helium atmosphere (200 mbar), which serves as coolant for substrate and mask in the irradiation chamber.[43] IMM, in collaboration with Jenoptik GmbH, developed an x-ray scanner for deep lithography, enabling irradiation of up to 1000-µm-thick resists. A mask-to-resist registration within ±0.3 µm is claimed.[68]

Stepped and Slanted Microstructures

For many applications, stepped or inclined resist sidewalls are very useful—consider, for example, the fabrication of multilevel devices or prisms or, more basic yet, angled resist walls to facilitate the release of molded part.* Using stepped absorber layers on a single mask to make stepped multilevel microstructures was discussed above under "Absorber Fabrication" (see also the discussion in Chapter 2 and Figure 2.11). We mentioned that structures made this way are not always very well resolved. To make better-resolved stepped features one can first relief print a PMMA layer, for example, by using a Ni mold insert made from a first x-ray mask. Subsequently, the relief structure may be exposed to synchrotron radiation to further pattern the polymer layer through a precisely adjusted second x-ray mask. To carry out this process, a two-layer resist system needs to be developed consisting of a top PMMA layer, which

* In using LIGA or LIGA-like techniques for plastic micromolding it is important to be able to control the resist wall inclination to facilitate the release of molded devices. Even a 2° angle can make the difference between form locking or easy release.

fulfills the requirement of the relief printing process, and a bottom layer, which fulfills the requirements of the x-ray lithography.[69] The bottom resist layer promotes high molecular weight and adhesion, whereas the top PMMA layer is of lower molecular weight and contains an internal mold-release agent. This process sequence combining plastic impression molding with x-ray lithography is illustrated in Figure 10.30. The two-step resist then facilitates the fabrication of a mold insert by electroforming, which can be used for the molding of two-step plastic structures. Extremely large structural heights can be obtained from the additive nature of the individual microstructure levels.

There are several options to achieve miniaturized features with slanted walls. It is possible to modulate the exposure/development times of the resist, fabricate an inclined absorber, angle the radiation, or, following Tabata et al.,[71] move the mask during exposure in so-called *moving mask deep x-ray lithography* (M^2DXL) (Example 10.2).

To make a slanted absorber, a slab of material can be etched into a wedge by pulling it at a linear rate out of an etchant bath. Changing the angle at which synchrotron radiation is incident on the resist, usually 90°, also enables the fabrication of microstructures with inclined sidewalls.[72] This way, slanted microstructures may be produced by a single oblique irradiation or by a swivel irradiation (see Figure 2.# for an example). One potentially very important application of microstructures incorporating inclined sidewalls is the vertical coupling of light into waveguide structures using a 45° prism.[73] Such optical devices must have a wall roughness of less than 50 nm, making LIGA a preferred technique for this application. The sharp decrease of the dose in the resist underneath the edge of the inclined absorber, and the resulting sharp decrease of the dissolution of the resist as a function of the molecular weight in the developer, results in little or no deviation of the inclination of the resist sidewall over the total height of the microstructure.

In Chapter 8, we described additional means to fabricate slanted and curved metal shapes using electrochemical and electroless plating.

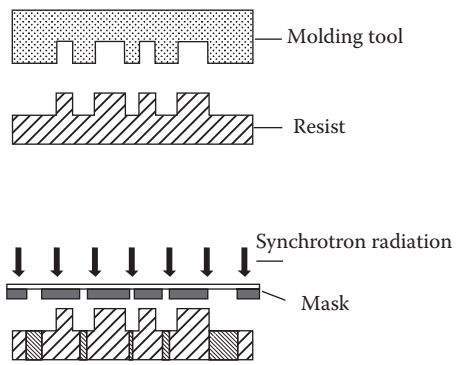

FIGURE 10.30 Stepped microstructures. (From Mohr, J., C. Burbaum, P. Bley, W. Menz, and U. Wallrabe. 1990. *Microsystem technologies 90.* Ed. H. Reichl. Berlin: Springer. With permission.[70])

Development

X-ray radiation changes the polymer in the unmasked areas, and chemicals etch away the regions that have been exposed during development. To fully use the accuracy potential of synchrotron radiation lithography, it is essential that the resist/developer system have a ratio of dissolution rate in the exposed and unexposed areas of approximately 1000 (see above). The developer empirically arrived at by KfK consists of a mixture of 20 vol% tetrahydro-1,4-oxazine (an azine), 5 vol% 2-aminoethanol-1 (a primary amine), 60 vol% 2-(2-butoxyethoxy) ethanol (a glycolic ether), and 15 vol% water.[52,55,74] This developer causes an infinitely small dissolution of unexposed, high-molecular-weight, cross-linked PMMA and achieves a sufficient dissolution rate in the exposed area. It also exhibits much less stress-induced cracking than developers conventionally used for thin PMMA resists.

Systematic investigation of different organic solvents and mixtures of the above developer systems shows that solvents with a solubility parameter at the periphery of the solubility range of PMMA dissolve exposed PMMA slowly but selectively and without stress-induced cracking or swelling of unexposed areas. Solvents with a solubility parameter close to those of MMA show a much higher dissolution rate but cause serious problems related to cracking and swelling. As we have already seen, the application of excessively strong solvents also leads to more pronounced conical shapes in the test structures shown in Figure 10.27. An improved developer found in the above systematic investigation is a mixture of

tetrahydro-1,4-oxazine and 2-aminoethanol-1. Its sensitivity is 30% higher, but the process latitude is much narrower compared with the developer described above.[55]

KfK has built a machine for the development process, enabling the continuous and homogeneous transport of developing and rinsing agents into deep structure elements and the removal of the dissolved resist from these structures. Several substrates are arranged vertically on a rotor, with each structure surface facing out. During development, the developing agent flows toward the resist surface being developed, circulates, is filtered continuously, and the temperature remains controlled at 35°C. To stop development, less-concentrated developer solutions are applied to prevent the precipitation of already-dissolved resist. Three independent medium circuits are available for immersion and spraying processes.[43]

After development, the microstructures are rinsed with deionized water and dried in a vacuum. Alternatively, drying may be done by spinning and blasting with dry nitrogen. At this stage, the devices can be the final product, for example, as microoptical components, or they can be used for subsequent metal deposition.

Metal Deposition in LIGA and Pseudo-LIGA

Introduction

Electroplating, which is sometimes also called *electrodeposition*, is a process in which a metal is coated on a conductive surface through electrochemical reactions that are facilitated by an applied electrical potential. In this process, the surface to be coated is immersed into a solution of one or more metal salts. LIGA and pseudo-LIGA depend critically on metal deposition to replicate the master photoresist mold. The additive metal deposition process was detailed in Volume I, Chapter 7, where we discussed the electroplating of metals in high-aspect-ratio crevices, and in Chapter 8, this volume, where we compared electroless with electrodeposition and the crafting of slanted and curved plated metal shapes. In this section we add some modifications to the metal process when applied to high-aspect-ratio resist molds encountered in LIGA and pseudo-LIGA.

Nickel Electrodeposition

Physical Properties of Electrodeposited Nickel

Nickel, together with copper, is one of the most widely used metals in electroplating LIGA and pseudo-LIGA structures. A nickel sulfamate bath composition, optimized for Ni electrodeposition, is presented in Table 10.14. In addition to nickel sulfamate and boric acid as a buffer, a small quantity of an anion-active wetting agent is usually added. Sulfur-depolarized nickel pellets are used as anode materials (sulfur-depolarized nickel has sulfur cast into it to aid in anode corrosion and keep the anode from going passive) and are held in a titanium basket.[75]

Table 10.14 also lists operational parameters. Nickel sulfamate baths produce low internal stress deposits without the need for additional agents, thus avoiding a cause for more defects. The bath is operated at 50–62°C and at a pH value between 3.5 and 4.0. Metal deposition is carried out at current densities up to 10 A/dm^2. Growth rates vary from 12 (at 1 A/dm^2) to 120 µm/h (at 10 A/dm^2).

The hardness of the Ni deposits can be adjusted from 200–350 Vickers by varying the operating conditions. Hardness decreases with increasing current density. To reach a high hardness of 350 Vickers, the electroforming must proceed at a reduced current of 1 A/dm^2. Also, for low compressive stress of 20 N/mm^2 or less, a reduced current density must be used. Internal stress in the Ni deposits is not only influenced by current density but also by the layer thickness, pH, temperature, and solution agitation. In the case of pulse plating (see below under Pulse Plating), pulse frequency has a distinct influence as well.[76] From Figure 10.31 we derive that for thin Ni deposits the stress is high and decreases very fast as a function of thickness. For thick Ni deposits (>30 µm),

Table 10.14 Composition and Operating Conditions of Nickel Sulfamate Bath

Parameter	Value
Nickel metal (as sulfamate)	76–90 g/L
Boric acid	40 g/L
Wetting agent	2–3 mL/L
Current density	1–10 A/dm^2
Temperature	50–62°C
pH	3.5–4.0
Anodes	Sulfur depolarized

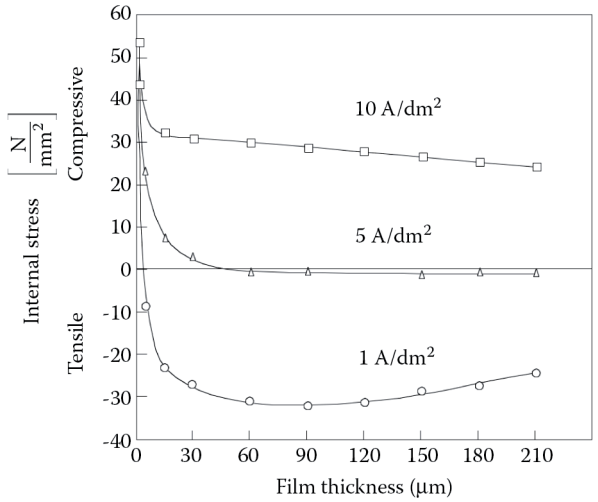

FIGURE 10.31 Influence of nickel layer thickness on internal stress. The electrolyte used is described in Table 10.14 (pH = 4; bath temperature = 52°C). (From Harsch, S., W. Ehrfeld, and A. Maner. 1988. *KfK report no. 4455.* Karlsruhe, Germany: KfK.[76]) (Courtesy of the Karlsruhe Nuclear Research Center.)

the stress as a function of thickness reaches a plateau. At a current density of 10 A/dm², these thick Ni films are under compressive stress; at 1 A/dm², they are under tensile stress; and at 5 A/dm², the internal stress reduces to practically zero. Stirring of the plating solution reduces stress dramatically, indicating that mass transport to the cathode is an important factor in determining the ultimate internal stress. Consequently, because high-aspect-ratio features do not experience the same agitation of a stirred solution as bigger features, this results in higher stress concentration in the smallest features of the electroplated structure. Because the stress is most severe in the thinnest Ni films, Harsch et al.[76] undertook a separate study of internal stresses in 5-µm-thick Ni films. For three plating temperatures investigated (42°C, 52°C, and 62°C), 5-µm-thick films were found to exhibit minimal or no stress at a current density of 2 A/dm². At 62°C, the 5-µm-thick films show no stress at 2 A/dm² and remain at a low compressive stress value of about 20 N/mm² for the whole current range (1–10 A/dm²). The internal stress at 2 A/dm² is minimal at a pH value between 3.5 and 4.5 of a sulfamate electrolyte (Table 10.14). Ni concentration (between 76 and 100 g/L) and wetting agent concentration do not seem to influence the internal stress. The higher the frequency of the pulse in pulse plating (see next section), the smaller the internal stress.

The long-term mechanical stability of Ni LIGA structures was investigated by electromagnetic activation of Ni cantilever beams by Mohr et al.[77] The number of stress cycles, N, necessary to destroy a mechanical structure depends on the stress amplitude, S, and is determined from fatigue curves, or S-N curves (applied stress on the x-axis and number of cycles necessary to cause breakage on the y-axis). Experimental results show that for Ni cantilevers produced by LIGA the long-term stability reaches the range of comparable literature data for bulk annealed and hardened nickel specimens. Usually, stress leads to crack initiation, which often starts at the surface of the structure. Because microstructures have a higher surface-to-volume ratio, one might have expected the S-N curves to differ from macroscopic structures, but so far this has not been observed. To the contrary, it seems that the smaller structures are more stable.

Pulse Plating

For the fabrication of microdevices with high deposition rates exceeding 120 µm/h, a reduction of the internal Ni stress can occur only by increasing the temperature of the bath or by using alternative electrodeposition methods. Increasing the bath temperature is not an attractive option, but using alternative electrochemical deposition techniques deserves further exploration. For example, using pulsed (≥500 Hz) galvanic deposition instead of a DC method can influence several important properties of the Ni deposit. Properties such as grain size, purity, and porosity can be manipulated this way without the addition of organic additives.[76] In pulse plating, the current pulse is characterized by three parameters: pulse current density, i_p; pulse duration, t_d; and pulse pause, t_p. These three independent variables determine the average current density, i_a, which is the important parameter influencing the deposit quality and is given by:

$$i_a = \frac{t_d}{t_d + t_p} i_p \qquad (10.5)$$

Pulse plating leads to smaller metal grain size and smaller porosity as a result of a higher deposition potential. Because each pulse pause allows some

time for metal cation replenishment at the cathode (e.g., Ni^{2+} enrichment) and for diffusion away of undesirable reaction products that might otherwise get entrapped in the metal deposit, a cleaner metal deposit results. The higher the frequency of the pulse, the smaller the internal stress in the resulting metal deposit.[76]

Pulse plating represents only one of many emerging electrochemical plating techniques considered for microfabrication. For more background on techniques such as laser-enhanced plating, jet plating, laser-enhanced jet plating, and ultrasonically enhanced plating, refer to the review of Romankiw et al.[78] and references therein.

LIGA and Pseudo-LIGA Plating Issues

Electrodeposition in High-Aspect-Ratio Resist Crevices In Volume I, Chapter 7 we studied how a microelectrode of the same size or less than the diffusion layer thickness δ could be expected to plate faster than a larger electrode because of the extra current resulting from the nonlinear diffusion (Volume I, Equation 7.131). This turns out to be incorrect: as derived from Volume I, Equation 7.132, describing the current to a metal electrode recessed in a resist layer, the nonlinear diffusion contribution increases with decreasing radius r, but it also decreases with increasing resist thickness, L. High-aspect-ratio features consequently plate slower than low-aspect-ratio features. Moreover, the hydrogen consumption accompanying cathodic reduction of the depositing metal in the high-aspect-ratio features causes the pH to locally increase. Because agitation is impossible in these deep crevices, an isolating layer might form (e.g., nickel hydroxide, in the case of Ni deposition), preventing further metal deposition. This all contributes to make the metal deposition rate, important for an economical production, much smaller than the rates expected from the linear diffusion model of current density in large, low-aspect-ratio structures.

A major cause of defects in electroplating in high-aspect-ratio features is an incomplete wetting of the microchannels in the resist structure. For example, the contact angle between PMMA and the plating electrolyte at 50°C lies between 70 and 80°. Thus, a wetting agent is indispensable for wetting the surface of the plastic structures for the electrolyte to penetrate into the microchannels. With a wetting agent, the contact angle between PMMA and the plating electrolyte can be reduced from 80 to 5°.[76] In the electroforming of microdevices, a much higher concentration of wetting agent is necessary than in conventional electroplating. A dramatic illustration of this wetting effect can be seen in the case of plating of Ni posts, as shown in Figure 10.32. In the case illustrated in Figure 10.32a, where only 2.5 mL/L of a wetting agent is added to the sulfamate nickel deposition solution (see Table 10.14), nickel posts with a diameter of 50 μm often fail to form. In the same experiment, no posts with a diameter of 5 and 10 μm form. Increasing the wetting agent concentration to 10 mL/L results in perfectly formed nickel posts with a diameter of 5 μm, as shown in Figure 10.32b.

Plating Compatibility Issues Two major sources of difficulty associated with plating of any metal structure in photoresist molds, not only the high-aspect ones described above, are chemical and mechanical incompatibility. Chemical incompatibility means that the photoresist mask may be attacked by the plating solution; mechanical incompatibility is film stress in the plated layer, which causes the plated structure to lose adhesion to the substrate.

If the plating solution attacks the photoresist even slightly, considerable damage to the photoresist layer may occur by the time a 200-μm-thick structure has been created. Therefore, the limiting thickness of a plated structure resulting from a chemical interaction is dependent on both the photoresist chemistry and the plating bath itself. In general, the plating bath must have a pH in the range of ~3–9.5 (acidic to mildly alkaline), a fairly wide range that can accommodate many of the commercially available photoresists. A surprising number of plating baths do not fall into that range, however. Baths, either very strongly acidic or more than mildly alkaline, tend to attack and destroy photoresist.

The plated structure must have extremely low stress to avoid cracking or peeling during the plating process. In addition, if the structure contains narrow features, the stress must be tensile because any compressive stress would result in buckling of the structure. The primary concern with regard to

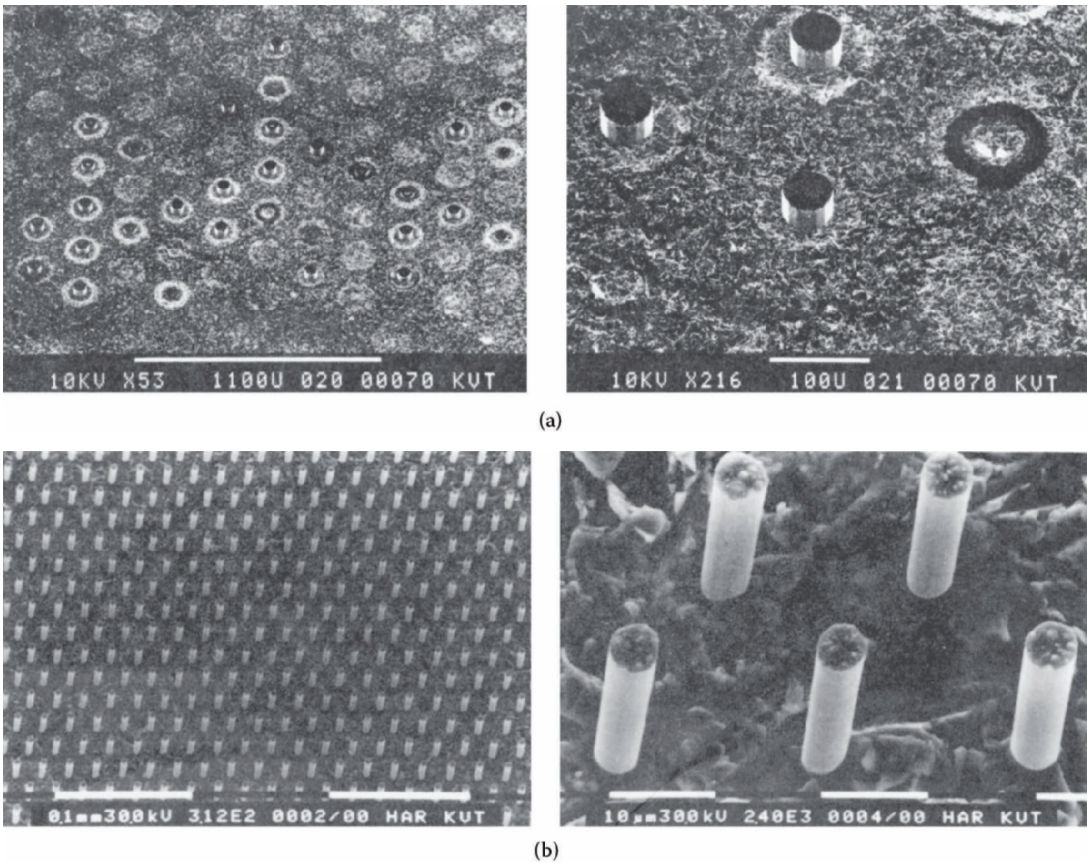

FIGURE 10.32 Electrodeposition of nickel posts of varying diameter. (a) Nickel posts with diameter of 50 µm. Only 2.5 mL/L wetting agent was added to the nickel sulfamate solution. Many 50-µm posts are missing, and posts with a diameter of 10 or 5 µm do not even form. (b) Nickel posts with diameter of 5 µm; 10 mL/L wetting agent was added, and all posts developed perfectly. (Courtesy of the Karlsruhe Nuclear Research Center.)

stresses is the incorporation of "brightening agents" into the plating solution. These can be selenium, arsenic, thallium, and ammonium ions, as well as others. The brightening materials often exhibit different atomic configurations and sizes compared with most materials that we would like to plate, such as Cu, Au, Ni, FeNi, Pt, Ag, and NiCo. This represents the source of a good deal of the stress intrinsic to the plating process. Ag and FeNi are notorious for their high stresses. The Ni-sulfamate bath, presently used extensively in LIGA, is used without brighteners, leading to Ni deposits with extremely low stress. Electroless plating baths (see Chapter 8) also are a good option: these *autocatalytic* baths coat indiscriminately but cause very low stress. They should be compatible with the LIGA process for certain applications, such as mold insert formation where significant overplating is required.

A third difficulty in finding plating baths compatible with LIGA is that most plating baths are not intended for use in the semiconductor industry. Information (including normal deposition parameters, uniformity, stress, compatibility with various semiconductor processes, and particulate contamination) normally supplied by a vendor is not available. Because the majority of the semiconductor industry does not incorporate these kinds of "thin film" processes, it may be difficult to determine whether a plating bath will be suitable simply from conversations with the vendor. In many instances, trial and error decide.

The treatise of electroplating in micropatterned resists is of importance for both micromachining and the IC industry. Additional reading on this topic is suggested (e.g., Masuko et al.,[79] Dukovic,[80] and Leyendecker et al.[81]).

Finishing Metal Parts and Metal Mold Inserts

Slight differences in final metal layer thickness cannot be avoided in the electroforming process. Finish

grinding of the metal samples with diamond paste is used to even out microroughness and slight variations in structural height. After finish grinding an electroplated LIGA or pseudo-LIGA work piece, a primary metal shape results from removing the photoresist by ashing in oxygen plasma or stripping in solvent. In the case of cross-linked PMMA, the resist may be exposed again to synchrotron radiation, guaranteeing sufficient solubility before stripping.

If the metal part needs to function as a mold insert, metal is plated several millimeters beyond the front faces of the resist structures to produce a monolithic micromold (see Figure 10.33). In the latter case, to avoid damage to the mold insert when separating it from the plating base, an intermediate layer sometimes is deposited on the base plate, ensuring adhesion of the resist structures while facilitating the separation of the electroformed mold insert from its plating base. In addition, it helps to prevent burrs from forming at the front face of the mold insert as a result of underplating of the resist structures. Underplating can occur because the resist does not adhere well to the substrate, allowing electrolyte solution to penetrate between the two, or the plating solution might attack the substrate/resist interface. Finally, microcracks at the interface might contribute to underplating. Burrs are easily eliminated then by dissolving the thin auxiliary metal layer with a selective etchant, removing the mold without the need for a mechanical load. In view of the observed underplating problems, it is surprising that Galhotra et al.[63] obtained good plating results by simply mechanically clamping the exposed and developed PMMA sheet to a Ni plating box.

Fabrication of microstructures with extreme structural heights by reaction injection molding. *First meeting of the European Polymer Federation, European symposium on polymeric materials*, pp. 241–51. Lyon, France. With permission.[28])

Plating Automation

An automated galvanoforming facility used by KfK is shown in Figure 10.34.[82] This setup includes provisions for on-line measurement of each electrolyte constituent in flow-through cells and concentration corrections when tolerance limits are exceeded. A computer-controlled transport system moves the individual plating racks, holding the microdevice substrates, through the process stages whereby the substrates are degreased, rinsed, pickled, electroplated, and dried and are then returned to a magazine, which can accommodate up to seven racks. The facility is designed as clean-room equipment because contamination of the microstructures must be prevented.[75] An instrument as described here can be bought, for example, from Reinhard Kissler (the µGLAV 750).[82] Although this type of automation is a must for the eventual commercialization of the LIGA technique, it should be recognized that at this explanatory stage overautomatization may be counterproductive.

Demolding

Introduction

Even high-aspect-ratio metal structures can be molded and demolded with polymers easily, as long as a polymer with a small adhesive power and rubber-elastic properties, such as silicone rubber, is used. However, rubber-like plastics have low shape stability and would not be adequate. Shape-preserving polymers, on the other hand, after hardening, require a mold with extremely smooth inner surfaces to prevent form-locking between the

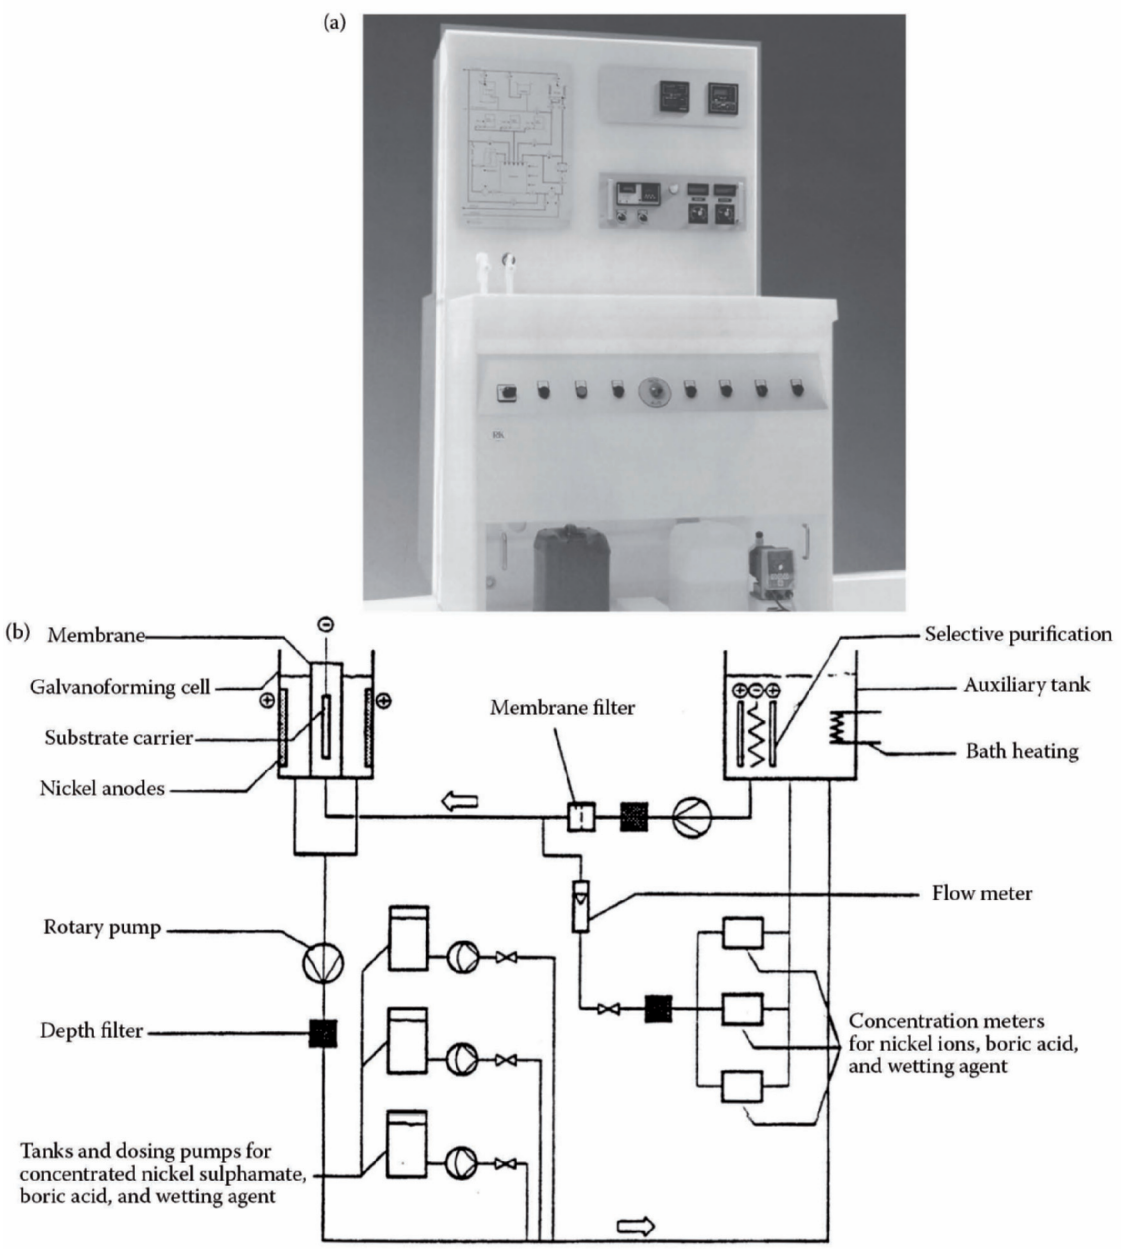

FIGURE 10.34 (a) The μGALV 750 comprises the galvanoforming cell with nickel anodes and substrate carrier and an auxiliary tank incorporating heating and purification auxiliary equipment. Three concentration meters measure nickel ions, boric acid, and the concentration of the wetting agent. The concentrations are adjusted automatically by adding via-metering pumps. mold and the hardened polymer. Mold release has a geometry aspect (i.e., smooth and slightly inclined mold walls) and a chemical aspect (i.e., mold release agents). A mold release agent may be required for demolding. Using external mold release agents is difficult because of the small dimensions of the microstructures to be molded because typically they are sprayed onto the mold. Consequently, internal mold release compounds need to be mixed with the polymer, hopefully without significantly changing the polymer characteristics.

Demolding in LIGA and LIGA-Like Applications

The demolding step in LIGA is often carried out by means of a clamping unit at preset temperatures and rates. Demolding is facilitated by slightly inclined

mold walls and an internal mold release agent such as PAT 665 (Wurtz GmbH, Bingen, Germany), normally used with polyester resins.[83] The optimum yield with this agent and Plexit M60 PMMA occurs at 3–6 wt%. The yield decreases very quickly to less than 3 wt% as adhesion between the molded piece and the mold insert becomes stronger. These adhesive forces are estimated by qualitatively determining the forces necessary to remove the plastic structures from the mold insert. An upper limit is 10 wt%, where the MMA does not polymerize anymore. At more than 5 wt%, the Young's modulus and hence the mechanical stability decrease, and at more than 6 wt%, pores start forming in the microstructures. The internal mold release agent also has a marked influence on the optimum demolding temperature. The demolding yield decreases quickly at more than 60°C for a 4 wt% PAT internal mold release agent. With 6 wt%, one can only obtain good yields at 20°C.[28,83] The molding process in LIGA initially led to a production cycle time of 120 min. For a commercial process, much faster cycle times are needed, for example, by optimizing the mold release agent. With that in mind, the KfK group started to work with a special salt of an organic acid, leading to a 100% yield at a release agent content of 0.2 wt% only and a temperature of 40°C (at 0.05 wt%, a 95% yield is still achieved). At 80°C, a 100% demolding yield was obtained, and significantly a cycle time of 11.5 min was reached. During these experiments the mold was filled at 80°C and heated to 110°C within 7.5 min. As the curing occurs at 110°C, the material needs to be cooled down to 80°C for demolding. Moreover, the 0.2 wt% of the "magic release agent" did not impact the Young's modulus and the glass transition temperature of Plexit M60.[83]

Use of Sacrificial Layers in LIGA

As in surface micromachining, sacrificial layers make it possible to fabricate partially attached and freed metal structures in the primary mold process.[84] The ability to implement these features leads to assembled micromechanisms with submicrometer dimension accuracies, opening up many additional applications for LIGA, especially in the field of actuators. The sacrificial layer may be polyimide, silicon dioxide, polysilicon, or some metal.[85] The sacrificial layer is patterned with photolithography and wet etching before polymerizing the resist layer over it. At KfK, a several-micrometers-thick titanium layer often is used as the sacrificial layer because it provides good adhesion of the polymer, and it can be etched selectively against several other metals used in the process. If before exposure the x-ray mask is adjusted to the sacrificial layer pattern, some parts of the microstructures will lie above the openings in the sacrificial layer, whereas other parts will be built up on it. These latter parts will be able to move after removal of the sacrificial layer.[70] The fabrication of a movable LIGA structure is illustrated in Figure 10.35.

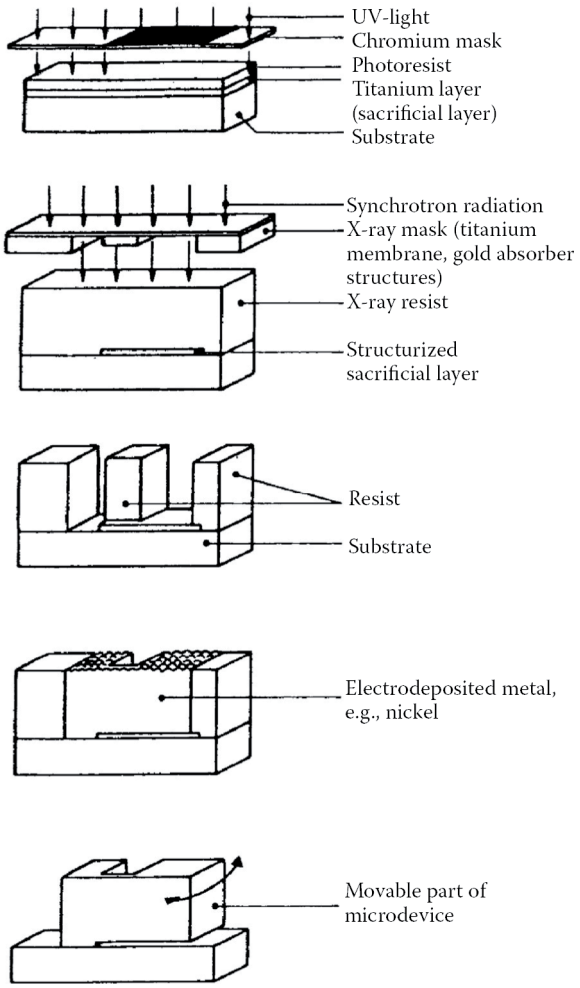

FIGURE 10.35 Movable LIGA microstructures. (From Mohr, J., C. Burbaum, P. Bley, W. Menz, and U. Wallrabe. 1990. *Microsystem technologies 90.* Ed. H. Reichl. Berlin: Springer. With permission.[70])

Molding Technology Applied to LIGA

Application of Reaction Injection Molding to LIGA

A laboratory-sized reaction injection molding (RIM) setup, as shown in Figure 10.36, was used by the KfK group for their LIGA work.[83] The setup consists of a container for mixing the various reactants, a vacuum chamber for evacuation of the mold cavity, the molding tool, and a hydraulic clamping unit to open and close the vacuum chamber and the molding tool. After the vacuum chamber has been closed and evacuated, the tool is closed by the clamping unit. The mixed reagents are degassed in the materials container and, under a gas overpressure of up to 3 MPa, pushed through the opened inlet valve into the tool holding the evacuated insert mold. To compensate for shrinkage caused by polymerization, an overpressure of up to 30 MPa must be applied during hardening of the casting resin. If the holding overpressure is too low, sunken spots appear in the plastic because of shrinkage of the polymer. For PMMA, the volume shrinkage is about 21%. If the mold material is not degassed and the mold cavity is not evacuated, bubbles develop in the molded piece, resulting in defects and possible partial filling of the mold. To harden the mold material and anneal material stress, the RIM machine is operated at temperatures up to 150°C.

To fabricate RIM-based microproducts, a variety of resins were tried, including epoxy resins, silicone resins, and acrylic resins. The most promising results are obtained with resins on an MMA base to which an internal mold release agent is added to reduce adhesion of the molded piece to the walls of the metal mold. The mold insert in the evacuated tool is covered by means of an electrically conductive perforated plate, called the *gate plate* (Figure 10.37a). For filling the mold, injection holes are positioned above large, free spaces in the metal structure, and low-viscosity reactants fill the smaller sections laterally. After hardening of the molded polymer, a form-locking connection between the produced part and the gate plate is established at the injection holes, permitting the demolding of the part from the insert (Figure 10.37b). No damage to the mold insert is observed after up to 100 mold/demold cycles, even at the level of an SEM picture. The secondary plastic structures formed are exact replicas of the original PMMA structures obtained after x-ray irradiation and development. If the final product is plastic, the molding process can be simplified considerably by omitting the gate plate. The mold insert is then cast over with the molding polymer in a vacuum vessel, building a stable gate block over the mold insert after hardening. The polymeric gate block is used to demold the part from the insert.

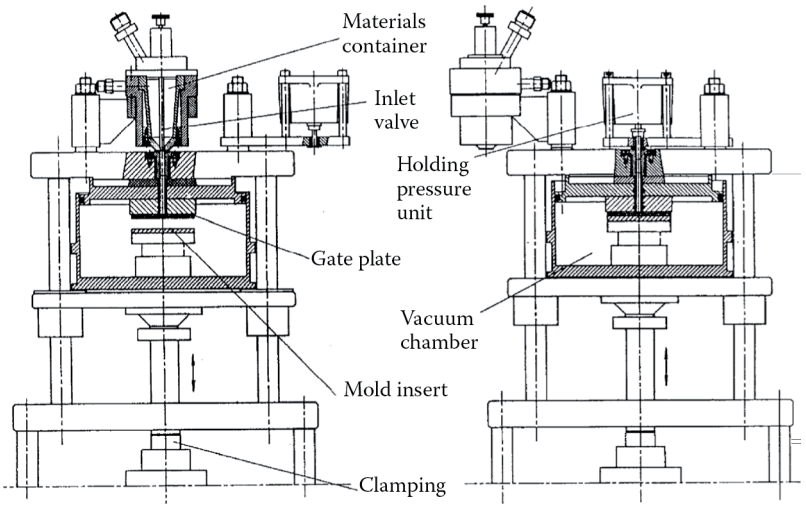

FIGURE 10.36 Schematic presentation of a vacuum molding setup. With minor changes, this setup can be used for reaction injection molding, thermoplastic injection molding, and compression molding. (From Hagmann, P., and W. Ehrfeld. 1988. Fabrication of microstructures of extreme structural heights by reaction injection molding. *J Polymer Process Soc* 4:188–95. With permission.[83])

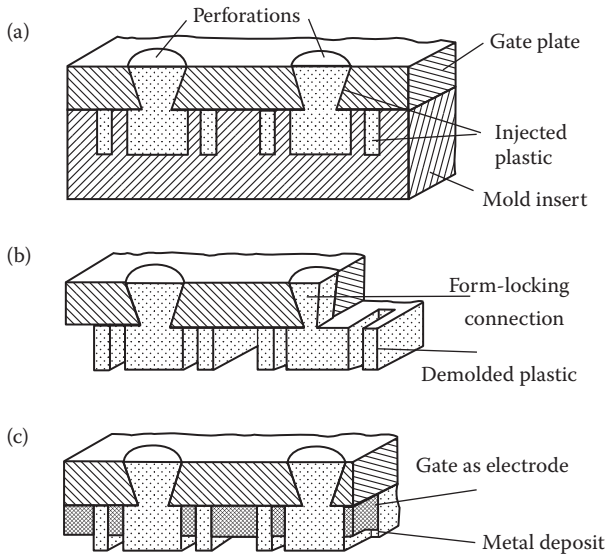

FIGURE 10.37 Molding process with a perforated gate plate. (a) Filling of the insert mold with plastic material. (b) Demolding. (c) Electrodeposition with the gate plate as plating base. (From Menz, W., and P. Bley. 1993. *Mikrosystemtechnik fur Ingenieure*. Weinheim, Germany: VCH Publishers.[67])

The secondary plastic templates may not be the final product and can be filled with a metal by electrodeposition as with the primary molds. In this case, the secondary plastic templates must be provided with an electrode or plating base. The gate plate can be used directly as the electrode for the deposition of metal in the secondary plastic templates (see Figure 10.37c). It is important that the mold insert is pressed tightly against the gate plate so that no uniform isolating plastic film forms over the whole interface between the gate plate and the mold insert; otherwise, electrodeposition might be impossible. Safe sealing between mold insert and gate plate is achieved by use of soft-annealed aluminum gate plates into which the insert is pressed when closing the tool. It was found that the condition to be met for perfect deposition of metal does not require that the gate plate be entirely free of plastic.[83] It suffices that a number of electrical conducting points emerge from the plastic film. Transverse growth of the metal layer produced in electrodeposition allows a fault-free, continuous layer to be produced. The secondary metal microstructures are replicas of the primary metal structures, and a comparison of, for example, a master separation nozzle mold insert with a secondary separation nozzle structure did not reveal any differences in quality. After the metal forming, the top surface must be polished and the plastic structures must be removed. Depending on the intended use of the secondary metal shape, one can leave it connected to the gate plate, or the gate plate can be selectively dissolved or mechanically removed.

Gate plates can be applied only if the microstructures are interconnected by relatively large openings. The injection holes in the gate plate are produced by mechanical means with openings of about 1 mm in diameter and must be aligned with large openings in the mold insert. Many desirable microstructures cannot be built this way. For example, in Figure 10.38, we show a Ni honeycomb structure with a cell diameter of 80 µm, a wall thickness of 8 µm, and a height of 70 µm.[86] The holes in a gate plate are too large to inject plastic into this structure, and the interconnections in the honeycomb are too small to provide a good transverse movement of the polymerizing resin. In this case an electrically conductive plastic is used instead. The Ni plating occurs on the conductive plastic carrier plate, which is fused with the insulating plastic of the microstructure.

Application of Compression Molding to LIGA

Compression molding or relief printing is the method of choice for incorporating LIGA structures on a processed Si wafer. In a first step, the mold material is applied by polymerization onto the processed wafer with an electrically isolating layer and overlaid with a metal plating base (Figure 10.39a). At the glass transition temperature, the plastic is in a viscoelastic condition suitable for the impression molding step. At more than this temperature (about 160°C for PMMA), the plastic is patterned in vacuum by impression with the molding tool. To avoid damaging the electronic circuits by contact with the molding tool, the mold material is not completely displaced during molding. A thin, electrically insulating residual layer is left between the molding tool and the plating base on the processed wafer (Figure 10.39b). The residual layer is removed by reactive ion etching (RIE) in an oxygen plasma etch (Figure 10.39c), freeing the plating base for subsequent electrodeposition. The oxygen RIE process is as anisotropic as possible so

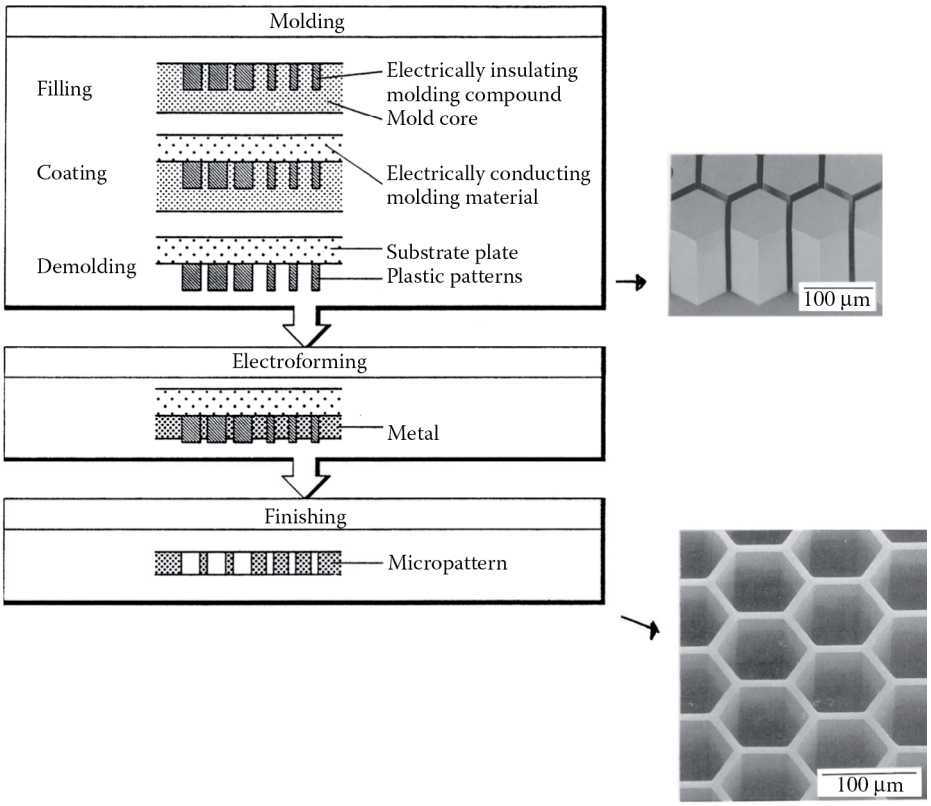

FIGURE 10.38 Ni honeycomb structure with cell diameter of 80 mm, wall thickness of 8 mm, and wall height of 70 mm. A structure like this could not be produced using a gate plate; a conductive plastic is used instead. [From Harmening, M., W. Bacher, and W. Menz. 1991. Molding plateable micropatterns of electrically insulating and electrically conducting poly(methyl methacrylate)s by the LIGA technique. *Makromol Chem Macromol Symp* 50:277–84. With permission.[86]]

that the sidewalls of the structures do not deteriorate, and the amount of material removed from the top of the plastic microstructures is small compared with the total height. After electrodeposition on the plating base, the metal microstructures are laid bare by dissolution of the mold material (Figure 10.39d). Finally, using argon sputtering or chemical etching, the plating base between the metal microstructures is removed so that the metal parts do not short circuit (Figure 10.39e). In the case of chemical etching, a very fast etch should be used to avoid etching of the plating base from underneath the electrodeposited structures.[5,50]

Comparison of Master Micromold Fabrication Methods

The high cost of x-ray lithography has caused many miniaturization engineers to search for alternate means for fabricating high-aspect-ratio metal, silicon, or polymer micromasters, or mold inserts.

Polymer micromold inserts are widely used in lost mold micromolding of metals and ceramics where the molds are removed by dissolving or thermal degradation after molding. However, this is not always the case; certain polymer micromold inserts, such as elastomeric mold inserts (e.g., polydimethylsiloxane), can be used repeatedly in soft lithography (see Chapter 2). The polymer mold inserts used for lost micromolding can be fabricated using photolithography, microstereolithography, and so on.

Most of the micromold inserts in micromolding are metal micromold inserts. Nickel is most commonly used because of the well-known nickel electroplating process and its low internal stress. However, the hardness of nickel is relatively low compared with metals such as iron and stainless steel, resulting in a limited lifetime for nickel mold inserts. Other materials such as nickel-iron or tungsten-cobalt alloys with higher hardness are considered for longer-lived metal micromold inserts. Metal micromold inserts (or micromasters) can be

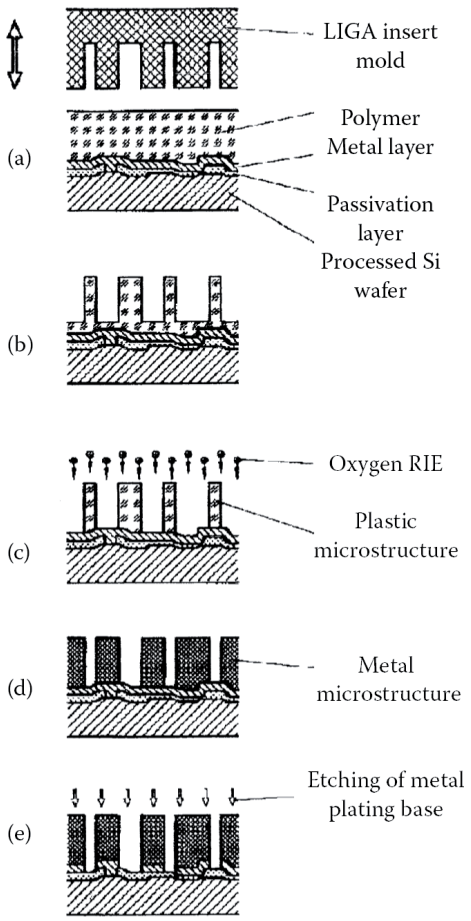

FIGURE 10.39 Fabrication of microstructures on a processed Si wafer. (a) Patterned isolation layer, conductive plating base, and in situ polymerization of PMMA. fabricated by a variety of alternate techniques, such as CNC machining, e-beam or ion-beam milling, precision EDM or excimer laser ablation of a piece of metal, thick deep UV resist photolithography, resist DRIE, silicon wet bulk micromachining, polymer excimer laser ablation, and polymer e-beam or ion-beam writing, all followed by electroplating (see Figure 10.1).

Both silicon wet and dry etching can be used for silicon mold insert fabrication. Silicon mold inserts have been applied to, for example, the hot embossing of polymer structures and for casting of ceramics. In Table 10.15, LIGA metal molds are compared with metal masters fabricated by other means. For example, comparing metal mold inserts made by spark erosive cutting and x-ray lithography, the latter proves far superior.[83] LIGA PMMA features as small as 0.1 μm are replicated in the metal shape with almost no defects. The electroformed structures have a superior surface quality with a surface roughness, R_{max}, of less than 0.02 μm.[28]

DRIE and thick deep UV-sensitive resists (DUV) such as polyimides, AZ-4000, and SU-8 are recent contenders for micromaster mold fabrication. With respect to dry etching, higher and higher aspect-ratio features are being achieved; especially when using highly anisotropic etching conditions as in cryogenic DRIE and in the Bosch process, remarkable results are obtained. Wall roughness, causing form locking, remains a problem with DRIE; the dry etching process was optimized for speed, not for demolding. For small-quantity production, where the lifetime of mold inserts is not crucial, a silicon

TABLE 10.15 Comparison of Micromolds

Parameters	LIGA	DUV	DRIE	LASER	CNC	EDM
Aspect ratio	100	22	10–25	<10	14 (hole drilling)	Up to 100
Wall roughness	<20 nm	~1 μm	~2 μm	1 μm–100 nm	Several micrometers	0.3–1 μm
Accuracy	<1 μm	2–3 μm	<1 μm	A few micrometers	See Figure 6.3	Some micrometers
Mask needed?	Yes	Yes	Yes	No	No	No
Maximum height	A few 100 μm up to 1 cm	A few 100 μm	A few 100 μm	A few 100 μm	Unlimited	Micrometers to millimeters

wafer etched by DRIE can be used directly as a mold insert for anywhere from 5–30 molding cycles.[88,89] Figure 10.40a shows such a Si mold for building a two-point calibration fluidic device on a compact disc (CD). Wet etching of Si leads to much smoother surfaces than DRIE (see, for example, the wet anisotropically etched Si nozzle in Figure 4.45b and compare that with the sidewall scalloping caused by Si DRIE in Figure 3.38) and is therefore the preferred method for making master molds out of Si. For much longer-lasting molds, metallizing the Si structure and using the metal as mold is preferred. Photoresist structures on a silicon substrate have also been tested as mold insert in plastic molding because of the simplicity and low cost of the process. Figure 10.40b shows an SU-8 photoresist mold for the same lab CD platform shown in Figure 10.40a. In low-pressure molding processes, such mold inserts work for a limited number of runs (applying a thin metal layer over the top of the resist may further extend the lifetime of the mold), but their applicability in high-pressure processes needs to be further verified. A better approach is to use DUV-photosensitive resists for electroplating to yield a metal tool, usually nickel or nickel-cobalt. Figure 10.40c shows a nickel mold insert made using SU-8 in our lab for the two-point calibration microfluidic platform. Both DUV and DRIE are more accessible than LIGA and will continue to improve, taking more opportunities away from LIGA. Like LIGA, both alternative techniques

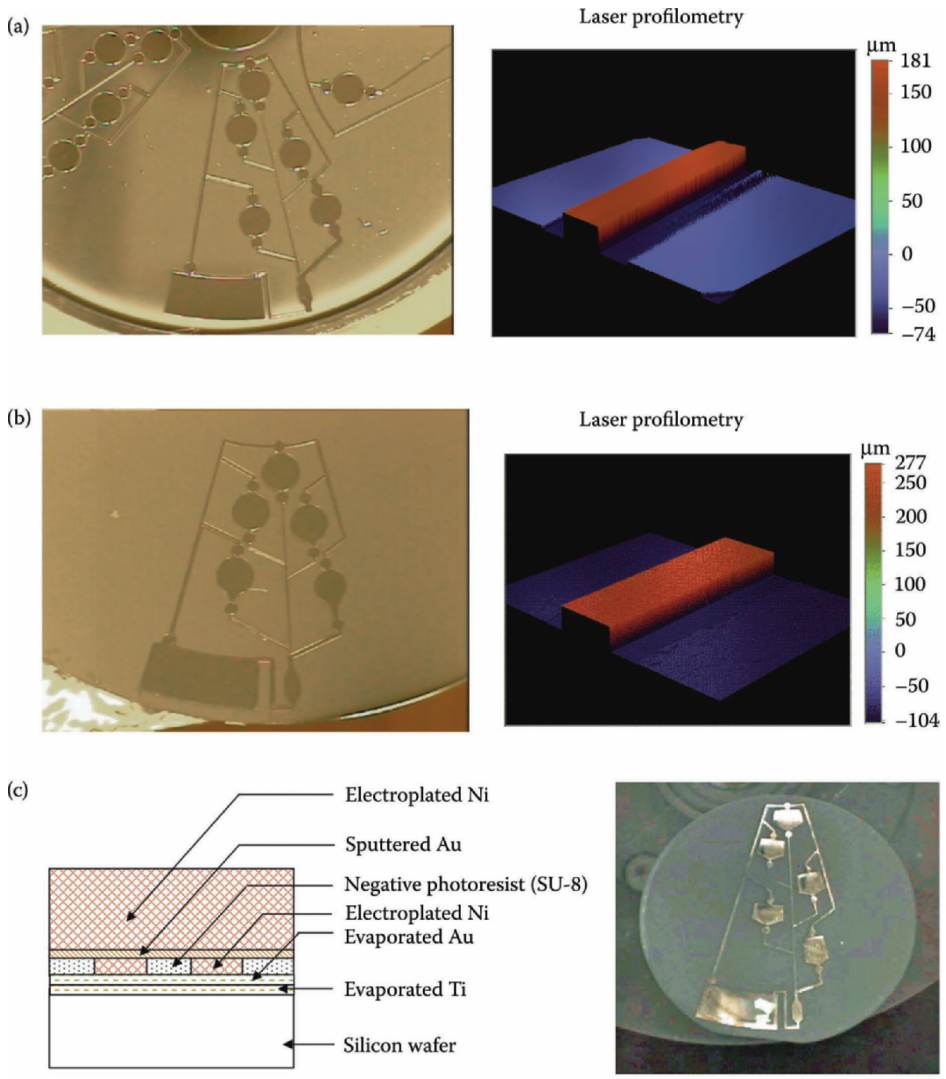

FIGURE 10.40 (a) Silicon mold insert made by UV photolithography and DRIE at Burstein Technologies/UCLA/OSU. can be coupled with plating, but neither technique can yet achieve the extremely low surface roughness and vertical walls of LIGA.

Other competing technologies for making metal masters are laser ablation methods and ultraprecision CNC machining. The latter two methods are serial processes and rather slow, but because we are considering the production of a master only these technologies are competitive for certain applications.

Laser microablation produces minimum features of about 10 µm width and aspect ratios of 1/10. Challenges include taper and surface finish control. Recast layers around the laser-drilled features cause form locking and infidelity in the replication. Femtosecond pulse lasers promise thinner or even the absence of recast layers and excellent resolution and should be investigated further for the manufacture of micromold inserts.[90]

For large features (>50 µm) with tolerances and repeatability in the range of about 10 µm, traditional CNC machining of materials like tool steel and stainless steel are often accurate enough for making metal mold inserts. The advantage of this technique is that the tool materials used are the same as those in conventional polymer molding; therefore, their design, strength, and service life are well established. Complicated 3D structures can also be machined easily. The main drawbacks are that it is difficult to make sharp corners or right angles, and the surface quality is usually poor (surface roughness is around several micrometers).[8] In contrast, lithographic methods can produce molds with excellent surface quality (surface quality <0.1 µm) and sharp corners or right angles. However, they cannot be used on conventional tool materials like steel. Diamond-based micromilling and microdrilling[91] reduce the surface roughness to 1 µm or less.[92] Although diamond-based machining methods can achieve features smaller than 10 µm, they are only applicable to "soft" metals such as nickel, aluminum, and copper.

From Table 10.15, a significant potential application of LIGA remains the fabrication of those metal molds that cannot be accomplished with other techniques because of the tight wall roughness tolerances,s small size, and high aspect ratios. From the table it is obvious that LIGA micromolds excel both in very low surface roughness and excellent accuracy.

Summarizing, the requirements for an optimal micromold insert fabrication technique are[93]:

- The master has to be removed from the molded structure, so the ease of release through wall inclination control is crucial (undercuts, for example, cannot be tolerated as they cause form locking)
- The most important parameter, including master lifetime and achievable aspect ratios, depends very strongly on the surface quality of the master
- The interface chemistry between master and polymer is a critical factor and must be controlled

Alternative Molding Materials in LIGA and Pseudo-LIGA

In this last section we discuss alternative molding materials for LIGA and pseudo-LIGA. Besides PMMA and POM (see above), used in a commercially available form, semicrystalline polyvinylidene fluoride (PVDF), a piezoelectric material, has been used to make polymeric microstructures.[69] The optimum molding temperature of PVDF is 180°C, and PVDF structures can be molded without using mold release agents. Fluorinated polymers such as PVDF will enable higher temperature applications than PMMA. PC, well known for molding CDs, is under development for LIGA and LIGA-like processes and should perform well.[51]

Other materials that have the ability to flow or be sintered, such as glasses and ceramics, can be incorporated in the LIGA and pseudo-LIGA processes as well. In the case of ceramics, for example, plastic microstructures are used as disposable or lost molds. The molds are filled with slurry in a slip-casting process. Before sintering at high temperatures, the plastic mold and the organic slurry components are removed completely in a burnout process at lower temperatures. First results have been obtained for zirconium oxide and aluminum oxide. An important application for ceramic microstructures is

the fabrication of arrays of piezoceramic columns embedded in a plastic matrix.

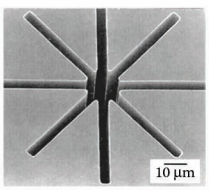
An alternative method to make LIGA and pseudo-LIGA ceramic or glass structures is based on sol-gel technology (see Chapter 8). This technique involves relatively low temperatures and may enable LIGA and pseudo-LIGA products such as glass capillaries for gas chromatography, piezoelectric arrays, and even high-T_C superconductor actuators. Sol-gel techniques should work well with LIGA and pseudo-LIGA-type molds if they are filled under a vacuum to eliminate trapped gas bubbles. In the sol-gel technique, a solution is spun on a substrate that is then given an initial firing at around 200°C, driving off the solvent in the film. Subsequently, the substrate is given a high-temperature firing at 800–900°C to drive out the remaining solvents and crystallize the film (see Figure 8.2). A major issue is the large shrinkage of sol-gel films during the initial firing. For example, the maximum thickness of high-T_C superconductor films currently achievable measures approximately 2 µm as a result of the high stress in the film caused during shrinkage. The latter is related to the ceramic yield or the amount of ceramic in the sol-gel compared with the amount of solvent. The sol-gel technique, in general, suits the production of thicker films well, as long as high-ceramic-yield sol-gels are used. Because LIGA-style films tend to be thick, a reduction in the amount of solvents to allow a high ceramic yield after firing would be to make sol-gel compatible with LIGA. This would require some development. Combining sol-gel technology with LIGA and pseudo-LIGA, lead-zirconium-titanate (PZT) piezoelectric devices can be made. In this case it is better to use the metal-plated structure rather than the direct PMMA template for the creation of the device because PZT must be processed in several elevated temperature steps. PZT sol-gel contains no particles that would prevent flow into small channels in a plated mold. The sol-gel contains high-molecular-weight polymer chains that hold the constituent metal salts, which are further processed into the final ceramic film. Thus, the sol-gel could be formed into the mold in a process much like reaction injection molding (RIM), with the mold filled with the chemistry under vacuum. Because the performance of piezoelectric actuator arrays is linked to the height and width ratio of the individual ceramic columns, as well as the distance between the columns in the array, LIGA, with its tremendous capacity for tall, dense, and high-aspect-ratio features, is an ideal fabrication tool.[94,95]

Examples

Example 10.1: LIGA Spinneret Nozzles

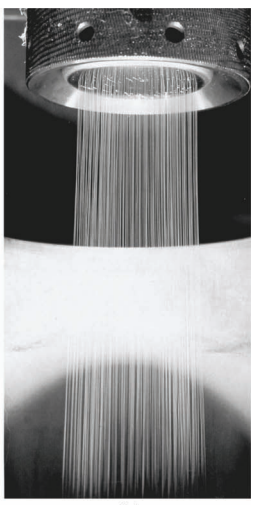
Profiled capillaries (nozzles) in a spinneret plate for spinning synthetic fibers from a molten or dissolved polymer, as shown in Figure 10.41, normally are produced by micro-EDM (see Chapter 5). This process establishes a practical lower limit of 20–50 µm for the minimal characteristic dimension, and the method cannot satisfy the requirements to produce complexly shaped, high-aspect-ratio spinnerets at a low cost. Smaller, more precise, and high-aspect-ratio nozzles can be produced by LIGA.[96]

Spinneret nozzles lend themselves to LIGA from the technical point of view. Compared with fabrication by micro-EDM, the minimum characteristic dimensions with LIGA can be reduced by an order of magnitude, and a high capillary length with excellent surface finish can easily be obtained. Moreover, the LIGA process makes all the nozzles in parallel, whereas micro-EDM operates as a serial technique. The market might focus on niche applications such as specialty, multilumen catheters. Also, medical use



(a)

(b)



(c)

FIGURE 10.41 LIGA spinneret nozzles. (a) Spinneret plate. (b) Profiled spinneret nozzles. (c) Spinning synthetic fiber. (Courtesy of IMM, Germany.)

of atomizers for dispensing drugs is projected to increase dramatically in the coming years; this might cause a run for a wide variety of precise, inexpensive micronozzles.

Shew et al.[97] used a conformal mask to fabricate a LIGA die with capillaries 2 mm deep and 70 μm wide for the mass production of electroplated spinnerets for the spinning of polyester fibers. The conformal mask eliminates the need of alignment steps accompanying the multiple exposure processes required in the deep x-ray lithography used by these authors. As illustrated in Figure 10.42A, a thin sputtered copper layer covers a thick PMMA layer on an Al substrate (a). A resist layer (JSR 137N, a negative photoresist from Japan Synthesis Rubber Co.) is then patterned on the copper layer by UV lithography, followed by plating gold absorbers (b). After stripping the resist and the Cu layer (c), the conformal mask is ready for multiple x-ray exposure and development steps (d) and die electroforming (e). The die (f) is made by electroforming of a NiCo alloy on the Al substrate from a Ni/Co sulfamate bath at current densities between 1 and 5 A/dm^2. The addition of increasing amounts of cobalt sulfamate increases the hardness of the deposit to about 420 Vickers. At a concentration higher than 20 g/L cobalt sulfamate, the hardness saturates. With increasing hardness also comes increased residual stress, which needs to be carefully controlled. Polypropylene (PP) was used to duplicate the NiCo microstructures by injection molding (IM) through a stainless steel tool as shown in Figure 10.42B. After removing sthe LIGA die, the result is a field of polymer microstructures standing up from the stainless steel tool. The stainless steel substrate is subsequently used for plating the spinneret structures.

Polyester fibers typically melt at 260°C and are extruded at speeds of more than 3,000 m/min. During this fiber extrusion, the spinneret suffers high-temperature excursions of up to 280°C, and high-temperature wear resistance becomes a problem when using a NiCo alloy. To improve the high-temperature hardness of Ni spinnerets, Shew et al.[97] plated a Ni/SiC composite. With the addition of SiC nanopowder to the sulfamate plating electrolyte, stable composite hardness of 500 Hv (Vickers hardness) at temperatures as high as 500°C was demonstrated. The authors suggest that these new types of spinnerets will enable the production of a new generation of fibers with ultrafine sizes and new functionalities at a low cost.

Example 10.2: Inclined LIGA Walls

Using LIGA, microstructures as high as hundreds or even thousands of micrometers can be achieved with an aspect ratio of 200, lateral

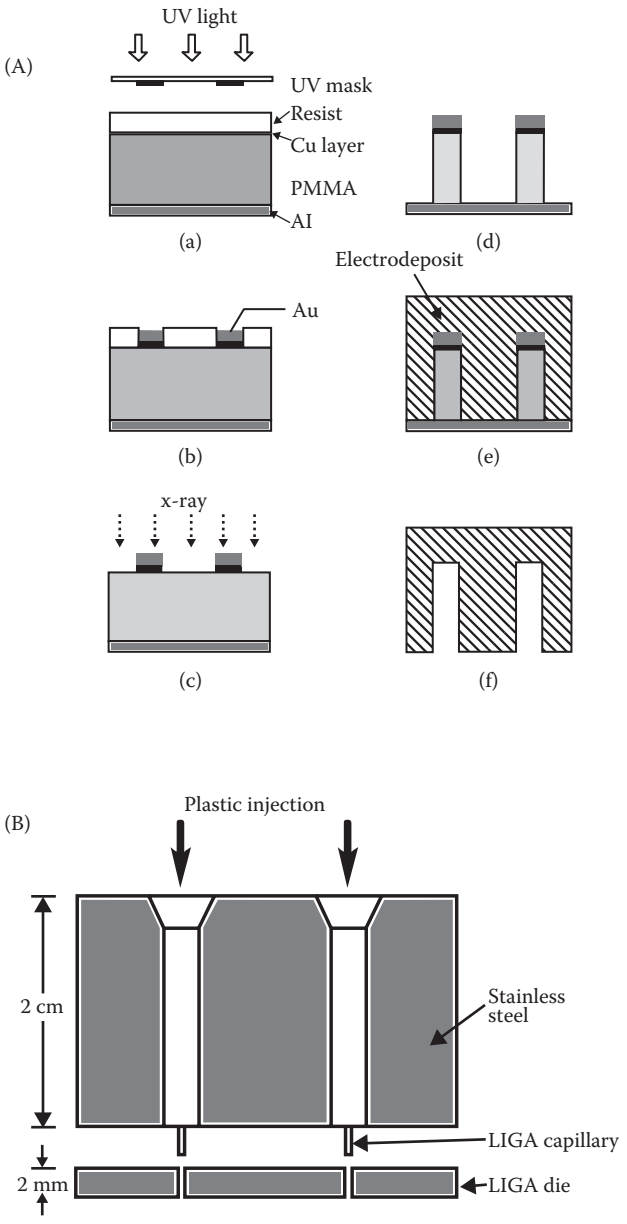


FIGURE 10.42 (A) Schematic diagram of the modified LIGA process (dimensions in this figure not to scale). (B) Replication process of the LIGA spinneret. (From Cheng, Y., B.-Y. Shew, C.-Y. Lin, D.-H. Wei, and M. K. Chyu. 1999. Ultra-deep LIGA process. *J Micromech Microeng* 9:58–63.[49])

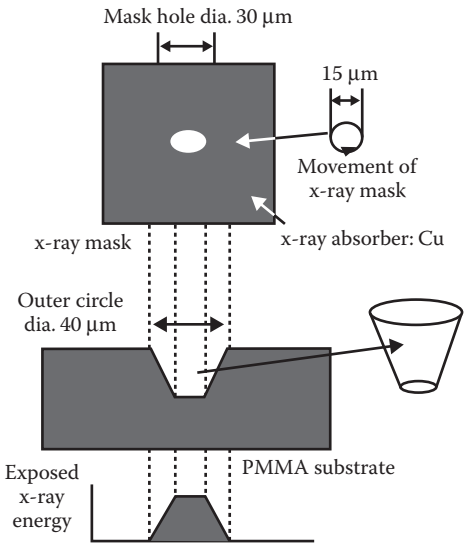

FIGURE 10.43 Principle of M²DXL. (Based on Tabata, O., H. You, H. Shiraishi, H. Nakanishi, T. Nishimoto, K. Yamamoto, and Y. Baba. 2000. *Micro total analysis systems 2000: proceedings of the μTAS 2000 symposium.* Enschede, the Netherlands: Kluwer Academic.[71])

dimensions smaller than 0.5 μm, accuracy of 0.1 μm, and wall perpendicularity of 90°. For many applications, inclined sidewalls would be a very useful addition to the LIGA tool box; for example, for making lenses or for easier release of molded parts. This second LIGA example concerns both these important applications. When using LIGA for plastic molding, such as through hot embossing, it is important to be able to control the resist wall inclination to facilitate the release of molded devices. To achieve this, one could make an inclined absorber or, following Tabata et al.,[71] one can also move the mask during exposure in M²DXL. The movement of the mask is realized by a precision *x-y* stage with a 10-nm step resolution. The principle of the technique is illustrated in Figure 10.43. Here, the x-ray mask with a circular hole of 30 μm is moved in a circle with a 15-μm diameter. The x-ray dose distributes according to the movement of the mask during exposure. As a result, the energy delivered to the PMMA photoresist shows a high constant value within the inner circle of the trajectory of the hole's movement and decreases with increasing trajectory diameter, becoming zero at the outside region. A truncated conical PMMA structure results with an inclination of the wall controlled by the diameters of the mask hole and its circular movement and the total x-ray dose.

For making inclined microfluidic channels whose depth is 40 μm, a mask with a channel width of 50 μm and mask movement of 10 μm was used. A good inclination for the sidewalls of microfluidic devices for easy release of molded parts is 80°. Tabata et al.[71] demonstrated that their technique may also be used to make microlens arrays. In the latter case, the mask hole diameter was 210 μm, and the mask movement 100 μm.

Example 10.3: LIGA Fiber-Chip Coupling

LIGA elements for coupling monomode fibers with integrated optical chips have been developed. These prealignment arrays may use fixed nickel guiding structures in combination with

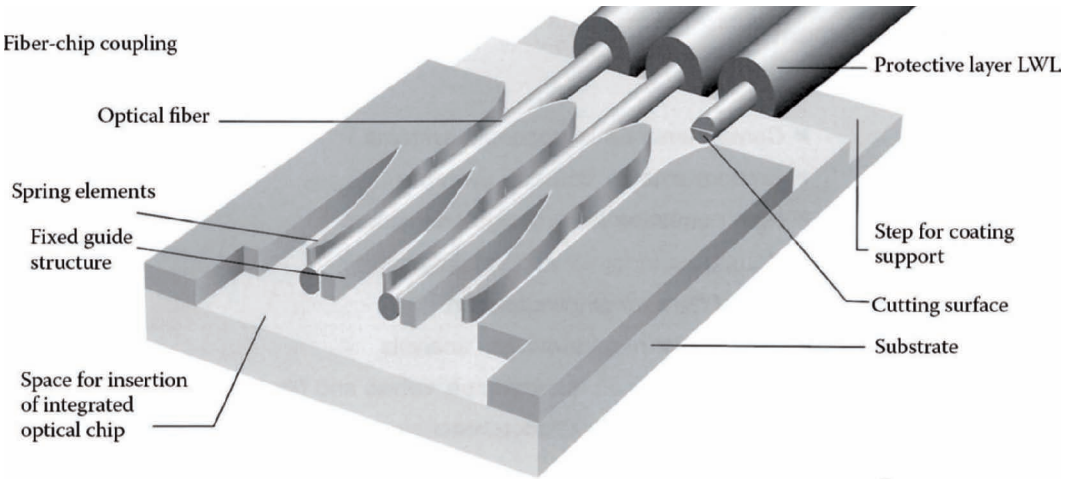

FIGURE 10.44 Coupling for monomode fibers with nickel spring elements. (Courtesy of IMM, Germany, http://www.imm-mainz.de/.)

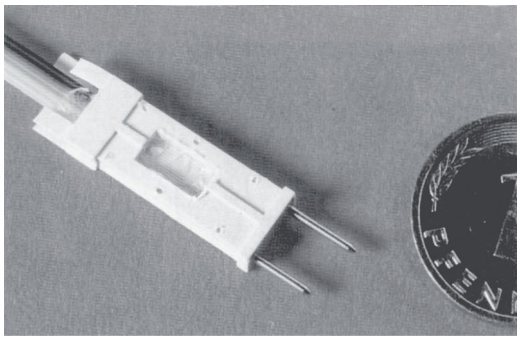

FIGURE 10.45 Pull-push connector for multimode fiber. (Courtesy of IMM, Germany, http://www.imm-mainz.de/.)

leaf springs to ensure a precise alignment of the optical fibers relative to the optical chip with accuracy in the submicrometer range, as shown in Figure 10.44. The thermal expansion coefficient of the substrate material is matched to the optical chip material—for example, a glass substrate is used for coupling fibers to glass chips—and the use of spring elements simplifies the handling of the fibers.[78] Alternatives involve the use of optical adhesives and silicon V-groove arrays (see Chapter 4). Both alternative technologies are more labor intensive and suffer from thermal expansion problems.

The use of microoptical LIGA components is especially attractive for the coupling of multimode fibers; here, the capability of exact lithographic positioning of mechanical mounting supports is used advantageously to position the multimode fibers very precisely with respect to the microoptical components without need for any additional adjusting operations.[73,98]

A pull-push LIGA connector for single-mode fiber ribbons, shown in Figure 10.45, incorporates a set of precision microsprings coupling up to 12 fibers spaced at 250 μm. It is now on the market and is one of the LIGA products with mass market appeal. To obtain good coupling efficiency, the fibers are positioned horizontally with a precision of 1 μm. LIGA is an excellent method to provide that type of precision. These connectors were developed at IMM.[99] In line with the micromanufacturing philosophy presented in this book (i.e., to optimize the use of each micromachining technique for optimal cost/performance application), those parts of the mold insert that do not require such high accuracy are fabricated using other methods of precision machining such as EDM (see Chapter 5).

Questions

10.1: Describe why a synchrotron is the best tool for producing the x-rays required to make the most accurate LIGA parts and make a table comparing x-ray lithography with UV lithography.

10.2: An electroplating solution containing nickel sulphamate is used to electroplate nickel LIGA structures. The formula incorporates 450 g of nickel sulphamate [$Ni(NH_2SO_3)2$] per liter of water (plus some additives). The solution is heated to 50°C. Assuming the plating is occurring on a nickel cathode.

(a) Calculate the concentration of the Ni^{++} ions in the solution.

(b) Calculate the equilibrium voltage across the nickel-solution interface at the cathode prior to electroplating.

(c) If the plating is occurring inside high-aspect-ratio PMMA cavities with a depth of 500 micrometers, and the diffusivity of Ni^{++} ions in water is 5×10^{-6} cm^2/s, calculate the limiting current density (mA/cm^2) assuming the boundary layer thickness is governed by the height of the PMMA.

(d) Plot the current density versus potential curve at the cathode using the values provided from part (c).

(e) If the current density is specified at 75 mA/cm^2, what is the likely result (qualitatively)?

(f) If the pH of the solution is 4 and the hydrogen ion diffusivity is 3×10^{-5} cm^2/s, calculate the limiting current associated with the reaction $H^+ + e \rightarrow 0.5\ H_2$.

10.3: What is the difference between a thermoplastic, a thermoset, and an elastomer? Give three examples of each.

10.4: Assume a polymer is under a tensile load at a variety of temperatures from –20°C to its

breakdown temperature at 150°C. Outline the potential stress-strain diagrams that may be found for a thermoplastic polymer under very short loading times.

10.5: What is viscoelastic polymer? Plot the stress-strain curve for a viscoelastic polymer.

10.6: Consider a laboratory setup (Galvanic cell) with a bar of copper (Cu) and a bar of silver (Ag) immersed in an electrolyte solution. The following are the redox half reactions and electrochemical potentials. The Gibbs free energy = (–) number of electron exchanged × electrochemical potential × Faraday constant. For a reaction to spontaneously occur, the Gibbs free energy must be negative.

$$Ag^{+} + e^{-} \rightarrow Ag \qquad E° = 0.80\ V$$
$$Cu^{++} + 2e^{-} \rightarrow Cu \qquad E° = 0.34\ V$$

(a) Will Ag react with Cu++ (i.e., will we be able to plate copper on the silver bar)?

(b) Will Cu react with Ag+ (i.e., will we be able to plate silver on the copper bar)?

(c) If you place a sheet of copper into an $AgNO_3$ solution, what would happen? What is the reaction?

10.7: Electrodeposition:

(a) In an electrochemical cell, we deposit Zn from a Zn^{2+} solution. After the deposition, we monitor the voltage of the Zn deposit with respect to a reference electrode (in this case we are using a standard hydrogen electrode, i.e., SHE). First we measure the potential in a $ZnSO_4$ solution at 10^{-2}M and then in a ZnSO4 solution of 10^{-3}M. What will be the change in potential of the Zn electrode between those two solutions? What is the potentsial in the 10^{-2}M solution? (E_o vs. SHE for Zn is –0.763V.)

$$Zn^{2+} + 2e^{-} \rightarrow Zn$$

(b) Explain the difference between electroless deposition and electro-deposition.

10.8: What issues do traditional plating and polymer molding companies face when trying to plate and mold LIGA-type structures?

10.9: Compare the pros and cons for injection molding, reaction injection molding, and hot embossing in LIGA. What are the differences in a micro part made with LIGA vs. pseudo-LIGA? How would you find out which technology was used, LIGA or pseudo-LIGA?

10.10: Describe two MEMS applications in which the use of LIGA may be justified.

10.11: Fabricate an x-ray mask detailing all materials and processes required. The mask should be adequate for the fabrication of Au parts with an aspect ratio of 50 (height over width).

10.12: For the following designs, decide which standard MEMS process (CMOS, LIGA, MUMPs) you would use and give a brief justification.

- You want to build a very cheap impact sensor.
- You want to build a rotating disk for a microoptical stroboscope.
- You want to build a strong microgear train.
- You want to build an array of structures with different resonance frequencies to test new theories on viscous damping.

10.13: Describe some techniques that may be employed for the fabrication of MEMS structures with slanted walls.

Index

A

Abrasive gas jet machining (AJM)
  abrasive powders, 375–376
  accelerometer in glass, 376–377
  erosion efficiency, 376
  erosion rate, 376
  material characteristics, 376
  microerosion process, 375–376
  powder blasting, 375–377
Abrasive machining
  categories of, 365
  conventional synthetic abrasives, 365
  electrolytic in-process dressing, nanofinishing of, 367–368
  grinding, 366–367
  jet machining-powder blasting, 375–377
  Knoop Hardness for, 366
  ultrasonic machining, 368–372
  water jet machining, 372–375
Abrasive water jet (AWJ) machining, 374–375
Additive (forming) processes, 386–389
Adhesion, of thin films, 445–447
Aerogel, 513–514
Aerosol decomposition synthesis, *see* Spray pyrolysis
Aerosol deposition (AD)
  characteristics, 412
  piezoelectrics in, 412–414
  schematic illustration, 412
  zirconate ceramics, 413
Aluminum oxide, 365
Analog devices accelerometer
  ADXL-50, 496–497
  IC chip preparation, for polysilicon, 498
  mechanical structure, 497
  polysilicon deposition and IC metallization, 498
  prerelease preparation and release, 499
Analog optical modulator, 470
Angle-dependent sputter rate, 175–176
Anisotropic etching
  ammonium hydroxide-water/tetramethyl ammonium hydroxide-water, 254
  Arrhenius plots, 255
  description, 250
  disadvantages, 251
  doping dependence
    etch stop region, 273
    mechanisms, 272
    moderate dopant concentration, 272–273
  etchants variety, 251
  ethylenediamine pyrocatechol, 253–254
  hydrazine (H_2N_4), 254–255
  masking for, 256–257
  potassium hydroxide, 252–253
  principal characteristics, 251–252
  procedure, 251
  semiconductor bias
    anodic dissolution, 280–281
    cyclic voltammogram, 280
    electroless etching, 280
    electropolishing, 281–282
    silicon, 282–296
  silicon wafer protection, 257
  Si surface roughness, 255–256
Anisotropy
  dopant-driven, 189–190
  energy-driven, 185–188
  inhibitor-driven, 188–189
Anodization, 556
Apertureless near-field scanning optical microscopy (ANSOM), 135–136
Aqueous development, 25
Arc-free plasma etching, 184–185
Arsine-doped epitaxial silicon, 427
Atmospheric plasma etching
  arc-free plasma etching, 184–185
  downstream plasma, 183–184
  voltage current plot, 182–183
Atmospheric pressure CVD (APCVD)
  carbon nanotubes, 428–429
  cold wall reactor type, 425
  continuous-feed, 427
  epitaxial Si, 425–427
  tetraethylorthosilicate (TEOS), with oxide, 427–428
Atomic layer deposition (ALD)
  Al_2O_3 process, 436–437
  applications, 435
  comparison of, 438
  flow of precursor, 436–437
  growth cycles, 435
  purge cycle, 436–437
  setup, 436
Atomistic model, Gosalvez–Kelly
  chemical oxidation, 267
  electrochemical mechanisms, 266–267
  nucleophilic attack representation, 265–266
  origin, 265
  Si etching process, 267
  surface microstructure, 268
  surface morphology, 267–268
Atomization, 568
Atom lithography/mechanosynthesis
  assembly sequence and schematic for, 134
  Au chains, STM topographic images, 132–133
  manipulation, for nanomatching, 132
5-Axis-HP-Milling Center Gamma High Performance 303 by WISSNER GmbH (Göttingen), 363

B

Backscattering, 177
Batch spray development, 25
Bis(aryl)azide rubber resists, 28–29
Black silicon, 181–182
Block copolymer lithography
  applications, 121–122
  diblock copolymer phase diagram, 118
  flash memory, 120
  investigation, 117
  patterned wettability, 120–121
  vs. traditional lithography, 119
Blocking mechanism, *see* Inhibitor-driven anisotropy
Blood gas sensor, excimer laser manufacture, 345
Boron nitride, 365
Borophosphosilicate glass (BPSG), 469
Bosch process, 197
Bulk matter, 405
Bulk micromachining, 392

C

Carbon nanotubes, APCVD, 428–429
Cathode dark space, 161
Charged-particle beam lithography
  DIB, 111–112
  direct write e-beam lithography, 104–105
  EBL, 104
  electron-and ion-beam applications, 103
  electron-beam resists, 106–107
  electron emission sources, 105–106
  electron projection lithography, 107–109
  FIB, 111
  IPL, 112–113
  maximum dose, 103
  micromachined electron emission sources, 109–111

Chemical forming, 510
organic layers, in bio-MEMS
glow discharge (plasma) polymerization, 518–520
Langmuir-Blodgett deposition and self-assembled monolayers, 523–524
organic film spin coating, 515
polymer casting, 517
polymer dip coating, 516
polymer doctor's blade/knife coating, 517–518
polymer dry film lamination, 516
polymer spraying, 516–517
silk screening/screen printing, 520–522
organic materials, patterning of
conductive polymer patterning, 534–535
digital mirror array patterning, 528–529
ink-jet printing, 528–532
mechanical microspotting, 532–534
microcontact printing, 534
photolithography, of hydrogels, gas-permeable membranes and ISEs, 524–525
proteins patterning, with lithography, 527–528
VLSIPS, 525–527
sol-gel technique
aerogel, 513–514
definitions, 512
gelation, 513
nanoparticle products and manufacture, 512
processes and products in, 513
silica sol formation, 514
xerogel, 514
Chemically assisted ion-beam etching (CAIBE), 185–186
Chemical machining, 149
Chemical-mechanical polishing (CMP) process, 70
Chemical milling, 218–219
Chemical vapor deposition (CVD), 69
advantages, 416
applications, 415
atmospheric pressure CVD (APCVD)
carbon nanotubes, 428–429
cold wall reactor type, 425
continuous-feed, 427
epitaxial Si, 425–427
tetraethylorthosilicate (TEOS), with oxide, 427–428
atomic layer deposition (ALD)
Al_2O_3 process, 436–437
applications, 435
comparison of, 438
flow of precursor, 436–437
growth cycles, 435
purge cycle, 436–437
setup, 436
cluster tools, 440
disadvantages, 416
epitaxy
epilayer thickness, 440
liquid phase epitaxy (LPE), 439
selective epi, 439–440
silicon, 438
solid-phase epitaxy, 439
equipment, 440
high-density plasma CVD (HDPCVD), 433
low-pressure CVD (LPCVD)
hot wall reactor, 429
polysilicon surface micromachining, 429–430
metalorganic CVD (MOCVD), 433–434
plasma-enhanced CVD (PECVD)
polysilicon, 432–433
reactor configurations, 431
silicon nitride, 432
vs. PVD method, 416
reaction mechanisms and reactor
atmospheric pressure CVD (APCVD), 421
boundary layer development, in gas phase, 418
configurations, 419
high-density plasma CVD (HDPCVD), 418
laminar development length, 419
low-pressure CVD (LPCVD), 421
mass transport, 420
material flux, 418–419
photon-and laser-assisted, 418
Reynolds number, 418
schematic of, 417
silicon growth rate, 420
temperature, 421
thermal entrance length, 419
transport and reaction processes, 416–417
reactions, 415
silane (SiH_4) with oxygen, 414
step coverage
arrival angle, 423
conformal coating, 422
deposited film, 422
mean free path, in various gases, 422
reactive sticking coefficient (RSC), 423–424
thin films, profile of, 421
transport of reactants, low pressures, 423
thin films, 414
Cold field emission (CFE), 105–106
Complementary metal oxide semiconductor (CMOS) transistors, 91
Compression molding
advantages, 599
application to LIGA, 630–631
cyclic and continuous process, 599–600
hot embossing, 600–601
principle of, 598
pros and cons, 601
Computer-controlled fabrication (CCF), 364
Computer numerical control (CNC) machining, 632, 634
Conductive polymer patterning, 534–535
Contact printing, 54–55
Conventional injection molding, 595–596
Copper electroplating
in printed circuit boards (PCB), 553–554
for thin film read-write heads, 551–553
Critical dimension (CD), 44
Critical modulation transfer function (CMTF), 62–63
Cross-linking resists, 26–27, 29
Curtain coating, 18, 20

D

Damage mechanism, *see* Energy-driven anisotropy
Damascene processes, 553–556
Deep ion-beam lithography (DIB), 111–112
Deep reactive ion etching (DRIE)
Bosch process, 197
characteristics, 197
electron cyclotron resonance, 198–199
inductively coupled plasma, 196–198
micromold, 632–633
MIT 59 method, 198
scalloping effects, 197–198
Deep UV-sensitive resists (DUV), 632–634
Deep x-ray lithography (DXRL), *see* X-ray lithography
Defocus tolerance, *see* Depth of focus (DOF)
Deposition method, 387–388
Depth of focus (DOF), 58–59
Descumming
definition, 25
dry resist
dry film roll, 38–39
high-aspect-ratio devices, 40
vs. liquid resist, 38–39
potential benefits, 40
dry stripping reactors, 43
glass transition temperature (T_g), 40–41
HMDS reaction mechanism, 41–42
negative resists
bis(aryl)azide rubber resists, 28–29
cross-linking, 26–27, 29

development, 26, 31–32
exposure, 26
lithographic sensitivity, 31
optical proximity effect, 30
pattern transfer, 26
vs. positive photoresists, 30
printed wiring boards (PWBs), 28
ozone-water method, 42–43
permanent resists
dry etching, 33
EPON resist, 34–35
flexible polyimide waveguide, 33
glycidyl ether, 34–35
imidization process, 32–33
LIGA, 37–38
photochemical acid generators (PAGs), 35
photosensitive polyimide process, 33–34
polyimides, 31–33
SU-8 resist, 34–36, 38
T-topping, 36–37
ultrahigh-aspect-ratio structures, 37
photoresist stripping, 42
positive resists
development, 26
diazonaphthoquinone ester (DNQ), 27–28
exposure, 26
pattern transfer, 26
PMMA, 27
polymer chain scission, 26–27
resist stripping
Dry, 43–44
wet, 42–43
resist tone, 26
solid-gas resist stripping, 43
tailoring resist sidewalls, 26
wafer priming, 41–42
Desktop factories (DTFs), 351, 355, 382
conventional and mesoscale machines, volumetric utilization, 380
die punching, 381
size of, 380
Diamond machining, 360–361, 365
Diazonaphthoquinone ester (DNQ) resist, 27–28
Digital micromirror device (DMD™), 461, 499–501
Digital mirror array patterning, chemical forming, 528–529
Dip coating, 20
Dip pen nanolithography (DPN)
principle of, 133–134
tDPN, 135
topographic image, AFM cantilever tip, 135
Direct write e-beam lithography, 104–106
Doctor blading, *see* Tape casting
DOF, *see* Depth of focus (DOF)
Dopant-driven anisotropy, 189–190
DRIE, *see* Deep reactive ion etching (DRIE)
Dry etching, 33
DC
glow discharge, 164–165
plasmas, 160–164
deep reactive ion etching (DRIE)
Bosch process, 197
characteristics, 197
electron cyclotron resonance, 198–199
inductively coupled plasma, 196–198
MIT 59 method, 198
scalloping effects, 197–198
definition, 156–159
dry *vs.*wet isotropic etching, 156
etch endpoint wavelength, 201–202
FTIR sensor capabilities, 202
isotropic etching, 159
methods, 157–158
models, in situ monitoring, 201–202
Paschen's law, 165–167
physical/chemical etching
carbon-containing additives, 195–196
chemically assisted ion-beam etching (CAIBE), 185–186
dopant-driven anisotropy, 189–190
energy-driven anisotropy, 185–188
etch ratios, 192, 194
F/C ratio, 193–194
features of, 190–191
gas compositions, 190–192
gas mixtures evolution, 192–193
hexode reactor, 185
III–V compounds, 195
inhibitor-driven anisotropy, 188–189
mask materials, 192, 195
metal etching, 195
organic films, 195
plasma etchants, 192, 194
reactive plasma gases, 192
selective *vs.* unselective, 194–195
substrate bias, 195
physical etching
energy requirements, 171
etching profiles, 175–177
focused ion beam (FIB), 174
ion-beam milling (IBM), 172–174
sputter deposition, 171
sputtering, 171–172
temperature control, 177–178
plasma-assisted, 157
plasmas, 159
polymeric materials, 208–209
post-CMOS processing, 207–208
profiles, 157–158
radical etching
atmospheric plasma etching, 182–185
macroscopic loading effects, 180–181
microloading effects, 181
reaction mechanism, 178–180
reactor configurations, 178
silicon grass/black silicon, 181–182
RF plasma reactors, 167–171
short dry etching synopsis, 157
silicon (Si), 203
single crystal reactive etching, 203–207
temperature control, 177–178
vapor-phase etching, 199–201
vs. wet etching, 209–211
Dry etching of silylated image resist (DESIRE) process, 75–76
Dry resist
dry film roll, 38–39
high-aspect-ratio devices, 40
vs. liquid resist, 38–39
potential benefits, 40
Dry stripping reactors, 43
Dynamic random access memory (DRAM), 91–92

E

EBL, *see* Electron beam lithography (EBL)
ECR, *see* Electron cyclotron resonance (ECR)
Edge-scattered radiation profile, 48
Electrical discharge machining (EDM), 347
characteristics, 321
μ-EDM, 323–327
sinker/cavity-type, 320–322
wire cutting, 322–323
Electrical discharge machining, wire cutting (EDM-WC), 322–323
Electrochemical fabrication (EFAB), instant masking, 557–559
Electrochemical forming, 511
applications of, 545
electroless metal deposition (*see* Electroless metal deposition)
IC industry and micromachining, 546
Electrochemical grinding, 225–226
Electrochemical isotropic silicon etching
apparatus, 246, 248
critical current density, 249
I-V curve, 248–249
reaction mechanisms, 249–250
two-electrode system, 248
Electrochemical jet etching, 229
Electrochemical machining (ECM)
advantages, 227
cathode tool characteristics, 227
schematic illustration, 226
service providers, 227–228
Electrochemical removal techniques
definition, 225
electrochemical jet etching, 229
grinding, 225–226
machining, 226–228
mask EMM, 230–231

metal removal rate determination, 231–232
microelectrochemical machining, 228–229
scanning electrochemical microscope (SECM), 230
Electroless metal deposition
electrodeposition
anodization, 556
copper electroplating for, 551–554
instant masking, in electrochemical fabrication, 557–559
localized electrochemical deposition, 560
microjet plating and laser-enhanced jet plating, 559–560
polymer masks, 556–557
principles, 549
single and dual damascene processes, 553–556
slanted and curved plated metal shapes, 560–561
through-mask electroplating, 550–551
plating
buried Cu conductor process, 548
in IC Industry, 548
in microfabrication, 549–550
principles
electroless and immersion deposition, 546
exaltants, 547
hydrogen reduction, 547
Ni deposition, 547
plating baths, 548
Electrolytic in-process dressing (ELID)
desktop machine, 369
grinding method, 368
setup for, 367
Electron beam lithography (EBL), 104–107
Electron beam machining, 348
Electron cyclotron resonance (ECR), 198–199
Electron cyclotron resonance CVD (ECR-CVD), 69–70, 433–434
Electronic ink, 521–522
Electronic stringency control, 564
Electron projection lithography (EPL), 107–109
Electron scanning probe lithography, bias effect, 130–131
Electrophoretic photoresist deposition (ED), 19–20
Electroplating, 622
Electrospray ionization (ESI), 574
Electrostatic spraying, 19
Elwenspoek et al.'s model
activation energy, 274
free energy change, 275–276
isotropic etching condition, 276–277
kinetic roughening, 276–277
roughening transition temperature T_R, 276
Energy-driven anisotropy, 185–188
Epitaxy
epilayer thickness, 440
liquid phase epitaxy (LPE), 439
selective epi, 439–440
Si, 425–427, 438
solid-phase epitaxy, 439
EPON resist, 34–35
Etch-back process, 69
Etch-stop techniques
boron, 258–260

I dedicate this third edition of Fundamentals of Microfabrication to my family in the US and in Belgium and to all MEMS and NEMS colleagues in labs in the US, Canada, India, Korea, Mexico, Malaysia, Switzerland, Sweden and Denmark that I have the pleasure to work with. The opportunity to carry out international research in MEMS and NEMS and writing a textbook about it has been rewarding in terms of research productivity but perhaps even more in cultural enrichment. Scientists have always been at the frontier of globalization because science is the biggest gift one country can give to another and perhaps the best road to a more peaceful world.

Roadmap

From MEMS to Bio-MEMS: Manufacturing Techniques and Applications consists of ten chapters in three parts. In Part I, we compare available manufacturing options for microelectromechanical systems (MEMS) and nanoelectromechanical systems (NEMS), introduce inspection options for the produced parts (metrology), and summarize available modeling software for MEMS and NEMS. Nonlithography-based (traditional) manufacturing techniques are contrasted with lithography-based (nontraditional) methods in Chapter 1. In Chapter 2, we investigate nature as an engineering guide, and we contrast top-down and bottom-up approaches in Chapter 3. In Chapter 4 we learn about packaging, assembly, and self-assembly from integrated circuits to DNA and biological cells. In these chapters we aim to help the reader decide upon an optimized manufacturing option to tackle specific manufacturing problems. We then introduce some selected new MEMS and NEMS processes and materials in Chapter 5. Finally, we cover metrology techniques for MEMS and NEMS and summarize MEMS and NEMS modeling in Chapter 6.

Of the three chapters in Part II, the first deals with scaling laws, the second with actuators, and the third with issues surrounding power generation and the implementation of brains in miniaturized devices. In Chapter 7, on scaling laws, we look at scaling from both intuitive and mathematical points of view. We are especially interested in deviations from linear scaling, where downscaling reveals new unexpected physical and chemical phenomena. The scaling chapter also constitutes an introduction to the subsequent treatises on actuators in Chapter 8 and on power and brains in Chapter 9. An actuator—like a sensor—is a device that converts energy from one form to another. In the case of an actuator, one is interested in the ensuing action; in the case of a sensor, one is interested in the information garnered. Scaling enables one to compare various actuator mechanisms, such as those proposed to propel a rotor blade, bend a thin silicon membrane, or move fluids in fluidic channels. Power generation poses quite a challenge for miniaturization science; the smaller the power source, the less its total capacity. We will consider the powering of miniaturized equipment, as well as the miniaturization of power sources themselves, in Chapter 9. In the same chapter, we also discuss the different strategies for making micromachines smarter.

In Part III, Chapter 10, we review the MEMS and NEMS markets. Today, the MEMS field has made the transition out of the laboratory and into the marketplace with a plethora of new products, including a strong entry into the consumer electronics field (mobile phones, cameras, laptop computers, games, etc.). If MEMS is entering adolescence, the word *nano* still seems to derive from a verb that means "to seek and get venture capital funding" instead of from the Greek noun for dwarf. Today, the market dynamics for MEMS and NEMS commercial products are very different, and we treat MEMS and NEMS applications separately in this chapter.

As highlighted in Chapter 1, which compares nonlithography-based (traditional) and lithography-based (nontraditional) manufacturing, we hope that a better understanding of how to match different manufacturing options with a given application will guide the identification of additional killer applications for MEMS and NEMS and encourage more companies and research organizations to innovate faster based on their in-house manufacturing tools and know-how.

Note to the Reader: *From MEMS to Bio-NEMS: Manufacturing Techniques and Applications* was originally composed as part of a larger book that has since been broken up into three separate volumes. *From MEMS to*

Bio-NEMS: Manufacturing Techniques and Applications represents the third and final volume in this set. The other two volumes include *Solid-State Physics, Fluidics, and Analytical Techniques in Micro- and Nanotechnology* and *Manufacturing Techniques for Microfabrication and Nanotechnology*. Cross-references to these books appear throughout the text and will be referred to as Volume I and Volume II, respectively. The interested reader is encouraged to consult these volumes as necessary.

Author

Dr. Madou is the Chancellor's Professor in Mechanical and Aerospace Engineering (MEA) at the University of California, Irvine. He is also associated with UC Irvine's Department of Biomedical Engineering and the Department of Chemical Engineering and Materials Science. He is a Distinguished Honorary Professor at the Indian Institute of Technology Kanpur, India, and a World Class University Scholar (WCU) at UNIST in South Korea.

Dr. Madou was Vice President of Advanced Technology at Nanogen in San Diego, California. He specializes in the application of miniaturization technology to chemical and biological problems (bio-MEMS). He is the author of several books in this burgeoning field he helped pioneer both in academia and in industry. He founded several micromachining companies.

Many of his students became well known in their own right in academia and through successful MEMS start-ups. Dr. Madou was the founder of the SRI International's Microsensor Department, founder and president of Teknekron Sensor Development Corporation (TSDC), Visiting Miller Professor at UC Berkeley, and Endowed Chair at the Ohio State University (Professor in Chemistry and Materials Science and Engineering).

Some of Dr. Madou's recent research work involves artificial muscle for responsive drug delivery, carbon-MEMS (C-MEMS), a CD-based fluidic platform, solid-state pH electrodes, and integrating fluidics with DNA arrays, as well as label-free assays for the molecular diagnostics platform of the future.

To find out more about those recent research projects, visit http://www.biomems.net.

Acknowledgments

I thank all of the readers of the first and second editions of Fundamentals of Microfabrication as they made it worthwhile for me to finish this completely revised and very much expanded third edition. As in previous editions I had plenty of eager reviewers in my students and colleagues from all around the world. Students were especially helpful with the question and answer books that come with the three volumes that make up this third edition. I have acknowledged reviewers at the end of each chapter and students that worked on questions and answers are listed in the questions sections. The idea of treating MEMS and NEMS processes as some of a myriad of advanced manufacturing approaches came about while working on a WTEC report on International Assessment Of Research And Development In Micromanufacturing (http://www.wtec.org/micromfg/report/Micro-report.pdf). For that report we travelled around the US and abroad to visit the leading manufacturers of advanced technology products and quickly learned that innovation and advanced manufacturing are very much interlinked because new product demands stimulate the invention of new materials and processes. The loss of manufacturing in a country goes well beyond the loss of only one class of products. If a technical community is dissociated from manufacturing experience, such as making larger flat-panel displays or the latest mobile phones, such communities cannot invent and eventually can no longer teach engineering effectively. An equally sobering realization is that a country might still invent new technologies paid for by government grants, say in nanofabrication, but not be able to manufacture the products that incorporate them. It is naïve to believe that one can still design new products when disconnected from advanced manufacturing: for a good design one needs to know the latest manufacturing processes and newest materials. It is my sincerest hope that this third edition motivates some of the brightest students to start designing and making things again rather than joining financial institutions that produce nothing for society at large but rather break things.

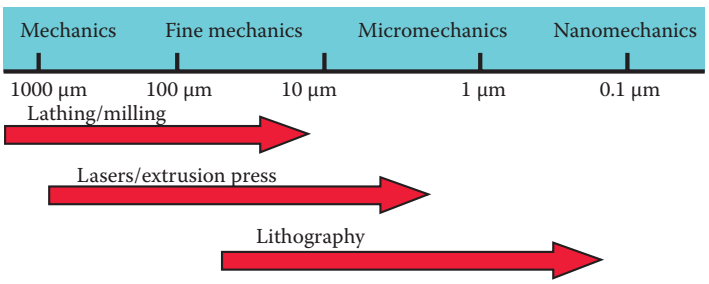
Part I

From Traditional Manufacturing to Nanotechnology

In ten years the only manufacturing left in the United States will be 1) those facilities vital to the defense industry, 2) those industries that are uniquely high-tech, 3) those that cannot absorb long-distance freight charges, and 4) those industries that service "on the spot" instantaneous demand (although even that is questionable).



From macromachining to nanomachining.

Introduction

Micromachining, or microelectromechanical system/nanoelectromechanical system (MEMS/NEMS), is emerging as a set of new manufacturing tools to solve specific industrial problems rather than as a monolithic new industry with generic solutions for every manufacturing problem. It is important to evaluate the merit of using one certain MEMS/NEMS technique above all the other available micromanufacturing options [say, lithography-based LIGA* (i.e., nontraditional manufacturing) vs. nonlithography computer numerical control machining (CNC) (i.e., traditional manufacturing)] so as to find the technique that is optimal for the application at hand—in other words, one needs to zero-base the technological approach to the problem.[1] For example, micromachinists are often not aware of the capabilities of traditional machining (nonlithography) and use Si micromachining for parts that could have been made better with a more conventional manufacturing technology. By applying the right tool to the machining job at hand, we hope that micromachining will lead to many more successful commercial applications than there are today.

We start this chapter by listing reasons why one might want to miniaturize a given device at all. We follow this with a short treatise on the maturation of MEMS into a bona fide manufacturing technique that is complimentary today to traditional manufacturing methods. We go on contrasting serial, batch, and continuous manufacturing processes and distinguish between lithography-based (nontraditional) and nonlithography-based (traditional) manufacturing methods, capturing all of this in a large comparison table. In this same context, we explore the difference between truly three-dimensional (3D) manufacturing with equal versatility of machining along all three axes and the more constrained manufacturing methods, such as lithography-based techniques, where the capabilities in one dimension (say the height or z-axis) are very different from those in the other two dimensions (say the x, y plane). We then justify our recommendation to design MEMS from the package inward rather than starting from the MEMS itself. Finally, we introduce a decision tree to help determine the best manufacturing choice for a miniature device when given its detailed specifications. The utility of this decision tree is demonstrated using, as an example, the micromanufacture of a disposable glucose sensor with glucose meter.

* LIGA is a German acronym for "**Li**thographie, **G**alvanoformung, **A**bformung," which in English is (x-ray) lithography, electroplating, and molding. It is a process in MEMS/NEMS that was developed in the early 1980s by a team under the leadership of E. Becker and W. Ehrfeld at the Institute for Nuclear Process Engineering [*Institut für Kernverfahrenstechnik* (IKVT)] at the Karlsruhe Nuclear Research Center. For details, Volume II, Chapter 10.

Why Use Miniaturization Technology?

Over the last twenty years, many MEMS applications have proven their mettle in the marketplace, and consumer electronic applications that started emerging over the last five years (MEMS are now found in iPods, computers, cameras, GPSs, etc.) have catapulted MEMS once more in the public eye. A long list of reasons confirms why miniaturization presents so many opportunities for product innovation in so many different areas. Some of the most obvious reasons for miniaturization are summarized in Table 1.1. Usually, not all those reasons apply at once. For example, the small dimensions of micromachines might be crucial in medical and space applications but often lack importance in the automotive industry, where cost is the more important driver.

Table 1.1 Why Use Miniaturization Technologies?

• Minimizing of energy and materials consumption during manufacturing
• Redundancy and arrays
• Integration with electronics, simplifying systems (e.g., single-point vs. multipoint measurement)
• Reduction of power budget
• Taking advantage of scaling when scaling is working for us in the microdomain, e.g., faster devices, improved thermal management
• Increased selectivity and sensitivity
• Minimal invasiveness
• Wider dynamic range
• Exploitation of new effects through the breakdown of continuum theory in the microdomain
• Cost/performance advantages
• Improved reproducibility
• Improved accuracy and reliability
• Self-assembly and biomimetics with nanochemistry
• More intelligent materials with structures at the nanoscale

In Volume I, Chapter 1, when analyzing Moore's law describing the exponential growth in integrated circuit (IC) transistor density, we pointed out that similar exponential improvement in technology sophistication pertains to engineering skills in optics, genetics, and magnetic storage density. Humankind seems "hard-wired" to continue to innovate at an ever-increasing rate (see also Ray Kurzweil's Accelerating Returns, in Volume II, Chapter 2). Miniaturization is just one of the most important means by which humankind is shaping its own destiny rather than being at the mercy of evolution. Adaptation through evolution operates at a pace too slow to produce humans who thrive in the ever faster environmental changes they have created for themselves. In other words, we might have no choice but to adapt through ever-increasing technology sophistication rather than our DNA.

From Perception to Realization
MEMS Finally Succeeds in the Market

In the early 1980s, Si micromachining seemed often applied to show the world that University X also had a clean room or that research group Y could make a yet longer-lasting surface micromachined micromotor. The earlier predicament of Si-based micromachining as the "GaAs of the 1980s and early 1990s" [that is, a very good technology with little acceptance from an entrenched and highly standardized industry (think also Mac vs. PC)] had something to do with the intellectual/philosophical climate of silicon MEMS research and development in the early 1980s. Francis Bacon (1561–1626) explained how, in the advancement of knowledge, one is easily misled by what he calls "idolatry." Two of the "idols" he identifies point in the direction of a universal tendency to oversimplify, often manifested by the assumption of more order in a given body of phenomena than actually exists, and a tendency to be struck by novelty.[2]

Both idols apply to how Si micromachining became misrepresented. Little commonality exists between the many different microdevices made possible by micromachining. Actually, MEMS products represent discontinuous innovations—they are not simply incremental improvements on a previously existing technology. Each new product requires some new thinking on the part of the developers. The striking visual aspects of Si micromachined devices easily give a sense of novelty to any observer. This second idol drove most of the interest in micromachining by the popular press and the efforts of many academics. This climate contributed to overly optimistic expectations for very fast results, with a market size dwarfing the IC industry, and an overemphasis on Si as an answer to all miniaturization problems. In Chapter 10, on MEMS and NEMS applications, we suggest that a realistic number for the market of Si MEMS products today is less than 3% of the IC market (even the $6.3 billion MEMS sales in 2006, i.e., 3% of the $211 billion IC market for 2006, does include non-Si devices). Subsequently, government and industry funding sources experienced a hangover.

Bacon's idols aside, the very large academic involvement in the micromachining field had some other explanations. The IC industry technologically and financially outdistanced universities and forcibly pushed the latter to explore topics requiring lower startup expenses and areas where innovation still seemed likely. It was a perfect fit, as micromachining is an excellent topic for numerous PhD topics. In the 1980s, Si micromachining became a favored filler for clean room overcapacity, especially in Europe, where the IC industry suffered major setbacks against US and Japanese competition. By the end of the century, it was apparent that the Si micromachining industry was still very small compared with the IC industry (less than 3%) but had large numbers of people involved in its research and development. Middlehoek and Dauderstadt estimated, as early as 1994, that about 10,000 researchers worldwide were involved in Si sensor research and that $7.5 billion had been spent over the preceding twenty-five years.[3] Many MEMS researchers have now switched to nanotechnology (NEMS) research instead.

Another major shortcoming in Si MEMS, as practiced in academia, pertains to the lack of interdisciplinary teams. More than any other field, microengineering requires interdisciplinary teamwork rather than specialists. Multidisciplinary work from the design phase on is crucial in the

development of a successful sensor product. Many of the participating university groups characterize themselves as multidisciplinary, but the opposite is often true; this lack of multidisciplinary focus continues to obstruct the production of more practical results. It reminds us of a statement by C.P. Snow (1905–1980), who remarked that the separate departments at a university had ceased to communicate with one another. The prefix *uni* in university, he said, lost its meaning as the institution, striving for more and more power as government funds replenished research dollars, had turned into a loose confederation of disconnected mini-states instead of an organization devoted to the joint search for knowledge and truth.

For micromachining to lose the stigma of a technology looking for an application, used in research backrooms and excess industrial clean rooms only, it became important for MEMS to realize some product successes. These industrial successes started appearing principally in the early to mid-1990s and include pressure sensors (on a small scale as early as 1972 at National Semiconductor), accelerometers (1992, from Analog Devices), projection displays (digital mirror devices from TI in 1995), ink-jet nozzles (thermal ink-jet from HP, 1984), electrokinetic platforms (Caliper and Agilent, 1999), fiber optic switches (NTT, 1995), and the first digital mirror device-based products (Texas Instruments, 1996). The first mechanical MEMS applications in industry were modest success stories only, with dollar evaluation in initial public offerings for mechanical MEMS companies typically only in the $5 million to $45 million range. Ever since biotechnology and information/communication industries started taking an interest in MEMS, huge stock market success stories began to appear, and large corporations bought small MEMS companies for billions of dollars. But today, many investors still cringe when they hear the terms *MEMS* or *NEMS*, because of the ill-fated optical MEMS bubble of the late 1990s and a BIOMEMS field that never seems to live up to its promises.

Fortunately, as we will learn in Chapter 10, on MEMS and NEMS applications, mechanical and optical MEMS in consumer electronics, started taking off over the last five years, and even MEMS for large optical switches in telecommunications is now regaining a foothold. The real MEMS breakthroughs continue to originate overwhelmingly from start-up companies (e.g., Illumina and Cepheid) and large corporations (e.g., ADI and Bosch) rather than academia. Micromachining in industry is more correctly seen as a diverse set of tools to solve practical problems in the crafting of subminiaturized 3D structures rather than as a goal by itself. The multidisciplinary approach and matrix organization of MEMS teams in industry further explains their more impressive MEMS accomplishments.

In academia, with its very vertical departmental structure and isolation from practical manufacturing and application understanding, miniaturization science is still often hyped beyond recognition in order to secure grants, tenure, or money from government agencies, large corporations, and venture capitalists. Describing academic MEMS efforts as unbiased fundamental work or fine-tuning of micromachining skills, rather than proclaiming each new result as the latest breakthrough in sensor technology or analytical chemistry, would often serve society better.

The new wave of nanomachining and nanochemistry efforts, mostly grounded in the fundamental research phase at this stage, holds the promise that university scholars might regain the miniaturization playing field in the near future. We can only hope that the hype surrounding nanotechnology settles down and that funding agencies and companies give researchers and scientists enough time to realize the stupendous opportunities that nanotechnology holds. To realize the economic potential of MEMS and NEMS, society will need a new generation of engineers who are comfortable with chemical and biological issues as well as many different types of micro- and nanomanufacturing considerations. Academia will have to become more matrix organized, if only to prepare the proper workforce for the coming age of nanomachining. From the fundamental point of view, micromachining and nanomachining are also of extreme interest, as these fields provide an excellent opportunity for operating experiments in a regime where continuum theory breaks down, holding the potential for discovery of important new chemical and physical phenomena. Unfortunately,

mounting funding pressures in the United States are forcing scientists to sell research as development and development as manufacturing. By putting their work in the context of a practical solution too early, academics might have lost some of industry's trust in the capabilities of micromachining and nanomachining. A breakthrough in deep, cryogenic etching or yet thicker vertical photoresist walls should stand by itself and does not necessarily need to be illustrated with the fabrication of wheels for micromotors! A better practice in the future might be to compare these new academic results (say, on new deep UV photoresists) with other, more traditional approaches so that the work becomes of generic value to a potential user for his or her own specific application.

Beyond Si-Based MEMS

New Si-based MEMS products are only a small part of the total projected MEMS markets, and there is ample room for non-Si-based companies in the MEMS markets of the future (e.g., microplastic molders, microelectroplaters, microceramic parts producers, etc.). Market predictions from the 1980s and early 1990s about the Si MEMS revolution were very mistaken; it is only by broadening the definition that MEMS is living up to the numbers that were quoted at that time. In Chapter 10 of this volume on MEMS and NEMS markets, we will see that when including non-Si MEMS, which many market studies do include now, and especially when also counting nonlithography-based MEMS (e.g., precision engineered microproducts; see below) (which very few market studies do yet), MEMS might very well constitute 10% of all current IC sales.

The market does not care about the type of miniaturization method employed for a new product, and for some time the Si micromachining community, especially in the United States, did not appreciate the tremendous accomplishments of alternative miniaturization methods. The HP Kittyhawk Personal Storage Module, a 1.3-inch disk drive, a compact disc (CD) optical pickup, and IBM's thin-film magnetic read-write head shown in Figure 1.1 are triumphs of precision engineering, and none involve Si-MEMS. The Kittyhawk (Figure 1.1a), introduced by HP in 1992, never caught on and seems to have been introduced before its time (Sony has continued its efforts on a similar MiniDisc). Kittyhawk was discontinued in September 1994. Approximately 160,000 units were sold (compared with a projected two-year sales of 700,000 units). In 1996, largely because of Kittyhawk's failure, Hewlett Packard closed its Disk Memory Division and exited the disk drive business. (The story of HP Kittyhawk was described in a Jan 26, 2006 Harvard Business School business case, "Hewlett-Packard: The Flight of the Kittyhawk."[64]) CD optical pickups and CD technology in general are other marvels of precision engineering, funded by billions of dollars in research and development (R&D) at Philips and Sony (see Figure 1.1b and 1.1c). This technology has not been exploited nearly as well as it should outside its traditional application area. We envision many nontraditional applications for this platform, such as its use as a sample preparation station and a molecular diagnostic tool as explored in this chapter, in Volume I, Chapter 6, and in Chapter 5, this volume. In diagnostic applications, the same CD technology may be used to read both analytical data (e.g., as a color change of a chromophore) and information (in the form of pits on the CD), to serve as a very inexpensive microscope (see Volume I, Figures 6.93 and 6.94) or as a high-precision x-y stage, etc. In this respect, one could legitimately ask the question, why are optical pickup heads not included in MEMS market studies when hard disc drive read-write heads often are? (See Chapter 10, this volume.) The answer is that these choices were made quite arbitrarily, underscoring the need to identify the criteria/definitions of MEMS and the manufacturing means used to make the microcomponents covered in any MEMS marketing report. The thin-film magnetic heads, shown in Figure 1.1d, are an excellent example of the commercial success one can achieve when identifying the correct machining option and materials combinations for a miniaturization task at hand. At $10 billion in sales in 2007, the thin-film magnetic head is still the most successful MEMS product today. The manufacture of the thin-film head is principally based on photolithography and electroplating of the coils and does not involve any Si. In 2009, read-write (RW) heads are still projected to have a market the size of all other Si MEMS

(b)

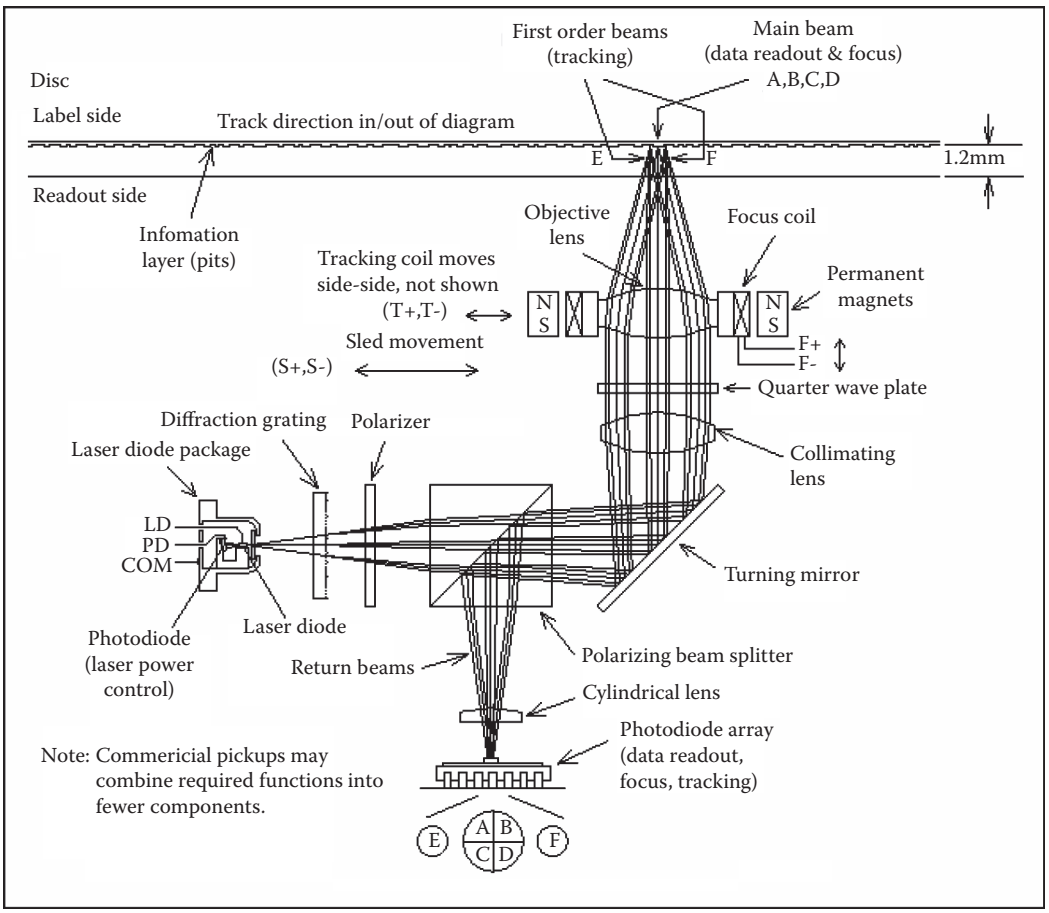

FIGURE 1.1 Triumphs of mechatronics. (a) HP's Kittyhawk. (From http://www.homebrewcpu.com/Pictures/kitty-hawk.jpg.) (b) CD optical pickup. General three-beam optical pickup organization. (From http://www.repairfaq.org/REPAIR/ F_cdfaq1.html.) (c) Physical realization embodied by the Sony KSS361A Optical Pickup (see http://www.repairfaq.org/REPAIR/kss110c.gif). (d) The evolution of magnetic read-write heads. From 1980 on, the magnetic coils were made by semiconductor-type technology (lithography and Cu plating) (http://dspace.cusat.ac.in/dspace/bitstream/123456789/2121/1/ GIANT%20MAGNETORESISTANCE%20EFFECT.pdf.)

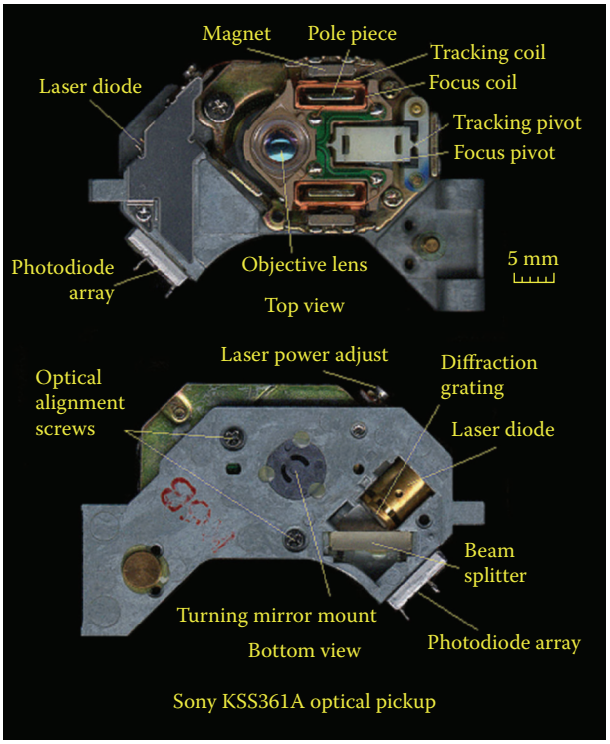
applications put together (see RW in Figure 10.15, this volume).

Because there are few established engineering rules and practices available to decide upon an ideal manufacturing technique from the wealth of options available for a given microapplication, good matches of machining methodology and application are often missed or rediscovered. Figure 1.2 illustrates the evolution of the types of manufacturing methods attempted for the construction of microfluidic elements. In the 1960s, microfluidic elements were principally made from photoglass; after attempting

(c)



(d)

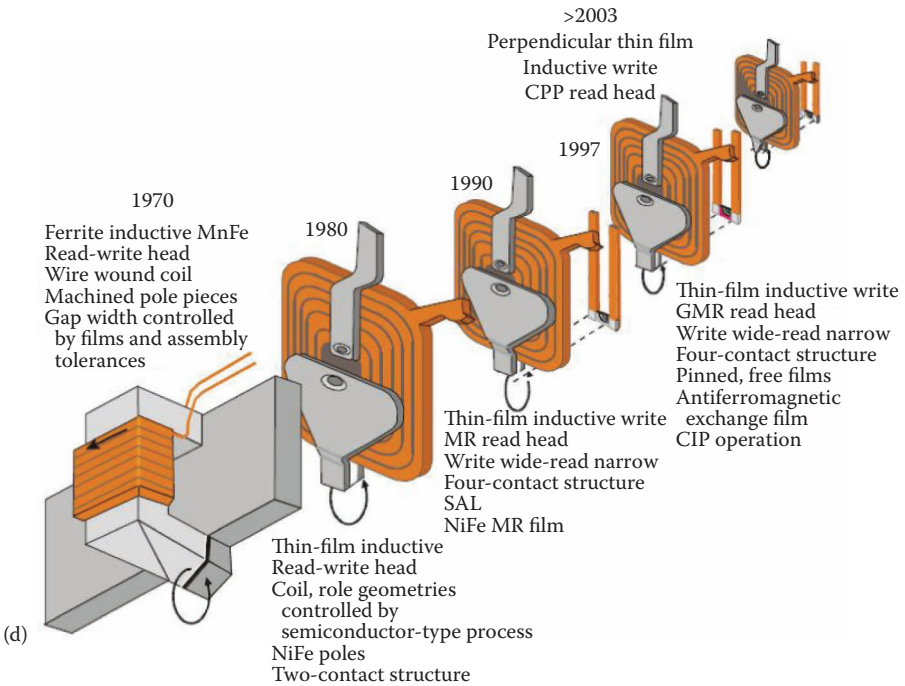


FIGURE 1.1 (*Continued*)

to craft the same devices by dry etching in Si in the 1980s at Stanford, LIGA was employed in the early 1990s. But by the mid-1990s, photoglass was rediscovered as the best machining option for some microfluidics applications. One might hope that by following a decision process flow researchers can avoid these costly loss and rediscovery cycles in the future.

As pointed out above, recent market studies cover Si and non-Si technology miniaturization applications, thereby achieving earlier projected large revenues that were expected to derive from Si micromachining alone. Some early market data on Si-based miniaturization were misleading in another way: they included big commercial successes

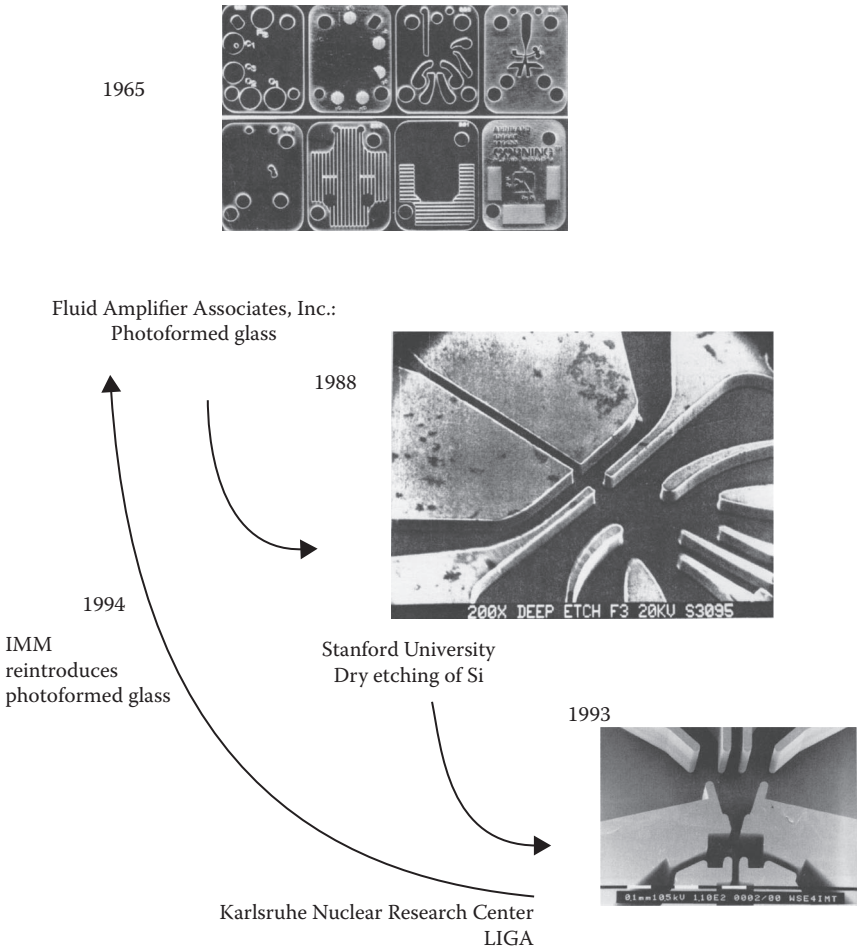

FIGURE 1.2 The rediscovery of photoformed glass for the manufacture of microfluidics.

in Si sensors such as simple photodiodes, charge-coupled detectors (CCDs), and Hall elements. The latter were, for the most part, developed before 1970 and are almost exclusively based on standard Si manufacturing techniques.

Serial, Batch, and Continuous Manufacturing Options

In serial manufacturing, a manufacturing station produces one product at the time. As an example for serial machining consider focused ion-beam milling, a mechanical removing technique detailed in Volume II, Chapter 6. Vasile et al., for example, describe a lathe mounted 20-keV Ga ion beam as the cutting tool for in-vacuum micromachining.[4,5] The ion beam they use is 0.3 μm in diameter, and they crafted tungsten needles, hooks, tuning forks, and specialized scanning probe tips. Two of their tungsten microstructures are shown in Volume II, Figure 6.33. Start-to-finish fabrication time for one of the objects shown here is about 2 hours! It should be noted that this expensive serial manufacturing technique might not make much sense for mass production of inexpensive consumer products but could be justified, for example, for the fabrication of an atomic force microscope probe tool set that could not be produced otherwise. On the other hand, to make a microshovel, as also shown in Volume II, Figure 6.33, is merely a fancy demonstration of the capabilities of this technique (call it a micro-"BS shovel"*).

In batch fabrication, a "group" or "batch" of identical products is produced in one single machining step. Batch fabrication techniques lend themselves to economies of scale that are unavailable with serial techniques. The use of batch processes is widespread throughout the manufacturing industry, producing a diverse range of products, including ICs,

* BS used to stand for *bullshit*; now it stands for *Bush Shit*.

pharmaceuticals, polymers, biochemicals, food products, and specialty chemicals. In the more advanced manufacturing techniques used for micromachining and nanomachining, batch fabrication typically involves some sort of a mask containing a desired repeated pattern that is positioned between the tool and work-piece. Then, that mask design is transferred to the work-piece using, for example, light (as in photolithography; Volume II, Chapter 1) or an abrasive slurry (as in abrasive jet machining; Volume II, Chapter 6). Alternatively, the tool itself contains an array of patterns that is transferred to the work-piece, for example, mechanically, through a slurry (as in ultrasonic machining; Volume II, Chapter 6), or thermomechanically (as in hot embossing; Volume II, Chapter 10). Most nontraditional micromachining carried out today, such as IC fabrication, relies on batch fabrication; that is, repetitive features are simultaneously defined on a work-piece. In the case of IC fabrication, an array pattern is photolithographically defined on a silicon wafer, and many wafers are then processed further to fabricate desired structures. We present as an example of batch fabrication, an array of finished CCD image sensors (to use, for example, in a digital camera), produced all in parallel on the same Si wafer, as shown in Figure 1.3. After production, these sensors need to be cut out of the Si wafer.

It is important to recognize that the use of a mask severely restricts the machining possibilities in the direction perpendicular to the mask. The resulting products, when using a mask, are projected shapes of the image on the mask only, with limited opportunities to shape the sidewalls of the work-piece perpendicular to the image on the mask. To illustrate this, think about precision mechanical machining, which is truly 3D since a diamond tool can cut in any direction, and contrast this with using a photomask in photolithography or a patterned tool in ultrasonic machining, where material removal forces work only in one direction and the resulting shapes are principally 2D. In the latter case, the dimension perpendicular to the mask may have differing heights (and indeed, we could say that we are dealing with a 2½D structure), but the shape of the sidewall can be modified only in a separate machining step.

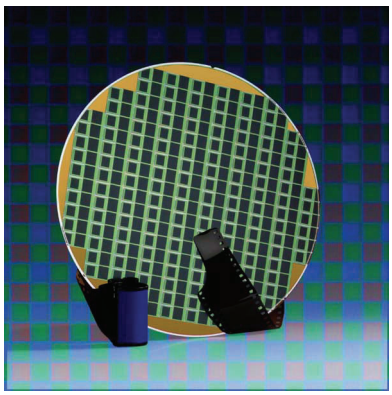

FIGURE 1.3 Charge-coupled detector (CCD) image sensors are formed on Si wafers and then cut apart. CCDs have replaced film as the image capture medium of preference. (Courtesy of IBM.)

Beyond batch manufacturing, the ultimate in automation of manufacturing is continuous or web-based manufacturing, with a web moving from supply roll to take-up roll [also called roll-to-roll (R2R) manufacturing*], with visions of low-cost photovoltaics (PVs), thin-film transistors (TFTs), large-area organic light-emitting diode (OLED) lighting, flexible displays, low-cost sensors, radio frequency identification (RFID) tags, etc. (see Figure 1.4). In this case, the product is made continuously, small or large, on flexible substrates, as shown in Figure 1.5. The flexible substrates replacing glass or Si must possess the desirable optical properties, thermal stability, low coefficient of thermal expansion, surface smoothness, and moisture and solvent resistance. Today, polymer films and stainless steel are the two flexible substrates of choice. R2R manufacturing dramatically increases throughput, with a significant reduction of capital and device costs.

Gordon Moore has argued that the only industry "remotely comparable" in its rate of growth to the semiconductor industry is the printing industry. It is worth noting that newspaper printing constitutes a continuous process; here, we promote the idea of continuous (beyond batch) miniaturization processes that, like a printer connected to a personal computer, will print out miniature objects in a continuous mode. Many of the manufacturing techniques we encountered in Volume II are already or can be modified to a roll-to-roll operation. This includes older

* Not to be confused with "run-to-run" or "run-by-run" control in semiconductor manufacturing.

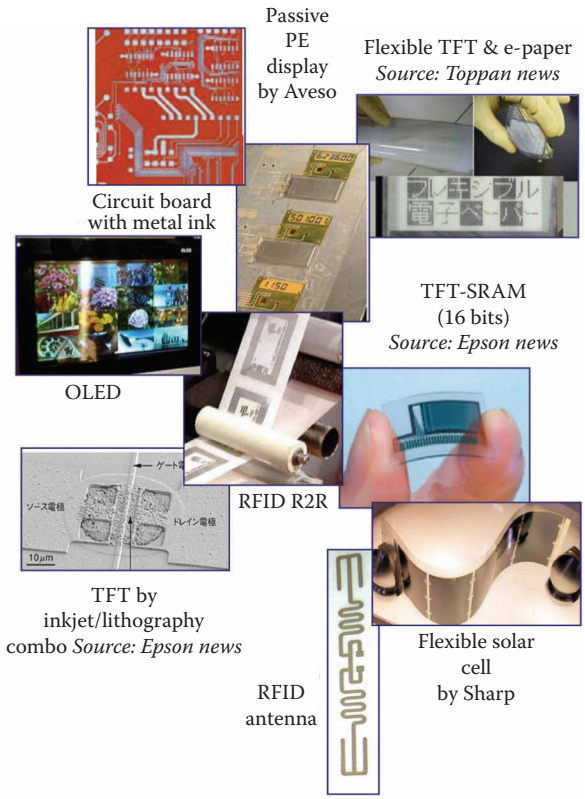

FIGURE 1.4 Examples of printed products on flexible substrates. For acronyms such as RFID, OLED, and TFT, please refer to the text.

technologies, such as doctor blade, ink-jet printing, laser machining, lamination, punching, drying and curing (in roll format ovens), picking and placing, hot-embossing, and sputtering (with cylindrical targets; see Volume II, Figure 7.12), and newer methods, such as imprint lithography [nanoimprint lithography (NIL) and step-and-flash imprint lithography (SFIL)], dip-pen lithography (DPL), etc. Soft lithography (patterning with flexible stamps; see Volume II, Figure 2.55) constitutes yet another possible means of transferring lithography patterns to a web-based process. In this case, the soft lithography pattern on the rubber stamp might be rolled up around a cylinder to ink a substrate continuously.

Processes, such as lithography, that need critical alignment and registration are the more challenging to incorporate in an R2R manufacturing process. But roll-to-roll or in-line equipment is also available for lithography. For illustration, in Figure 1.6, we show the lithography equipment procured by The Center for Advanced Microelectronics Manufacturing at Binghamton University in New York (http://camm.binghamton.edu). Established in 2005, this center is meant to spearhead development of next generation R2R electronics manufacturing capabilities. In Figure 1.6a we show a wet stripper/developer from Hollmuller-Siegmund that can handle a web of a width up to 15 in. The in-line lithography setup (Figure 1.6b) is from Azores Corporation and can handle webs that are 8 in. wide (expandable to 24 in.). This g-line machine comes with an accuracy of about 4 µm and can process photosensitive material at a speed of 230–760 mm/min. Hole-punch patterns are used for alignment. Many governments are taking notice of this important trend in electronics manufacturing. In Korea, for example, the Department of Printed Electronics Engineering in the World Class University (WCU) program of Sunchon National

FIGURE 1.5 Roll-to-roll (R2R) manufacturing. Production in kilometers and use and sale in centimeters.

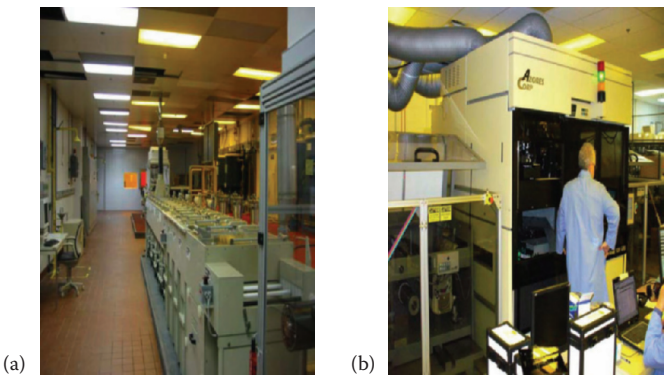

FIGURE 1.6 In-line lithography equipment. (a) wet stripper/developer from Hollmuller-Siegmund (can handle a web up to 15 in. wide). (b) in-line lithography setup from Azores Corporation can handle webs that are 8 in. wide (expandable to 24 in.).

University has been launched to lead in the fields of printed RFID and flexible lighting through Korean Government support that started in 2009.

Advances are being made continuously in "ink" technologies and printing processes and control; organic and printable electronics are expected to be a $35 billion industry by 2015 and reach over $300 billion in 2025, that is, almost twice the size of the Si industry today.

In Example 1.1, at the end of this chapter, we introduce a scenario for the continuous manufacture of polymer/metal-based biosensors—beyond batch.

Comparison Table

In Table 1.2, the most popular manufacturing techniques in crafting micromachines are compared. These tools are used to fabricate microstructures either in serial (Se), parallel (Ba for batch), or continuous (C) mode; the techniques can be organized in many different other ways, for example on the basis of the type of energy involved in the machining or as nonlithography-based (i.e., traditional—group 1) or lithography-based (i.e., nontraditional—group 2), i.e., truly 3D vs. truly 2½D. Table 1.2 is a listing of lithographic and nonlithographic miniaturization techniques with their respective resolutions, defined here as the smallest lateral features that have been generated. As a very rough rule of thumb, one might say that with dimensions below 100 μm one needs to switch from mechanical tooling (group 1) to optical tooling (group 2) to cut into a material.

Wet bulk micromachining, a very popular MEMS technique, had its genesis in the Si-based IC industry, but further development required the adoption and adaptation of several different processes and materials. Si-based wet bulk micromachining techniques involve anisotropic etching in the bulk of the material, often resulting in stunningly beautiful scanning electron microscope micrographs, are one of the most visual and "sexy" micromachining tools used—the MTV of miniaturization science. But in the trend toward miniaturization, almost a law of nature ever since the first oil crisis and the IC revolution, many other precision machining techniques on many different materials have also found commercial applications. Wet bulk Si micromachining, the most traditional form of Si micromachining (dominated by electrical engineers), has found acceptance in traditional precision machining circles (dominated by mechanical engineers) and vice versa: silicon micromachinists are starting to look at precision engineering techniques as a way to extend their tool kit. The most important characteristic for both disciplines is the ever-increasing quest for improved accuracies, higher aspect ratios, and reduced cost, and practitioners have recognized the complementary nature of their respective fields.

Whereas mechanical sensor manufacture is moving toward more integration of sensing functions with electronics, embodied in increased reliance on surface micromachining mostly involving the deposition and etching of thin films on top of a Si substrate, which is most compatible with IC fabrication, chemical and biosensors are moving away from integration and toward hybrid thick technology. This trend in chemical and biological sensors is caused by the need for modularity and the tremendous compatibility problems that arise when attempting to integrate chemical sensor materials with ICs.

From Table 1.2, Si micromachining then emerges as only one of the many options for precision machining. To emphasize the need for micromachinists to look beyond Si as the ultimate substrate and/or building material, we have presented many examples of non-Si micromachinery throughout this book. The need to incorporate new materials and processes is especially urgent for progress in chemical sensors and microinstrumentation, which rely on non-IC materials and often are relatively large.

The renewed interest in some of the non-Si-based machining methods stems principally from two major deficiencies of IC-based machining techniques: the difficulty of creating truly 3D microstructures and the problem of interfacing microstructures with the macroworld. A machining method with a range that covers macroscopic- to microscopic-scale devices is needed, as often micromachines cannot easily be handled. Laser beam machining (LBM), electrodischarge machining (EDM), ultraprecision machining, dry reactive ion etching (DRIE), LIGA, and pseudo-LIGA techniques are steps in that direction, forming so-called "handshake technologies," bridging the micro- and macroworlds. These

Table 1.2 MEMS Miniaturization Methods: Nonlithography-Based (Traditional) and Lithography-Based (Nontraditional)

Machining Method	Material/ Application	Typical Min/Max Size Feature	IC Compatible?	Tolerance	Important Reference on Technique	Aspect Ratio (Depth/ Width)	Initial Investment Cost/Access
Group 1: Traditional Techniques (Not Involving Photolithography-Defined Masks)							
Chemical milling (S), (Ba)	Almost all metals	From submillimeter to a few meters (x, y); max thickness (z) ±1 cm	Yes	Lateral tolerance 0.25–0.5 mm	Harris[6]	~1	Low/good
Electrochemical machining (S/A), (Ba)	Hard and soft metals, turbine blades, pistons, fuel-injection nozzles	Minimum-size devices larger than in chemical milling because of contacting need	Fair	Lateral tolerance <10 μm	(A) Romankiw,[7,8] (S) Phillips[9]	(S) 100	~$400,000/good
Electrodischarge machining (S), (Se)	Hard, brittle, conductive materials used for tools and dies	Minimum holes of 0.3 mm in 20-mm-thick plate	No	Lateral tolerance 5–20 μm	Kalpajian[10]	100	High/good: equipment with numerical control is common
Electrodischarge wire cutting (S), (Se)	Hard, brittle materials; many punch-and-die applications	Minimum rods 20 μm in diameter and 3 mm long	No	Lateral tolerance 1 μm	Saito[11]	>100	High/good: does not require special electrodes

Electron beam machining (S/A), (Se) 	Hard-to-machine materials	(S) Most suited for large numbers of simple holes (<0.1 mm)	Fair	(S) ~10% of feature size (5 μm on a 50-μm hole)	Taniguchi[12]	(S) 10 is typical but 100 is possible	Very high/fair ~$100,000 when using a modified scanning electron microscope
Continuous deposition (A), (C); e.g., doctor's blade technology, tape casting	With all materials available in inks, e.g., glucose sensors	Most suited for inexpensive disposables, from 100 μm to a few millimeters	No	15 μm	Harper,[13] Fiori and De Portu[14]		Low/good
Focused ion-beam on a lathe (S/A), (Se) 	Very pure IC materials	From submicrons to millimeters	Yes	(S) 50–100 nm	Vasile et al.[5]		High/poor
Hybrid thick film (A), (Ba)	Wide variety of materials available in inks	Minimum feature size 90 μm	Fair	12 μm	Harper[13]		~$30,000/good
Laser beam machining (S/A), (Se) 	Complex profiles in hard materials	(S) Holes from 10 μm to 1.5 mm at all angles	Fair	1 μm	Helvajian[15]	(S) 50	~$50,000 but up to ~$400,000 for a five-axis system/ good
Plasma-beam machining (S/A), (Se/Ba)	Very-high-temperature materials	(A) Only used for thick films >25 μm; (S) for very thick films >2.5 mm	No	(A) 20 μm for a 25-μm-thick film; (S) typical ± 3 mm but 0.8 mm is possible	Pfender[16]		~$600,000/fair

Table 1.2 MEMS Miniaturization Methods: Nonlithography-Based (Traditional) and Lithography-Based (Nontraditional) (*Continued*)

Machining Method	Material/ Application	Typical Min/Max Size Feature	IC Compatible?	Tolerance	Important Reference on Technique	Aspect Ratio (Depth/ Width)	Initial Investment Cost/Access
Stereolithography (A), (Se) 	Polymeric photosensitive materials	Maximum 10 × 10 × 10 mm (*x, y, z*)	Yes	Minimum solidification 5, 5, 3 μm (x, *y, z*)	Ikuta,[64] stereo lithography[17]		$100,000–500,000/ good
Ultraprecision mechanical machining (S), (Se)	Form-stable materials	From submillimeters (e.g., 0.2-mm hole) to meters	No	1 nm	Boothroyd and Knight[18]		$400,000/good
Ultrasonic machining (S), (Se)	Hard and brittle materials	Holes from 50 μm to 75 mm	No	Lateral tolerance 10 μm	Bellows and Kohls[19]	2.5 μm for a 250-μm hole	$20,000/good
Microdispensing (A), (Se/Ba)	Wide variety of materials available in inks, especially suited to biomaterials	Minimum membrane volume: nanoliters to microliters	Yes	~3% volume	Li et al.[20]		Medium/poor
Injection molding, hot embossing (A), (Ba)	Plastics, ceramics, and metals	Minimum 250 μm; maximum several centimeters	No	±0.13% (e.g., ±2.6 μm for a 1.998-mm diameter)	Sakai,[21] Rak[22]	>5	Medium/good

Powder blasting (S), (Se)	Ceramics and hard materials >40 HRC	Minimum 50 μm up to several millimeters	No	1–2 μm	Belloy et al.[23]		Medium/poor
Abrasive water jet (S), (Se)	Metals, plastics, and ceramics	Min 0.8 mm typical, 80 μm possible	No	±50 μm	Waterjet[24]	>100	$80,000–200,000/ poor

Machining Method	Material/ Application	Typical Min/Max Size Feature	IC Compatible?	Tolerance	Important Reference on Technique	Aspect Ratio (Depth/Width)	Shape and Height/Depth	Initial Investment Cost/Access
Group 2: Nontraditional Techniques (Involving Photolithography-Defined Masks)								
Photofabrication (S)	Plastic, glass (ceramic), e.g., fluidic elements	Max *x, y* = 40 × 40 cm and max *z* = 0.6 mm	Yes	Lateral tolerance 20 μm	Trotter[25]	~3 for photoplastics; ~20 for photoglass	*x, y* is free; *z* up to 6 mm	Medium/ poor to medium
Photochemical milling (S)	Printed circuit boards, lead frames, shadow masks	Max 60 × 60 cm, max thickness <0.5 mm	Yes	13 μm (printed circuits)	Allen[26]	~1	*x, y* is free; *z* up to 0.5 mm	Medium/ good
Wet etching of anisotropic materials (S)	Crystal Si, GaAs, quartz, SiC, InP	Max wafer size, min feature a few microns	Fair	1 μm	Kern[27]	100	*x, y, z* shape locked in by crystallography, *z* height of the wafer	Low/good
Dry etching (S)	Most solids	Max wafer size, min feature submicron	Good	0.1 μm	Manos and Flamm[28]	10	*x, y* shape free; *z* up to 200 μm	High/good
Poly-Si surface micromachining (S/A)	Poly-Si, Al, Ti, etc.	Max wafer size, min feature submicron	Good	0.5 μm	Johnstone and Parameswaran[29]		*x, y* free; *z* 0.1–10 μm, but preferably 1–2 μm	High/fair

(*Continued*)

Table 1.2 MEMS Miniaturization Methods: Nonlithography-Based (Traditional) and Lithography-Based (Nontraditional) (*Continued*)

Machining Method	Material/ Application	Typical Min/Max Size Feature	IC Compatible?	Tolerance	Important Reference on Technique	Aspect Ratio (Depth/Width)	Shape and Height/Depth	Initial Investment Cost/Access
Si on insulator (S) 	Crystalline Si	Max wafer size, min feature submicron	Good	0.1 μm	Diem et al.[30]		*x*, *y* free; *z* height depending on the epilayer, e.g., 100 μm	High/poor
LIGA (S/A)	Ni, PMMA, Au, ceramic, etc.	Max 10 × 10 cm or more, min 0.2 μm	Fair	0.3 μm	Ehrfeld[31]	>100	*x*, *y* free, *z* up to 100 μm	High (>$35M)/ poor
UV-transparent resists (S/A) 	Polyimide, SU-8, AZ-4000	Max size equals the wafer size	Good	0.5 μm	Ahn et al.,[32] SOTEC[33]	25	*x*, *y* free, *z* up to 1 mm	High/poor
Molded polysilicon HEXSIL (Keller) (S/A)	Poly-Si, Ni, etc.	Max several millimeters, min few microns	Good	0.5 μm	Keller and Ferrari[34]	10	*x*, *y* free; *z* up to 100 μm	High/poor
Erect polysilicon (Pister) (S/A)	Poly-Si	Max several millimeters, min submicron	Good	0.5 μm	Pister[35]	10	*x*, *y* free, *z* up to 1 mm	High/poor
Micromolding (A), (Ba)	Ceramics, plastics, metals	Max wafer size, min feature several microns	No		Bride et al.,[36] Zhao et al.,[37] Sander et al.[38]	3–20	*x*, *y* free, *z* up to 200 μm	Medium/ poor to fair

A, additive; Ba, batch; C, continuous; IC, integrated circuit; max, maximum; MEMS, microelectromechanical system; min, minimum; PMMA, poly(methylmethacrylate); S, subtractive; Se, serial. LIGA is a German acronym for "**Li**thographie, **G**alvanoformung, **A**bformung," which in English is (x-ray) lithography, electroplating, and molding. For a more in-depth study on manufacturing options, we refer to the literature: Harris,[6] Shaw,[39] DeVries,[40] Slocum,[41] and Evans.[42] Also visit the Louisiana Tech University's Institute for Micromanufacturing (http://www.latech.edu/ifm).

handshake technologies should be of importance beyond micromachines—for example, in ICs, where one is faced with the same dilemma of packaging, mounting, and wiring large-scale integrated chips (LSIs) and very large-scale integrated chips (VLSIs). Several of these new technologies are maskless and enable very fast prototyping. The merging of bulk micromachining with other new fabrication tools, such as surface micromachining and electroplating, and the adaptation of materials such as Ni and polyimides have fostered powerful new nontraditional precision engineering methods.

Table 1.2 comprises both additive (A) and subtractive (S) techniques. For additive techniques, a further comparison of thick-film versus thin-film deposition methods is presented in Table 1.3. The decision to go with a thin versus thick film has very important ramifications and has to be considered very deliberately. Resolution and minimum feature size for thin films are obviously superior. Also, the porosity, roughness, and purity of deposited metals are less reproducible with thick films. Finally, the geometric accuracy is poorer with thick films. On the other hand, the thick-film method displays versatility, which is often key in chemical sensor manufacture. Silk screening forms an excellent alternative when size does not matter but cost, in relatively small production volumes, does. For biomedical applications the size limitations, clear from Table 1.3, make thick-film sensors more appropriate for in vitro applications. For in vivo sensors, where size is more crucial, IC-based technologies might be more appropriate. Thin-film technology does not necessarily involve IC integration of the electronic functions. Table 1.4 provides a comparison of the economic and technical aspects in implementing thin-film technology, IC fabrication, thick film, and classic construction for sensors.[43] It should be mentioned that in sensor fabrication, 60–80% of the cost consists of packaging, an aspect not addressed in Table 1.4. In comparison with complementary metal-oxide-silicon (CMOS)-compatible thin-film sensors, the packaging of thick-film sensors usually is more straightforward. Since packaging expenses overshadow all other costs, this is a decisive criterion. In the case of chemical sensors, where the sides of the conductive Si substrate might shunt the sensing function through contact with the electrolyte, encapsulation is especially difficult compared with the packaging of an insulating plastic or ceramic substrate (see also Chapter 4, this volume, on packaging).

Table 1.3 Comparison of Thin- versus Thick-Film Technology

Property	Silicon/Thin Film	Hybrid/Thick Film
In-plane resolution	0.25 μm and better	12 μm
Minimum feature size	0.75 μm and better	90 μm
Temperature range	<125°C	>>125°C
Sensor size	Smaller	Small
Geometric accuracy	Very high	Poor
Deposition methods	Evaporation, sputtering, CVD*	Screen printing, stencil printing
Patterning methods	Etch through photomask; lift-off stencil	Screen photomask, etched stencil, machined stencil
Reliability nonencapsulated device	Low	High
Electronic compatibility	Good	Moderate
Versatility	Low	Very good
Roughness, purity, and porosity of deposited materials	Superior	Moderate
Energy consumption	Low	Moderate
Handling	Difficult	Easy
Approximate capital costs per unit	Very large, but very low in large volumes	Low; very low in moderate volumes

*CVD, chemical vapor deposition

Table 1.4 Comparison between Different Sensor Technologies: Economic and Technical Aspects

	Classic Construction	Thick-Film Technology	Thin-Film Technology	IC Technology*
Technology substrate	Wires and tubes	Screen printing Al_2O_3, plastic	Evaporation-sputtering Al_2O_3, glass, quartz	IC techniques silicon, GaAs
Initial investment	Very low	Moderate	High	High
Production line cost	>$10,000	>$100,000	>$400,000	>$800,000
Production	Manual production	Mass production	Mass production	Mass production
Units per year	1–1,000	1,000–1,000,000	10,000–10,000,000	100,000 and up
Prototype	Cheap	Cheap	Moderate	Expensive
Sensor price	Expensive sensor	Low cost per sensor	Low cost per sensor	Low cost per sensor
Use	Multiple use, in vitro, in vivo	Disposable, in vitro	Disposable, in vivo	Disposable, in vivo
Markets	Research, aerospace	Automotive, industrial	Industrial, medical	Medical, consumer
Dimensions	Large	Moderate	Small	Extreme miniaturization
Solidity	Fragile	Robust	Robust	Robust
Reproducibility	Low	Moderate	High	High
Maximum temperature	800°C	800°C	1,000°C	150°C (silicon)
Interfacing	External discrete devices	Smart sensors, surface mount	Smart sensors, surface mount	Smart sensors, CMOS,† bipolar

Selection criteria for the additive processes reviewed in Volume II depend on a variety of considerations, such as the following.

1. Limitations imposed by the substrate or the mask material: maximum temperature (T_{max}), surface morphology, and substrate structure and geometry
2. Apparatus requirement and availability
3. Limitations imposed by the material to be deposited: chemistry, purity, thickness, T_{max}, morphology, crystal structure, etc.
4. Rate of deposition to obtain the desired film quality
5. Adhesion of deposit to the substrate; necessity of adhesion layer or buffer layer
6. Total running time, including setup time and postcoating processes
7. Cost
8. Ease of automation
9. Safety and ecological considerations

Table 1.5 compares some of the additive processes important in microsensors and micromachining. This table and the above criteria complement the questions in the check-off list presented in Table 1.11. The latter is meant as a guide toward a more intelligent choice of an optimum machining substrate for the micromachining task at hand.

A subset of subtractive machining techniques from Table 1.2 is compared in Table 1.6. Here, metal removal rates, tolerance, surface finish, damage depth, and required power are listed.

The metal removal rate by electrochemical machining (ECM) and plasma arc machining (PAM) is much higher than that of the other machining processes. Compared with conventional mechanical CNC machining, the metal removal rates by ECM and PAM are, respectively, 0.3 and 1.25 times that of CNC, whereas others are only a small fraction of it. Power requirements for ECM and PAM are also comparatively high. The tolerance obtained

TABLE 1.5 Comparison of Additive Processes Important in Microsensors and Micromachining

	Species Deposit Ion Mechanism	Deposit Ion Rate	Depositing Species	Coverage of Complex-Shaped Objects	Coverage into Small Blind Holes	Metal Deposit Ion	Alloy Deposit Ion	Refractory Compound Deposit Ion	Energy of Depositing Species	Bombard-ment of Substrate/ Deposit by Inert Ions	Substrate Heating by External Means	Cost

Table 1.6 Machining Characteristics of Different Processes

	MRR (mm^3/min)	Tolerance Maintained (μm)	Surface Finish Required (μm)	Surface Damage Depth (μm)	Power Required for Machining (W)
USM	300	7.5	0.2–0.5	25	2,400
AJM	0.8	50	0.5–1.22	2.5	250
ECM	15,000	50	0.1–2.5	5	100,000
CHM	15	50	1.5–2.5	5	N/A
EDM	800	15	0.2–1.2	125	2,700
EBM	1.6	25	0.5–2.5	250	150–2,000
LBM	0.1	25	0.5–1.2	125	2–200
PAM	75,000	125	Rough	500	50,000
CNC	50,000	50	0.5–5	25	3,000

AJM, abrasive jet machining; CHM, chemical machining; CNC, computer numerical control machining; EBM, electron beam machining; ECM, electrochemical machining; EDM, electrodischarge machining; LBM, laser beam machining; MRR, metal removal rate; PAM, plasma arc machining; USM, ultrasonic machining.
Source: Based on http://www.cemr.wvu.edu.

by various processes except PAM is within the range of CNC machining, which means satisfactory dimensional accuracy can be maintained. Satisfactory surface finishes are obtained by all processes except PAM. Depth of surface damage is very small for abrasive jet machining (AJM), electrochemical machining (ECM), and chemical machining (CHM) processes, whereas it is very high in the case of electrodischarge machining (EDM), electron beam machining (EBM), PAM, and the like. [As we saw in Volume II, these techniques give rise to a heat-affected zone (HAZ).] For this reason, ECM can be employed for making dies and punches. AJM may be suitably employed for machining super alloys and refractory material; ECM has good applicability for machining steels and super alloys; CHM is very useful for aluminum and steel; EDM may well be adopted for machining steels, super alloys, titanium, and refractory material; and PAM can be suitably employed for machining aluminum, steels, and super alloys. Capital cost for ECM is very high compared with conventional CNC machining, whereas capital costs for AJM are PAM are comparatively low. EDM has a higher tooling cost than other machining processes. Power consumption cost is very low for PAM and laser beam machining (LBM) processes, whereas it is greater in case of ECM. Metal removal efficiency is higher for EBM and LBM than for other processes. Tool wear is very low for ECM, CHM, EBM, LBM, and PAM, whereas it is high for electrical discharge machining.

Given the tremendous variety of micromachining tools available, as evident from Tables 1.2–1.6, a truly multidisciplinary engineering education will be required to design miniature systems with the most appropriate building philosophy.

Design from the Package Inward

When approaching the development of a microdevice, we prefer using the terminology *miniaturization* rather than *MEMS*, as the latter term is still too loaded with the notion that Si technology represents the only solution. The choice of processes for manufacturing a 3D microdevice can best be made after studying the detailed requirements of the application. Since the package serves as the interface between the microstructure and the macroworld, and since it is the major contributor to cost and size, one should start the design with the package and work toward the best machining process for the micromachine inside. The package is often made with a traditional machining method such as turning and grinding or possibly with ultrasonic or wire electrodischarge machining.

For the micromachine inside the package, there may be many machining options, as both batch IC and traditional serial production techniques, perhaps in combination with micromolding, must be considered. Several new, batch Si micromachining techniques derived from the IC industry are

gaining acceptance, but serial, precision machining techniques with specialized tools (e.g., ultrasonic machining or laser beam machining) are often the only commercially available methods to make intricate, small, 3D microcomponents.

Decision Tree for the Optimized Micromanufacturing Option

Introduction

In this section we develop a checklist on how to arrive at an optimum miniaturization strategy for a new MEMS/NEMS product, choosing between MEMS manufacturing options: from nonlithography-based to lithography-based, as captured in Table 1.2. To become a proficient MEMS/NEMS engineer one needs to first understand the application and market for the product very well. These aspects should be apparent from a very detailed specification list and discussions with the user/client. Once an appropriate sensor/actuator principle for the MEMS/NEMS has been chosen, on the basis of the specifications, through brainstorming sessions with the user and/or client and by making preliminary designs, one needs to develop a clear understanding on how this sensor/actuator principle scales into the microdomain. Then one must choose the optimum manufacturing approach and the optimized materials, including substrate material, for the most cost-effective practical implementation. These choices are tested through a new design phase and evaluation of critical process steps. A major challenge in this regard often concerns partitioning, i.e., how far to push the integration of electronics with the sensing function (hybrid vs. monolithic)? If the MEMS-based product compromises both a disposable and a fixed instrument the question becomes, what should be included with the MEMS disposable and what should be included in the fixed instrument? With partitioning decisions made, a computer-aided design (CAD) is followed by research prototyping, engineering prototyping, and finally α and β products for the user/client to test. With a satisfied customer, manufacturing of a new MEMS product may begin.

Throughout the rest of this chapter, we illustrate the use of our proposed decision tree with the search for a sensor to measure glucose in a drop of blood. Glucose sensing represents the single largest biosensor market, and a significant amount of all R&D in biosensors worldwide is geared toward improving this technology. Glucose self-testing by diabetics is one of the fastest-growing segments of the world diagnostics market. The World Health Organization estimates a worldwide diabetic population of more than 200 million (1–2% of the world population). Diabetes is the fifth leading cause of death in the United States, and 30% of our children will be diagnosed with diabetes in the future. The US healthcare costs related to diabetes are $132 billion per year. The specifications for a glucose self-test meter with disposable sensor include very low cost disposable (<15 cents), in vitro use, millions of devices manufactured per month, size of active area on the sensor of a few millimeters square (dictated by the size of the drop of blood), linear response with glucose concentration, and a simple handheld measuring device. Examples of glucose sensors/meters for diabetic care are shown in Figure 1.7. Our analysis will clarify why the current glucose sensors are constructed the way they are.

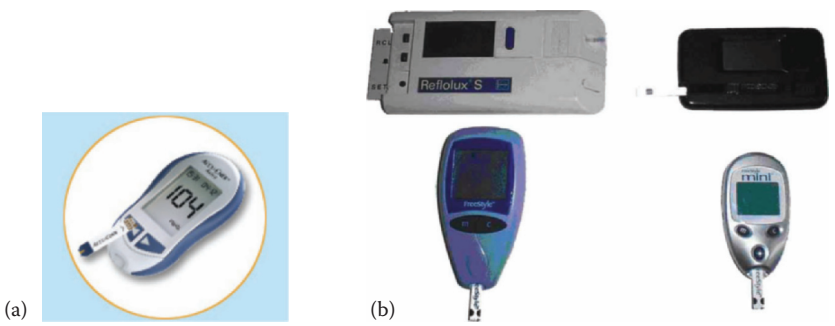

FIGURE 1.7 Blood glucose monitor. (a) Glucometer from Roche (Accu-Chek). (b) Other examples of blood glucose meters, 1993–2005.

Specifications

Applied miniaturization starts with a thorough understanding of the sensor or microsystem specification list, interviews with client/users, understanding of the application environment, and, equally important, a firm market appreciation. In choosing a sensor/actuator principle for a miniaturization application, the various possible sensing/actuating principles (see Table 8.2) need to be challenged with this detailed specification list. During discussions of the specifications required for measuring a certain measurand, jargon confusion is common; making face-to-face meetings with clients/user is mandatory. A specification list should include static and dynamic performance characteristics. Static specifications for a biomedical product with both a reader and a disposable might include the following.

- Package/interface with the world.
- Esthetics/design of package.
- Sensitivity. Change in signal (response) per change in concentration (or mass).
- Lower limit of detection (LOD). The minimum concentration (mass) that can be detected at a given confidence level. The detection limit is affected by the level of noise in the data. One can determine the level of noise by repetitively measuring the signal of a blank.
- Resolution. The smallest increment of change in the measured value that can be determined from the instrument's readout scale; e.g., for a pH electrode the accuracy is ±0.2 pH and the resolution is 0.1 pH.
- Selectivity/specificity. The ability to accurately quantify one species or component in the presence of variable amounts of other components. It has a great effect on the accuracy of the method.
- Stability (long-term and short-term).
- Response time.
- Ambient conditions (e.g., temperature, under or above water, pressure).
- Sample size.
- Operating life.
- Drift. Gradual change in signal that is not due to change in analyte content.
- Shelf life.
- Cost, size, weight of reader.
- Cost, size, weight of disposable.
- Number of devices needed.
- Accuracy.
- Precision.
- Output format/display.
- Operating voltage, current, power.
- Quality.
- Reliability, i.e., mean time between failures.
- Hysteresis.
- Threshold.
- Nonlinearity.

Typical dynamic specifications for such a biomedical product are as follows:

- Dynamic error response.
- Dynamic range. Typical sensor response reaches saturation because of either saturation of binding sites or instrument factors.
- Hysteresis.
- Instability and drift.
- Noise.

Given the very fragmented nature of the microsystems business, it is impossible to present a generic specification list, as a good list must also detail all application-related intricacies. As an example, consider a pH sensor for sensing pH in the secondary cooling flow loop of a nuclear reactor. The presence of radiation and water at high temperature and pressure will significantly reduce the potential sensor principles one may consider. The example also clarifies why a specification list can hardly ever be detailed enough.

The specifications for our example disposable glucose sensor and glucose meter are as follows.

- Package/interface. Handheld device with a slot that accepts disposable glucose sensor strips.
- Esthetics/design. Esthetics are more and more important: good design, easy to use. Letters must be large. Many diabetics are elderly people and have poor eyesight.
- Sensitivity. Sensitivity is about 100 nA/M.
- Lower LOD. Lowest measurable level should be 0.06 mM glucose or less.
- Dynamic range. Glucose assay range is from 1.1 to 33.3 mmol/L.

- Selectivity/specificity. Glucose test results are automatically adjusted for common interfering medications, vitamins, and endogenous substances, including up to 100 µg of acetaminophen, 20 mg/dL uric acid, 3 mg/dL ascorbic acid, 500 mg/dL cholesterol, and 3000 mg/dL triglycerides.
- Response time. The time it takes to read a glucose sensor may range from 5 to 60 seconds (modern meters are typically below 15 seconds).
- Ambient conditions. Sensor operating temperature range = 18–30°C.
- Sample size. Sample sizes vary from 30 to 0.3 µL.
- Operating life. Nonreplaceable battery life = 4000 tests.
- Shelf life. Six months.
- Cost, size, weight of reader. The glucose reader should be approximately the size of the palm of the hand, and it should be battery powered.
- Cost, size, weight of disposable. Very low cost (less than 15 cents). Strip is a few centimeters square in size, and the active spot is a few millimeters square. A consumable sensor element containing chemicals, which react with glucose in the drop of blood, is used for each measurement. Since sensors may vary from batch to batch, a provision might be required for the user to enter in a code that may be found on the batch of sensors. By entering the code into the glucose meter, the meter will be calibrated to that batch of glucose sensors.
- Number of devices needed. Each strip can be used only once and is then discarded. Millions of glucose sensor strips will be manufactured per month.
- Accuracy. The minimum acceptable accuracy for results produced by a glucose monitoring system shall be as follows: 95% of the individual glucose results shall fall within ±15 mg/dL (±0.83 mmol/L) of the results of the manufacturer's measurement procedure at glucose concentrations less than 75 mg/dL (4.2 mmol/L) and within ±20% at glucose concentrations greater than or equal to 75 mg/dL (4.2 mmol/L).
- Precision. Determined as a coefficient of variation on replicate tests on fresh blood in the 3.5–6% range.
- Output format/display. The glucose value in mg/dL or mmol/L displayed in a window. The preferred measurement unit varies by country. In the United States, mg/dL is preferred, and mmol/L is preferred in Canada and Europe. To convert mmol/L of glucose to mg/dL, multiply by 18.
- Reliability. Does not apply for glucose sensor: one-time use only.
- Hysteresis. Does not apply for glucose sensor: one-time use only.
- Nonlinearity. Linear glucose sensor response.

The specifications for a glucose meter listed above suggest a very low cost disposable (<15 cents) with an active area of a few millimeters square (dictated by the size of the drop of blood). These two data points alone preclude the use of Si technology, as this would represent a too-expensive solution. Since we desire a small, simple, and inexpensive measurement device, and a linear response to the glucose in blood, an amperometric approach stands out as the most attractive sensing option (see Volume I, Chapter 7). An amperometric sensing approach is very simple and inexpensive—one pair of thin-film metal electrodes on an insulating substrate—and the method produces a signal linear in glucose concentration. See, for example, the MediSense/Abbott sensor, the Precision QID, in Volume I, Figure 7.80. The linear response makes it more sensitive than a potentiometric device that features a log dependency of the voltage signal on concentration. As we learned in Volume I, Chapter 7, an optical approach tends to be more expensive than an electrochemical approach (see Volume I, Table 7.21).

Having established a sensing mechanism, we now need to know how the chosen effect (amperometry) scales into the microdomain.

Scaling Characteristics of Micromechanisms

To make the right choice from the different available sensing/actuating principles, it is also important to know how the phenomena scale in the microdomain.

Scaling effects are explored in detail in Chapter 7, this volume, and some intuitive guidance (rules of thumb) is provided in Table 1.7.

Scaling understanding is crucial early on when deciding on a sensing/transduction principle. For example, both absorption and amperometric detection approaches scale poorly compared with a luminescent or a potentiometric sensing approach.

We apply these scaling rules now to the glucose sensor example. From the above, we appreciate that an amperometric device scales more poorly than a potentiometric device (the smaller an amperometric device, the smaller the current, while the signal for a potentiometric device is scaling invariant), but an in vitro glucose sensor may be relatively large, and sensitivity is more important in this case. A potentiometric device would be as inexpensive as our chosen amperometric approach, but its sensitivity is not as good. Moreover, we saw in Volume I, Chapter 7, that by making an array of electrodes, the signal to noise ratio of a microamperometric glucose sensor may be enhanced because of increased mass-transport at the electrode edges. So we stick with the amperometric sensor as our choice for the proposed glucose meter.

Partitioning

Introduction

A major challenge in the manufacture of MEMS and NEMS revolves around correct partitioning, that is, how far to push integration of electronics with the MEMS or NEMS sensing function (hybrid vs. monolithic). What do we include with the MEMS disposable, and what can we put into the fixed reader instrument? Onboard or offboard fluidics? Battery or mains power? We first compare hybrid versus monolithic approaches and then illustrate the challenges of partitioning a MEMS instrument by looking at an example from the burgeoning field of microfluidics. Partitioning of electronics and instrument components obviously affects packaging needs, and we will come back to this point in Chapter 4, this volume, on packaging.

Monolithic versus Hybrid MEMS

Hybrid integration in the IC industry means combining thin-film ICs with thick-film technology.

Table 1.7 Some Important Effects of Scaling on Design of Miniaturized Devices

1. Scaling of forces: weak forces are preferred in the microdomain. Electrostatic forces [with a quadratic dependency on dimension (1^2)] under certain conditions outperform magnetic torque [with a cubic dependency on dimension (1^3)] since they become relatively stronger in small devices.
2. Increasing strength of materials in the microdomain. Single-crystal whiskers may be more than 1000 times stronger than the bulk material.
3. The dominance of surface effects in the microworld: for example, because of an increase in S/V (surface-to-volume ratio), better heat dissipation results (thermal isolation is difficult and cooling is excellent) and frictional forces increase.
4. Decrease of manufacturing accuracy of micromachines (see Volume II, Figure 6.3).
5. The need for error-insensitive design (fewer parts, flexible materials) and the use of nature as a guide in design philosophy for very small devices.
6. Amperometric and absorption measurements scale poorly into the microdomain compared with potentiometric and chemiluminescence (see Volume I, Chapter 7, and Chapter 7, this volume, for details). Our proposed glucose sensor is amperometric, so we need to look in some more detail into whether this averse scaling should influence our choice.
7. Mechanical, thermal, and electromagnetic response time constants and many other time constants shrink with advanced miniaturization, generally resulting in shorter response times. Microsystems, with their small inertial mass, are faster, leading to higher speed or frequency, but higher frequency of a cyclic process generally leads to larger losses and consequently to lower efficiency.
8. Power consumption is often dramatically reduced, especially if good thermal isolation is possible for elements with small heat capacity.
9. Energy sources scale very poorly (1^3), making onboard energy sources (e.g., batteries and fuel cells) less attractive for powering micromachines than radiating in energy (e.g., solar or laser light with micromachined photovoltaic converters or microwaves if extremely small receivers and converters were available).
10. Most actuators, which rely on power for inducing a movement, also scale poorly with reducing size, and it is often better to consider a "macroactuator," which can produce a micromotion, than a micromachined actuator with too small of a stroke.

Viewed from the Si MEMS sensor angle, a hybrid sensor keeps the electronics separate from the sensor. The hybrid might then consist of two pieces of Si on the same substrate connected by a short wire bridge, or it might be a Si sensor mounted in a header

plugged into an electronics board. In a monolithic MEMS approach, on the other hand, electronics and MEMS elements are cofabricated within one single (lengthy!) sequential Si process. Each step in such a sequence has a nonzero failure probability and, since probabilities multiply fast, the yield may be dramatically reduced for long process sequences. In this light, there are some positive aspects to a hybrid MEMS approach. In the latter, MEMS and electronics are fabricated in separate high-yield processes and joined within a common package/substrate, improving the overall yield. Microassembly in hybrid manufacture enables the mixture of components from separate optimal processes, including nonstandard processes and materials that are incompatible. For example, many optoelectronics require GaAs substrates that are incompatible with standard Si electronics (see also under microassembly in Chapter 4, this volume). In addition, in hybrid MEMS, *all* components needed for a complete MEMS function can be accommodated. Somewhat unexpectedly, parasitics are sometimes lower in a hybrid than in an integrated approach. The device components in a hybrid remain serviceable and, because the sensor package determines the final size, hybrids often are not much larger than their Si integrated counterparts. Hybrids usually are simpler to design and can be produced more economically in smaller-production volume runs. For chemical sensors and biosensors, they often represent the most viable option to implement micromachining technology. Prices for Si mechanical sensors given in market reports mostly refer to hybrid devices with the Si sensor mounted in a header and the signal conditioning kept on separate chips. As an example, Figure 1.8 represents an accelerometer built using a 3-inch Si wafer and involves a fusion bonding process to produce a proof mass, spring, and fixed capacitor plate. The interface circuits are designed to function with different sensors. The specific sensor configuration and calibration data are written into an EEPROM. It is a ±2-g device with 2-mg resolution at 60 Hz. These accelerometers are used for aerospace navigation, in navigation in small commercial airplanes, and in helicopters.

From the precision engineering angle, a hybrid device is one in which parts produced by different

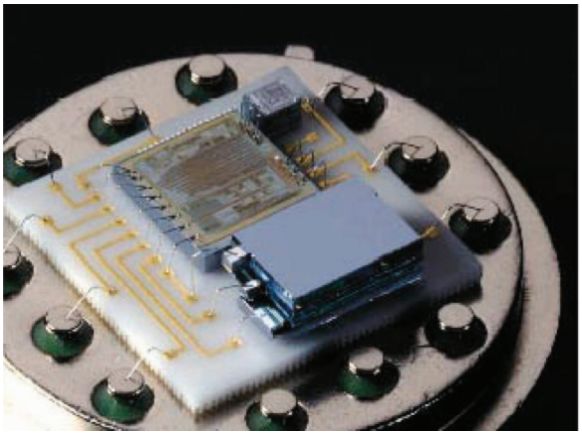

FIGURE 1.8 Commercially available Si accelerometer based on hybrid technology. CSEM 6100 accelerometer with interface circuitry in a T08 package. (From CSEM.)

technologies are joined and assembled. In the electronics industry thick film is often synonymous with hybrid manufacturing and thin film with front-end IC manufacturing. For more details on choosing between thin- and thick-film processes, consult Tables 1.3 and 1.4 above.

For the proposed glucose meter, we will have all the electronics in the reader rather than in the disposable. It makes no sense to throw the electronics away with each used glucose sensor. Moreover, the glucose sensor will be constructed on an inexpensive nonsilicon substrate.

Many chemical sensors come with a pump and some fluidics, say for sample collection, calibration, rinsing, etc. In what follows, we decide what pumping mechanism to employ and how to partition the fluidics between sensor disposable and permanent instrument.

Partitioning in a Microfluidic Instrument

As we saw in Volume I, Chapter 6, microfluidic systems comprising nozzles, pumps, channels, reservoirs, columns, mixers, oscillators, diodes, amplifiers, and valves can be used for a variety of applications, including separation chemistry, drug dispensation, ink-jet printing, and general transport of liquids, gases, and liquid/gas mixtures. The advantages of these devices include lower fabrication costs, enhancement of analytical performance, lower power budget, and lower consumption of chemicals than traditional pumping and spraying systems. Ultimately, these developments will

revolutionize applications where precise control of fluid flow is a necessity.

Generic technical challenges in making a microfluidic instrument—for a biotechnology application for example—include the partitioning of the various instrument functions such as power supply, polymerase chain reaction (PCR) for DNA sample amplification, mechanism for getting the sample into and out of the instrument, providing fresh viable reagents, and detection. Depending on the specific biotechnology application (say, clinical diagnostics or high-throughput drug screening), the electronics, the power for the propulsion mechanism, heaters (e.g., for PCR), etc., may be integrated with a disposable cassette holding the disposables or within the fixed instrument. For diagnostics, both the disposable and the reader instrument should be inexpensive; the disposable should thus involve as little complexity as possible—perhaps only reagents, plastic substrate, and fluidic conduits. The reader instrumentation should be inexpensive, small (perhaps hand-held), and very user friendly. For high-throughput screening, much more sophisticated fluid handling is typically incorporated into a tabletop, expensive research instrument. The disposable in the latter does not need to contain sealed fluids or dry stored chemicals, often making it less sophisticated than disposables in diagnostic application. In one extreme, one might envision a totally integrated option such as the micro-total analysis system[44] illustrated schematically in Figure 1.9a.[45] More realistically, one might look at a hybrid construct, as sketched in Figure 1.9b. For most

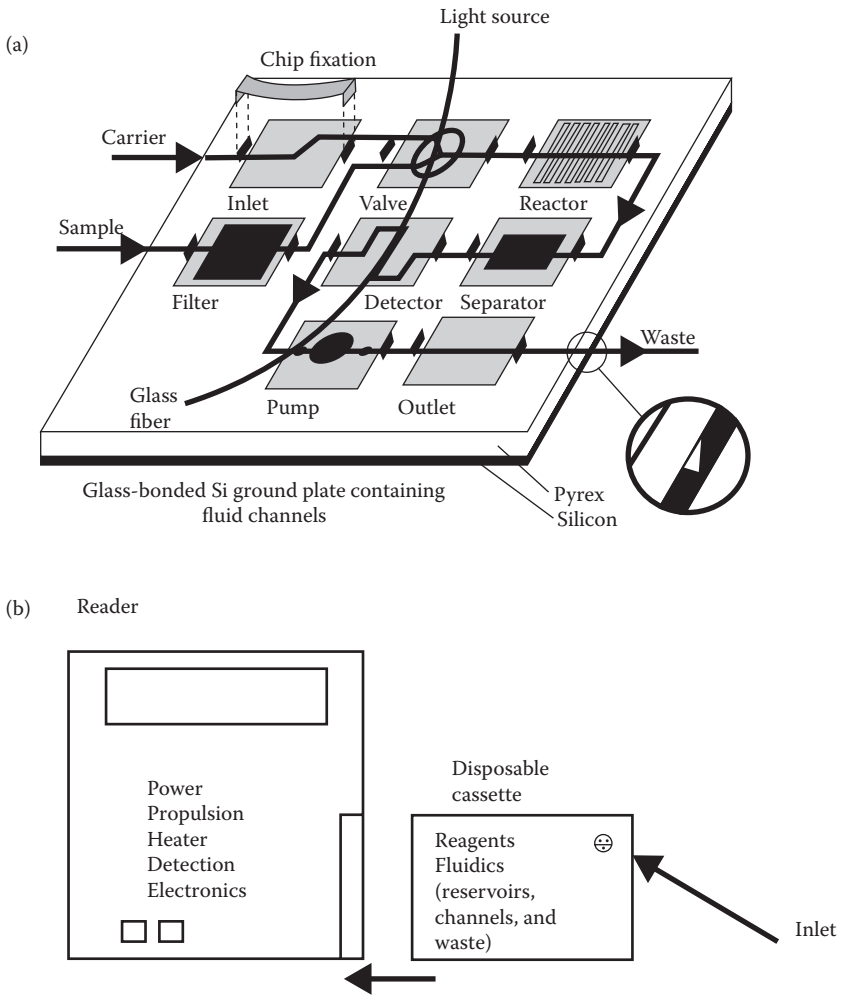

FIGURE 1.9 Partitioning of functions between instrument and a disposable. (a) Configuration for a micro-total analysis system (μTAS). (Based on Bergveld, P. 1995. In *Micro total analysis systems*, eds. A. van den Berg and P. Bergveld, 1–4. Twente, the Netherlands: Kluwer Academic Publishers. With permission.[45]) (b) Generic hybrid microinstrument, with inlet, valves, fluid propulsion, detection, waste, and thermal control. Various options exist for partitioning between cassette and reader.

diagnostic microinstruments, it indeed makes more sense to envision a disposable cassette incorporating the specific reagents needed for a certain test and a separate reader instrument. In a diagnostic application, a major challenge is how to store wet or dry chemicals in sealed reservoirs within the disposable package, making a microfluidic diagnostic instrument actually more challenging to develop than a high-throughput drug screening station.

Our disposable glucose sensor will only have a substrate, electrodes, a chemical cocktail and perhaps a very simple fluidic mechanism to make blood collection on the sensor surface easier. In the context of glucose sensing we will now briefly refer to systems that employ pumps to deliver insulin depending on the glucose sensor reading.

Fluid Propulsion Methods and MEMS Integration

Introduction

As we saw in Volume I, Chapter 6, there are various technologies for moving small quantities of fluids or suspended particles from reservoirs to mixing and reaction sites, to detectors, and eventually to waste or to a subsequent instrument. Methods to accomplish this include syringe and peristaltic pumps, electrochemical bubble generation, acoustics, magnetics, direct current (DC) and alternating current (AC) electrokinetics, and centrifuge. In Table 1.8 we compare some promising fluid propulsion means.[46] Only the simplest and least expensive pumping schemes should be integrated within the disposable itself.

Mechanical Pumps

From Volume I, Chapter 6, we remember that the pressure that mechanical pumps have to generate to propel fluids through capillaries will be higher the narrower the conduit (see Volume I, Equation 6.54). Piezoelectric (acoustic), electro-osmotic (DC electrokinetic), electrowetting (DC electrokinetic), and electrohydrodynamic pumping (AC electrokinetic) all scale more favorably in the microdomain and lend themselves better to pumping in MEMS devices. Despite this promise, almost all biotechnology equipment today is based on traditional external syringe or peristaltic pumps. Although integrated micromachined pumps based on two "one-way" valves may achieve a precise flow control on the order of 1 µl/min with fast response, high sensitivity, and negligible dead volume, these pumps require complicated fabrication processes, generate only modest flow rates and low pressures, and consume a large amount of chip area and considerable power. As a consequence of the low pumping pressure, they often become useless when device dimensions are reduced and resistance to fluid flow and required driving pressure increase. An example of a Si micromachined pump from Animas-Debiotech is shown in Figures 1.10 and 1.11. This belt-worn drug delivery pump features a piezoelectric design pioneered at the

Table 1.8 Comparison of Microfluidics Propulsion Techniques

	Fluid Propulsion Mechanism				
Property	Centrifuge (see Figure 1.14 and Volume I, Figure 6.89)	Pressure (e.g., blister pouch)	Acoustic	Electro-osmosis	Electrowetting
Valving solved	Yes, for liquids	Yes, for liquids and vapor	No	Yes, for liquids	Yes, for liquids
Maturity	Research and development	Products	Research	Products	Research
Propulsion force influenced by	Density and viscosity	Generic	Generic	pH, ionic strength	pH, ionic strength
Power source	Rotary motor	Mechanical roller (see Figure 1.12b)	5–40 V (peak to peak)	10 kV	1–10 kV

Flow rate	From less than 1 nL to greater than 100 µl/s	20–500 µl/s	20 µl/s	0.001–1 µl/s	0.3 µl/s

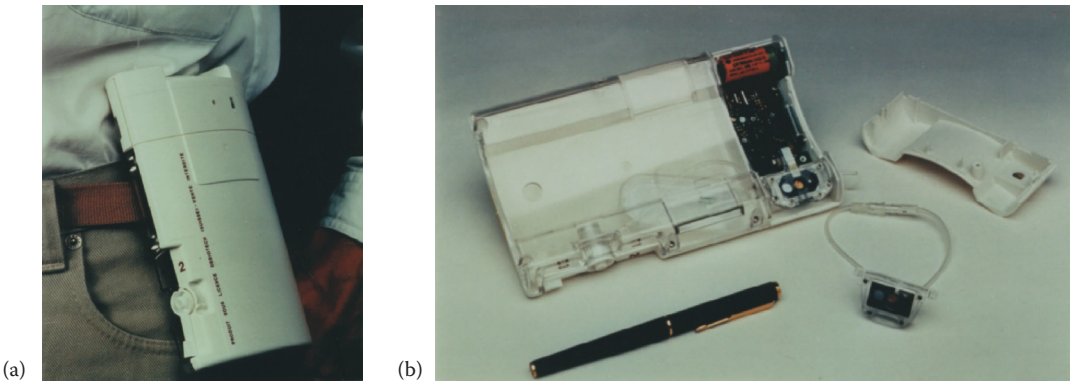

FIGURE 1.10 Micropump technology. (a) Animas-Debiotech's micropump is a Si micromachined piezopump meant to be a belt-worn drug delivery mechanism. The Oncojet is disposable and may deliver a drug at a rate of 10–50 mL/day. (b) The glass-Si sandwich pump is about 2 × 1 cm in size. (Courtesy of Ary Saaman, Animas-Debiotech.)

University of Twente, and a generic example of this MEMS pump is shown in Figure 1.11a.[47] A close-up of the actual Animas-Debiotech MEMS pump is shown in Figure 1.11b. The size of most Si micromachined pumps is quite large, and one wonders why Si was chosen as a substrate (http://www.diabetesnet.com/diabetes_technology/insulinpumps_debiotech.php). Reasonably, plastic molding technology is now being explored as a viable solution.[48,49]

The advantages of using larger peristaltic pumping today are that it relies on well-developed and commercially available components, that a wide range of flow rates is attainable, and that the pumping mechanism is not easily fouled.

Another example of a mechanical pump is embodied in the Johnson & Johnson blister pouch human immunodeficiency virus (HIV) test shown in Figure 1.12.[50] Automated sample preparation and amplification coupled with detection systems would revolutionize the medical diagnostic application of DNA amplification with PCR. An elegant example of progress in this direction comes from Johnson & Johnson (see also US patent 5422271).[50] This company's simple fluidic structure for the detection of the HIV is shown in Figure 1.12. The device was invented at Kodak and bought by Johnson & Johnson in 1994. The disposable pouch-based PCR instrument features a total amplification time of 43 min and a sensitivity and specificity adequate for the detection of HIV. An unknown sample and the PCR cocktail are injected into the amplification compartment through a fill port in the plastic pouch. Eight pouches are

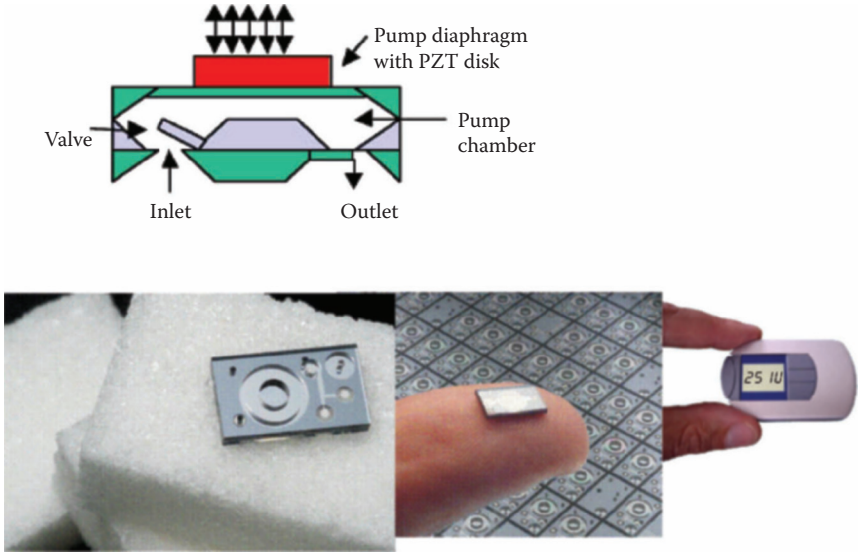

FIGURE 1.11 (a) Generic design of a piezopump.[47] (b) The Animas-Debiotech Si-based microelectromechanical system micropump (http://www.diabetesnet.com/diabetes_technology/insulinpumps_debiotech.php).

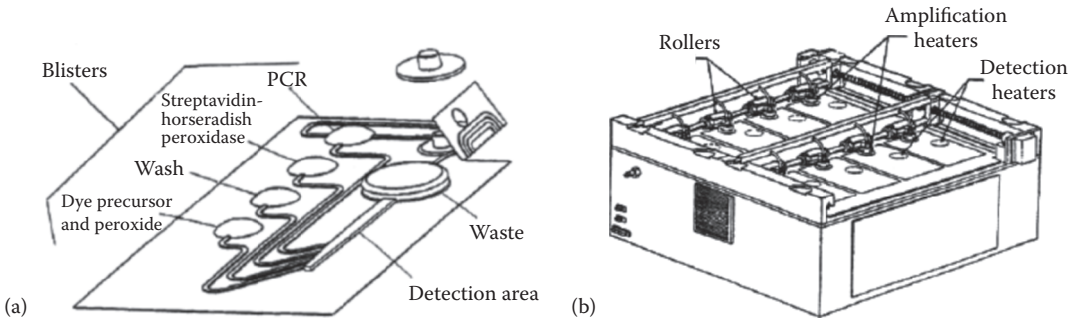

FIGURE 1.12 Johnson & Johnson blister pouch HIV test (a) and tabletop instrument with rollers, amplification, and detection heaters (b). See also reference 50 and US patent 5422271.

aligned on a fixed instrument with the amplification compartments on the upper amplification heaters, and the detector areas on the lower detection heaters. Upon completion of the amplification, the next analysis step is accomplished by an automatic roller that forces detection chemistry fluids and amplified samples from compartments through channels leading to a temperature-controlled detection area. The plastic channels in the pouch contain small nips that close off the channel and break open upon pressurization with a roller system, similar to the one used in credit card image transfer. These nips in the plastic form very inexpensive, single-use, normally closed valves. In the detection zone, biotinylated PCR products are captured via hybridization to probes immobilized on latex particles. Multiple probe sites can be accommodated in the detection areas. Streptavidin-horseradish peroxidase is mixed with those probes to allow for binding between the biotinylated probes and the streptavidin-horseradish peroxidase. Any material left unbound is then removed with the subsequent wash solution. In the presence of peroxidase, leuco dye is oxidized to a visible blue color, indicating a positive hybridization event. Replacing the relatively thick walls of traditional, low surface-to-volume ratio, polypropylene reaction tubes with the pouch "blisters," with their relatively high surface-to-volume ratio and very thin walls (100 μm), which are readily conformable to the shape of the instrument heaters, permits rapid heating and cooling.

The above PCR-based instrument is an example of optimum partitioning between disposable and fixed instrument for use in a medical diagnostic application. For this purpose, sample receptacle, reagents, and all fluidics, such as mixing, valving, and waste area, are integrated in an inexpensive disposable. Power supply, heaters, coolers, readout electronics, etc., are kept separate in an inexpensive disposable plastic pouch. This inexpensive and ingenious way to couple PCR and detection is difficult for a Si-based micromachining approach to compete with. Despite its promise, this HIV test was taken off the market, presumably because of manufacturing problems.

A disadvantage of the pouch approach is that it is rather difficult to further miniaturize because it is a pressure-driven system. The disposable cartridge in the i-STAT (now Abbott) blood analyzer device illustrated in Figure 10.42b of this volume also contains a blister pouch containing calibrant solution.

The proposed glucose meter of our example does not come with an insulin delivery pump, but, in addition to the Animas-Debiotech pump (Figures 1.10 and 1.11), many such insulin delivery pumps are commercially available. Some glucose meters communicate wirelessly to the pump, and some pumps include the meter.

Acoustic Streaming

Acoustic streaming is a constant (DC) fluid motion induced by an oscillating sound field at a solid-fluid boundary (see Volume I, Chapter 6, on fluidics). Transducers do not need to be integrated with the disposable; the cassette with capillary flow channels can simply be laid on top of the acoustic pump network in the reader instrument. Acoustic streaming is also well suited for mixing reagents.[51] The method is considerably more complex to implement than electro-osmosis (see below), but the insensitivity of acoustic streaming to the chemical nature of the fluids inside the fluidic channels

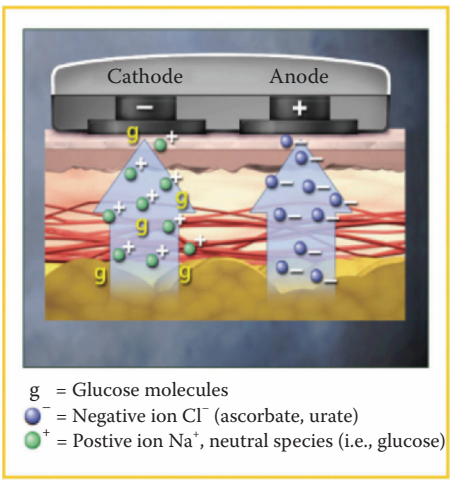
and its ability to mix fluids very effectively make it a potentially viable approach. A typical flow rate measured for water in a small metal pipe lying on a piezoelectric plate is 0.02 mL/s at 40 V, peak to peak.[52] Today acoustic streaming as a propulsion mechanism remains in the research stage.

Electro-osmosis and Iontophoresis

Electro-osmosis is capable of delivering an appreciable DC electrokinetic flow rate in a capillary, does not involve any moving parts, and is easily implemented (see Volume I, Chapter 6, on fluidics). All that is needed is a metal electrode in some type of a reservoir at each end of the flow channel. Typical electro-osmotic flow velocities are on the order of 1 mm/s, with a 1200 V/cm applied electric field. For example, Jorgenson reported electro-osmotic flows of 1.7 mm/s.[53] This is fast enough for most analytical purposes. Some disadvantages of electro-osmosis are the required high voltage (1–30 kV power supply) and direct electrical-to-fluid contact with resulting sensitivity of flow rate to the charge of the capillary wall and to the ionic strength and pH of the solution. It is consequently more difficult to make it into a generic propulsion method. For example, liquids with high ionic strength cause excessive Joule heating; it is therefore difficult or impossible to pump biological fluids such as blood and urine. The sensitivity of the electrokinetic potential to the nature and strength of the electrolyte brings with it the insidious problem of pressure buildup at intersections where liquid columns of different ionic strengths meet. Micromachinists are starting to address the connection between the outside world and the capillaries in electrokinetic equipment. Gluing glass reservoirs for holding the platinum bias electrodes to the glass plate substrate with room temperature vulcanizing (RTV) silicone is a research solution but not an attractive manufacturing option.[54]

In the context of our glucose meter example, we need a blood collection/sampling mechanism. One method for interstitial fluid collection uses iontophoresis. The GlucoWatch® Biographer (cost, $599–799), shown in Figure 1.13, collects glucose through the skin, and no finger pricks are needed (Cygnus Corp.: http://www.glucowatch.com).* In this method, one draws out interstitial fluid by iontophoresis, and the charge and size exclusion properties of the reverse iontophoretic extraction lead to a very clean sample. Iontophoresis utilizes the passage of a constant, low-level electric current (~0.3 mA/cm^2) passed through the skin between two electrodes applied onto the surface of the skin. Electrolyte ions in the body act as the charge carriers for this current to iontophorese substances from within the body outward through the skin. Only small compounds pass through the skin,

(a)



(b)

FIGURE 1.13 The GlucoWatch® G2™ Biographer (a) collects glucose through the skin via iontophoresis (b). (Cygnus Corp., http://www.glucowatch.com; http://www.animas.com.*)

* On March 1, 2006, Cygnus, who made the GlucoWatch Biographer, was closed down, and its assets were bought by Animas (who makes insulin pumps, see Figure). Animas is no longer making GlucoWatch Biographers. The U.S. Food and Drug Administration reports that at least 50% of users experienced mild or moderate skin irritation.

so there are no proteins (e.g., hemoglobin) in the extract. Because the skin has a net negative charge at physiological pH, positively charged sodium ions are the major current carriers. This migration of sodium ions toward the cathode induces an electro-osmotic flow toward this electrode. Uncharged molecules (e.g., glucose) are carried along by this electro-osmotic flow and thus preferentially extracted at the cathode. While glucose is collected at the cathode, interfering species (ascorbate and urate) collect at the anode. Micromolar concentrations of glucose are extracted by the process of iontophoresis compared with 5–10 mM concentrations normally seen in blood samples. To accurately measure this small amount of glucose, the GlucoWatch® Biographer utilizes an amperometric biosensor. Glucose oxidase enzyme located in the hydrogel discs of the AutoSensor reacts selectively with glucose to produce hydrogen peroxide (H_2O_2). The hydrogen peroxide is detected at a platinum-containing working electrode via an oxidation reaction producing an electric current that is measured by the circuitry of the Biographer. After a 2-hour warm-up period and a single-point calibration, the GlucoWatch® G2™ Biographer can provide glucose readings every 10 min for up to 13 hours. Obtaining a blood glucose value from a traditional finger stick glucose meter and then entering the value directly into the Biographer during the calibration phase constitute a single-point calibration. This calibration phase occurs at the end of the 2-hour warm-up cycle. The GlucoWatch provides information on trends and not necessarily in real time for treatment adjustments.

Concerns with the merit of trending only, calibration time, risk of infection and irritation,* and the irreproducibility of the watch eventually spelled the demise of this approach. So we will combine our glucose meter with a more conventional lancet or laser pricking (see below) to obtain a blood sample.

Centrifugal Pumping

Using a rotating disc, centrifugal pumping provides flow rates ranging from less than 10 nL/s to greater than 100 µL/s depending on disc geometry, rotational rate (revolutions per minute), and fluid properties (see Figure 1.14).[55] Pumping is relatively insensitive to physicochemical properties such as pH, ionic strength, or chemical composition (in contrast to AC and DC electrokinetic means of pumping). Aqueous solutions, solvents (e.g., dimethyl sulfoxide), surfactants, and biological fluids (blood, milk, urine) have all been pumped successfully. As explained in Volume I, Chapter 6, fluid gating may be accomplished using "capillary" valves in which capillary forces pin fluids at an enlargement in a channel until rotationally induced pressure is sufficient to overcome the capillary pressure (at the so-called "burst frequency"). Since the types and the amounts of fluids one can pump on a centrifugal platform span a greater dynamic range than for electrokinetic pumps, this approach seems more amenable to sample preparation tasks. The example fluidic platform based on a CD in Figure 1.14 is used by RotaPrep for cell lysis and DNA purification. This specific product uses magnetism, centrifugal force, and capillary action for system operation.

The disposable in this case is an inexpensive polycarbonate disc, containing only fluid manifolds, glass beads, and a metal disc. The permanent instrument has a motor, controls, and permanent magnets.

Vacuum Pressure Reservoir

Fluid transport can also be accomplished by employing chambers within the cassette or reader that are at a higher or lower pressure than the sample and reagent reservoirs. Valves are required to separate

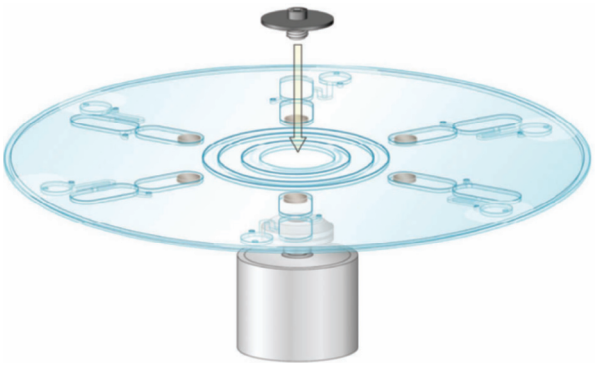


FIGURE 1.14 RotaPrep system for cell lysis (http://www.rotaprep.com). This specific product uses magnetism, centrifugal force, and capillary action for system operation. (Courtesy of Dr. Kido, CEO, RotaPrep.)

* On March 1, 2006, Cygnus, who made the GlucoWatch Biographer, was closed down, and its assets were bought by Animas (who makes insulin pumps). Animas is no longer making GlucoWatch Biographers. The U.S. Food and Drug Administration reports that at least 50% of users experienced mild or moderate skin irritation.

the evacuated or pressurized chambers from the rest of the fluid path until fluid motion is required. Opening a valve initiates the flow of fluid toward an evacuated chamber or away from a pressurized chamber. An advantage of this mechanism over those previously described is that it is a straightforward way to generate a large fluid-motive force. Its drawbacks are that it can only be actuated once, valves may be difficult to implement, and the reliable manufacture of pressurized or evacuated chambers may be challenging. Unless one uses osmotic pumping by implementing a salt reservoir, external actuation seems the safest implementation method for pressure-gradient actuation.

Heating and Cooling and MEMS Integration

Heating and cooling of fluid within a microinstrument, like fluid propulsion, can be accomplished with elements that are either contained within a disposable cassette or the reader. There are, superficially, some arguments to be made for integrating heating and cooling in the disposable. We learned in Volume II, Example 9.1, "Spray Pyrolysis Application: Taguchi Gas Sensor" that electrical current passing through resistors integrated on thin membranes can cause a very rapid temperature increase. This is because the resistor has very little thermal mass and is in intimate thermal contact with the membrane and the fluid to be heated. Integrated heaters are, in principle, simple to fabricate on a variety of materials. On the other hand, temperature control can also be accomplished with a heating and cooling system that is external to the microsystem. For example, the Johnson & Johnson pouch, surveyed earlier, uses two external heaters (Figure 1.12). The heaters are cooled with forced air to speed cycling times. Fast heating and cooling are possible with external heaters. Wittwer and Garling[56] and Wittwer et al.[57] have demonstrated 30-s PCR thermal cycling using a hot-air cycler and glass capillary PCR chambers (see the discussion on PCR in Chapter 10, this volume). External heaters offer the advantages of simpler (less expensive) microinstruments and no cassette-to-reader electrical connections. In general, however, external heaters are slower and require more electrical power than integrated heaters.

A third option is to heat fluid within the microinstrument using radiation generated in the reader. The radiation could be infrared, radio wave, or microwave; it could be adsorbed by the fluid or by absorptive structures (such as black ink) placed on the cassette. An advantage of radiative heating is that it avoids electrical contact from reader to disposable. Our proposed glucose sensor strip has no heater on board.

Sample Introduction

The exact mechanism for introducing samples into the microinstrument depends on the target sample. This is one of the most difficult areas—not only is pretreatment of the sample often required, but one also must transition from a relatively bulky external receptacle structure, which can be handled and accessed manually, to the microfluidic components inside without incurring too much dead space. Very few machining techniques cover the whole dynamic size range required. Because the sample introduction method may place important constraints on the manufacturing process, a few sample introduction options are considered here. Traditional sample injection systems, such as that for flow injection analysis, rely on some sort of commutating valve, either rotary or sliding, actuated manually or mechanically. Harrow and Janata[58] compared different commercially available sample injection systems, and Shoji et al.[59] were among the first to micromachine a sample injector consisting of two three-way microvalves and a channel. These valve systems today are too complex and expensive to consider their integration in a disposable. Perhaps the simplest way to introduce the sample into the microinstrument is by creating wells into which the sample is dropped. For example, most of the substrates with electro-osmotic pumps have plastic tubes glued to them to make sample reservoirs. Similarly, the Biotrack blood coagulation device requires that a drop of sample be placed in a depression on the instrument surface.[60] The sample is then wicked into an internal chamber by capillary action. Problems with sample wells include the large volume that they require and the need to accurately align the sample with the well if the sample well is small. Because the wells are open, one risks sample

contamination or the inclusion of air bubbles in the sample. The latter are a major problem in miniature fluidic systems because of the associated surface tension, and debubblers, which are typically bulky, are often a necessity. Samples may also be injected directly into the microinstrument or disposable cassette. An example of this is the Johnson & Johnson pouch HIV test, where an injection septum is provided in the disposable pouch (Figure 1.12). This reduces the chance of sample contamination but again requires exact alignment of the injection needle with the sample injection port. Furthermore, the manufacture of the cassette pouch is complicated by the need for an injection septum. In an integrated sample, the collection device could be the cassette. For example, the cassette could be manufactured in the form of a blood collection tube (Vacutainer), a syringe, a pipette, or a swab. However, this would complicate the cassette manufacture considerably and may limit the cassette design to a specific type.

For the sample collection of our example glucose sensor, we came to understand earlier that iontophoresis still poses problems. Therefore, we will use a traditional lancet (Figure 1.15a). The Transdermal Biophotonic System from SpectRx (Figure 1.15b) collects interstitial fluid through micropores punctured in the outer layer of the skin by a laser (not FDA approved at this time), and glucose is measured in a patch that contains the glucose sensor. Measuring in interstitial fluids rather than blood, this collection method is similar to the GlucoWatch (see above) in that it provides information only on trends and not necessarily real time for treatment adjustments.

Manufacturing Technique of the Disposable Cassette

The choice of how to partition fluid transport and heating techniques must go hand in hand with the choice of disposable/cassette manufacturing technique. The principal advantages of nontraditional methods for making microinstruments are that very intricate structures with very fine features can be

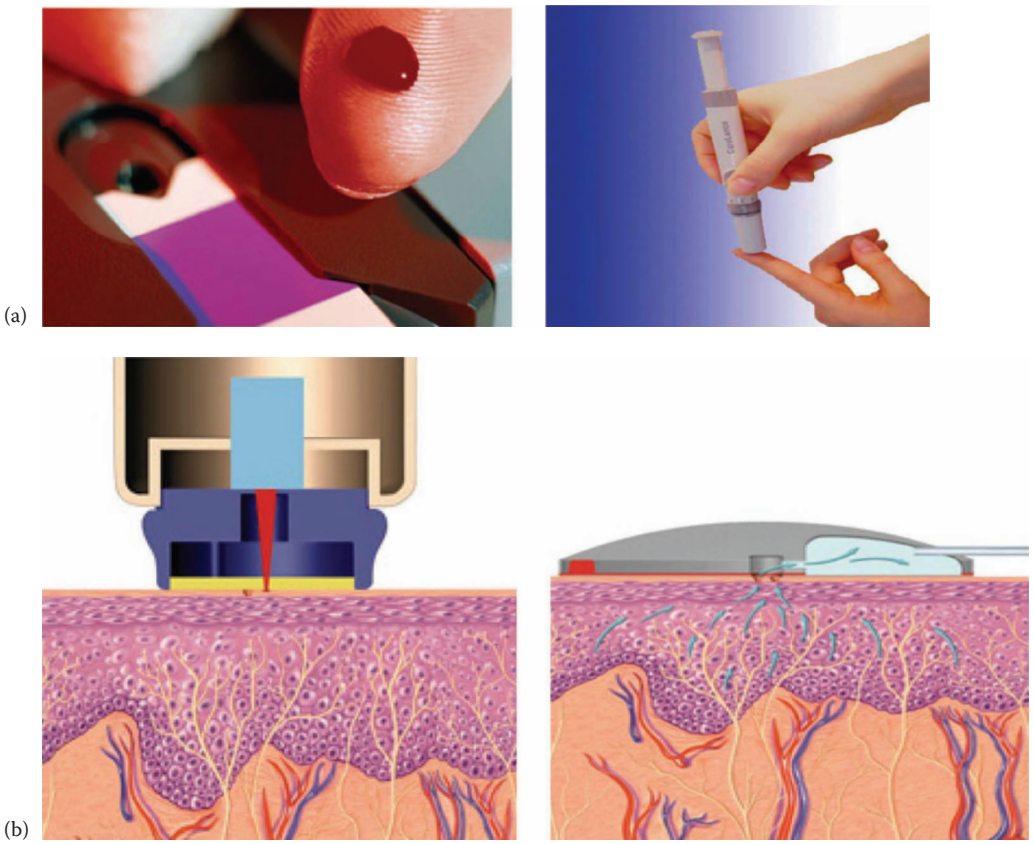

FIGURE 1.15 (a) Lancet for blood collection. (b) The Transdermal Biophotonic System from SpectRx collects interstitial fluid through micropores punctured in the outer layer of skin by a laser (http://www.spectrx.com).

produced, and heaters, electro-osmosis electrodes, and acoustic streaming pumps can be readily realized. On the other hand, nontraditional microfabrication is optimized for making devices that are considerably smaller than most biochemical reaction sample volumes. A 100-µl reagent volume is the same size as a Si chip; that is, 14 mm on a side—huge by microelectronics standards. It is certainly possible to make Si micromachined parts that are as large as the starting wafer (typically 4 in. in diameter); however, the costs of the wafer and wafer processing are likely to be much higher than for other manufacturing techniques. In addition, variation from a previously developed microfabrication sequence can require an expensive and time-consuming process development effort. In the meantime, traditional methods have provided answers to most of the miniaturization needs in diagnostic applications. Where MEMS contributes is in realizing some crucial components of the instrument, for example, the detector, the fluidic conduits, and the actuators. Most solutions rely on plastic rather than Si. We will settle on a choice for our glucose sensor's substrate and manufacturing method after we introduce some background on substrate choices and have launched our check-off list.

Substrate Choice

Here we compare substrate choices such as Si, ceramic, glass, plastics, and others in terms of traditional mechanical machinability, metallization ease, and cost.

For many mechanical sensor applications, single-crystal Si, based on its intrinsic mechanical stability and the feasibility of integrating sensing and electronics on the same substrate, presents an excellent substrate choice. For chemical sensors, on the other hand, Si, with few exceptions,* is merely the substrate and as such it is not necessarily the most attractive option.

In Table 1.9, we show a performance comparison of substrate materials in terms of cost, metallization ease, and machinability. Both ceramic and glass substrates are difficult to machine, and plastic substrates are not readily amenable to metallization. Silicon has the highest material cost per unit area, but this cost can often be offset by the small feature sizes possible in a Si implementation. Silicon, with or without passivating layers, due to its extreme flatness, relative low cost, and well-established coating procedures, is often the preferred substrate—especially for thin films. A lot of thin-film deposition equipment is built to accommodate Si wafers, and as other substrates are harder to accommodate, this lends Si a convenience advantage. There is also a greater flexibility in design and manufacturing with Si technology compared with other substrates. In addition, the initial capital equipment investment, although much more expensive, is not product-specific. Once a first product is on-line, a next generation of new products will require changes in masks and process steps—but not in the equipment itself.

The disadvantages of using Si are usually most pronounced with increasing device size and low production volumes and when electronics do not need to be, or cannot be, incorporated on the same Si substrate. The latter could be either for cost reasons (e.g., in the case of disposables, such as glucose sensors) or for technological reasons (e.g., the devices will be immersed in conductive liquids, or they must operate at temperatures above 150°C).

An overwhelming determining factor for substrate choice is the final package of the device. A chemical sensor on an insulating substrate is almost always easier to package than a piece of Si with conductive edges in need of insulation.

Table 1.9 Performance Comparison of Substrate Materials

Substrate	Cost	Metallization	Machinability
Ceramic	Medium	Fair	Poor
Plastic	Low	Poor	Fair
Silicon	High	Good	Very good
Glass	Low	Good	Poor

* The ion-sensitive field effect transistor (ISFET) is one example where chemistry and electronics are intimately integrated.[61] The difficulties encountered while integrating chemistry with electronics in an ISFET were highlighted in Volume I, Chapter 7. This device, thirty years after its invention, is finally commercially available. A second example is Nanogen's high-density DNA array (see Volume II, Chapter 8, on chemical-, photochemical-, and electrochemical-based forming). The problem of wiring a very high-density DNA array (e.g., 10,000 sites) makes on-site electronics attractive in this case, outweighing both packaging and cost issues.

As we pointed out earlier, packaging is so important in sensors that, as a rule, sensor design should start from the package rather than from the sensor. In this context, an easier-to-package substrate has a huge advantage. The latter is the most important reason why chemical sensor development in the industry retrenched from an all-out move toward integration on Si in the 1970s and early 1980s to a hybrid thick film on ceramic approach in the late 1980s and early 1990s. In US academic circles, chemical sensor integration with electronics continued until the late 1980s, stopped for a while, and then re-emerged with the successful introduction of a commercial ion-sensitive field effect transistor (ISFET)[61] and DNA arrays with integrated electronics;[62] in Europe and Japan, such efforts were never completely abandoned.

A good engineering guideline to determine whether Si is suitable for a given mechanical application is the following: there should be at least two benefits arising from the use of Si over other substrates (aside from the possibility of integrating the electronics on the same substrate). For example, in the case of a torsional micromirror, as shown in Figure 1.16, fabricated based on a silicon-on-insulator (SOI) approach, the two Si-derived benefits are 1) excellent mirror-like surface and 2) superior torsional behavior of the Si mirror hinges. On the basis of these two important properties, Si has become a formidable contender for making arrays of micromirrors for optical switching. Note that the mirror in Figure 1.16 is not optimized for a high-density mirror switch array. For such an application, the hinges should be very short or hidden behind the mirror, as the mirror surface exposed to the incoming light should be maximized. The design as shown could be used, for example, for a linear scanner.

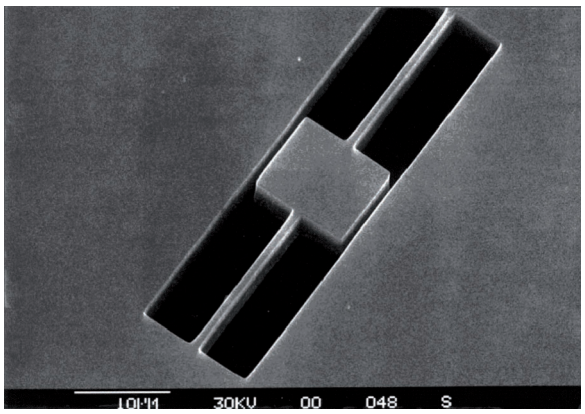

FIGURE 1.16 Silicon-on-insulator (SOI) micromirror.

In Table 1.10 we compare some of the material properties for single-crystal SiC, Si, GaAs, and diamond with relevance to their role as substrates in electronics and MEMS. Not enough good data are available yet to assemble a similar table for the polycrystalline version of the listed semiconductors. From a comparison of Si and GaAs for micromachining applications in this table, we conclude that GaAs is a better material for thermal isolation and for higher-temperature operation. Single-crystal GaAs lends itself as a material for micromechanics because of its attractive optoelectronic and thermal properties. The material is less attractive for mechanical devices, with a yield load smaller by a factor of 2 compared with Si. The many heterostructures possible with GaAs make a wide variety of optical components, such as lasers and optical waveguides, feasible. The piezoelectric effect enables piezoelectric transducers. On the basis of the high-electron mobility, the material is also ideal for the measurement of a magnetic field through the Hall effect. "Macro" pressure, temperature, and vibration sensors, making use of the influence of external pressure and temperature on the band gap, have been built.

Micromachining is proving to be a good method to incorporate micromirrors in resonant optical cavities for tunable lasers. Moreover, micromachining using gallium arsenide and group III–V compound semiconductors is a practical way to integrate radio frequency switches, antennas, and other custom high-frequency components with ultrahigh-speed electronic devices for wireless communications (see Chapter 10, this volume).

Checklist

Some twenty years ago, Stephen Senturia (Massachusetts Institute of Technology) posed a rhetorical question about building micromachines: "Can we design microrobotic devices without knowing the mechanical properties of the materials involved?" In subsequent years, characterizing mechanical properties of MEMS materials became popular. However, an equally important question—"Would

Table 1.10 Material Properties of Four Important MEMS Materials at 300 K

Property	3C-SiC	GaAs	Si	Diamond
Melting point (°C)	2,830 (pressure is 35 bar; decomposes)	1,238	1,415	4,000 (phase change occurs)
Maximum operating temperature (°C)	873	460	300	1,100
Thermal conductivity (W/cm °C)	4.9	0.5	1.57; comparable to metals such as carbon steel (0.97) and Al (2.36)	20
Linear thermal expansion coefficient (× 10–6 °C–1)	4.7	5.9	2.35; the low expansion coefficient of Si is closer to that of quartz (7.1) than that of a metal (e.g., 25 for Al), making it insensitive to thermal shock	0.08
Young's modulus (GPa)	448	75	190 (111); the elastic modulus is similar to that of steel (206–235)	1,035
Physical stability	Excellent	Fair; sublimation of As is a problem	Good	Excellent
Energy gap (eV)	2.39	1.42, direct	1.12, indirect	5.5
Chemical resistance	Very good	Poor	Good	Excellent
Electron mobility (cm2/V s)	1,000	8,500	1,500	2,200
Hole mobility (cm2/V s)	50	400	600	1,600
Density	3.2	5.3	2.32; lower density than Al (2.7); thus, it has a high stiffness-to-weight ratio	3.5
Yield strength (GPa)	21 (for 6H-SiC)	2.0	7 (steel is 2.1); IC-grade Si is stronger than steel	53
Breakdown voltage (× 106 V/cm)	2	0.4	0.3	10
Dielectric constant	9.7	13.1	11.9	5.5
Lattice constant (Å)	4.36	5.65	5.43	3.57
Knoop hardness (kg/mm2)	3,980	600	1,000 (stainless steel is 660)	10,000
Saturated electron drift velocity (× 107 cm/s)	2.2	2	1.1	2.7

you build a microstructure without knowing all the available construction methods?"—often remains unaddressed. Choices of materials and machining processes are intertwined, and both must be confronted early on in the preliminary design phase.

In Table 1.11, we introduce a checklist to help make the decision of optimized manufacturing option and substrate material easier. For the checklist, which serves as a control gate, we start from the assumption that the market and specifications list are well understood and that the detailed specifications list, scaling appreciation, and market understanding agree best with one particular sensing approach (in the example of the glucose sensor, we decided on an amperometric approach).

The checklist starts with a question about the design of the interface of the micromachine with the real world—in other words, with its package. Once the package design is established, one can look for the best manufacturing technique for the micromachined part inside. This strategy dictates

Table 1.11 Checklist to Determine Substrate and Machining Approach for a New Micromachining Application

1. What will the package of the sensor or system be, and how does it interface with the real world? The package and the interface with the environment determine size and cost of the total product and the nature of the microdevice inside, as well as the answers to most of the following questions.
2. Is there a need for integration of electronic functions in the micromachine? Such need (e.g., because the sensor has a very high impedance) necessitates a semiconductor substrate. Above, we proposed a rule of thumb to justify Si as a substrate; there must be at least two compelling reasons besides the possibility of integrated electronics [for the Si on insulator (SOI) micromirror in Figure 1.16, e.g., the reasons are the optical quality mirror surface of silicon and its excellent torsional behavior].
3. How many of the microdevices will be made (production volume or number of units) and what is the unit complexity (number of devices in a unit)? The number might suggest a serial (small number), hybrid (large number), batch (very large number), or even a continuous (moving web-based) approach.
4. Cost per device? The cost may suggest a serial (high cost, >$40) or Si batch (low cost, <$2) approach. For very low cost (glucose sensor strips, <$0.20), a very large batch or continuous fabrication process becomes mandatory.
5. Does the substrate merely function as a support? If so, glass, ceramic, or even plastic and cardboard all become options. If the substrate has a mechanical function, Si is an excellent candidate. If the substrate must have good optical properties, materials such as GaAs and poly(methylmethacrylate) are candidates.
6. Is there a need for modularity? Modularity is important with chemical sensor arrays, in which integration often is counterproductive because of the incompatibility issues faced when depositing different chemical sensor coatings on an integrated chip.
7. What are the expected relative tolerances on the lateral dimensions, and what is the required depth-to-width aspect ratio of features built into the substrate? Very small relative tolerances on lateral dimensions cannot be achieved yet; 1% lateral tolerance on a 100-μm line, in optical lithography, is considered good, but 10^{-3} on 1 cm in diamond milling is very poor (see Volume II, Figure 6.3). Large aspect ratios (say, >20) might necessitate wet anisotropic etching of a single-crystalline material, room temperature and cryogenic dry etching, or LIGA and pseudo-LIGA processes.
8. To what environment (air, water, or other) will the device be exposed? Sensors exposed to aqueous environments such as blood present more packaging problems and make integration of electronics difficult.
9. Which substrate makes packaging requirements less stringent? For a sensor in aqueous solutions, for example, a ceramic substrate requires no protection of the sides of the ceramic strip; a Si sensor, on the other hand, is difficult to insulate and package since a conductive medium might electrically short out the chemical sensor signal via the conductive Si sidewalls.
10. Is the desired microstructure a truly 3D part (e.g., a contact lens), or is it a projected form? A truly 3D part suggests traditional precision machining, for example, diamond turning or a molding process; projected forms allow for a lithography process.
11. What are the thermal requirements?
    - Maximum temperature of exposure (temperatures >150°C may make integrated Si functions impossible). If integration and high temperature are needed, specially processed Si, SOI, or GaAs become candidates.
    - Is thermal conductivity needed?
    - Is a thermal match with other materials important?
12. What are the flatness requirements (often in connection with the optical properties of the substrate)?
    - Average roughness, Ra?
    - One or both sides polished?
13. What are the optical requirements?
    - Transparency in certain wavelength regions?
    - Index of refraction?
    - Reflectivity?
14. What are the electrical and magnetic requirements?
    - Conductor versus insulator?
    - Dielectric constant?
    - Magnetic properties?
15. What is the process compatibility?
    - Is the substrate part of the process?
    - Chemical compatibility?
    - Ease of metallization?
    - Machinability?
16. What are the strain-dependent properties?
    - Piezoresistivity?
    - Piezoelectricity?
    - Fracture behavior?
    - Young's modulus?

itself, because the packaging cost contributes largely to the overall cost of any micromachined product and often overwhelms size specifications as well. The reason for expensive packaging can be ascribed to the many serial labor processes involved. Also, each device may require individual attention. The size of the package is dictated by the need to interface to a bigger structure, by limitations of traditional machining methods, or by the need for manual handling of the structure. Micromachining techniques such as fusion bonding, anodic bonding, and other integrated encapsulation techniques, commonly used in bulk and surface micromachining, might help transform more and more of the serial packaging steps into parallel batch steps even for ICs, which will prove advantageous in keeping costs of the total structure down. In the author's opinion, micromachined batch packaging solutions represent one of the most unmined micromachining opportunities.

Next in the checklist, one needs to establish whether to integrate active electronics on the substrate and confirm the expected temperature range of operation (if too high, the latter might void the integration option). A further consideration concerns number and cost of the devices and which substrate will make packaging easier. When faced with a new micromachining problem, one should consider all available precision manufacturing options—that is, zero-base the approach, be willing to forget all preconceived notions about how the part should be manufactured.

Different markets dictate different machining approaches. For example, chemical sensors, serving a fragmented market, are better constructed in a modular hybrid thick-film approach, but automotive accelerometers, serving a huge and uniform market, are better built in an integrated polysilicon design. The choice of materials for miniaturization of sensors, actuators, and power sources will depend also on the particular sensing principle employed.

We now return once more to the glucose meter example summarized in Figure 1.17. In this exercise, the first round of brainstorming (based on the specification list, and the scaling input) for a disposable glucose sensor resulted in the suggestion of an amperometric approach. We are ready now to face the first design iteration by looking at material and machining options for the proposed electrochemical glucose sensor. For implementation of the preferred sensor materials and manufacturing technology, we challenge the electrochemical conversion option with the list of manufacturing options presented in Tables 1.2 to 1.6 and substrate materials options (Tables 1.9 and 1.10). In the decision process, we use the checklist in Table 1.11 as the control gate. For the glucose sensor this results in thick-film sensor electrodes on disposable plastic (polyvinyl chloride) as the best suggested approach. Screen printing is a well-known technique for making patterns on various substrates (i.e., paper, plastic, wood, glass, ceramics, etc.). This coincides with the principal solution pursued by industry. See, for example, the MediSense/Abbott sensor, the Precision QID, which was shown in Volume I, Figure 7.80. This sensor consists basically of a two-electrode system with a carbon working electrode (carbon ink) and counter—and reference—electrode combined in a Ag/AgCl electrode (Ag/AgCl ink) (Figure 1.18). The working electrode is covered with another ink for the enzyme/mediator system.

Example 1.1: Proposed Scenario for Continuous Manufacture of Polymer/ Metal-Based Biosensors

While the number of new tools available for microfabrication has grown dramatically, few methods have been gainfully applied to disposable biosensor construction for clinical applications. In contrast to mechanical sensors, where the excellent mechanical properties of single-crystalline Si often tend to favor Si technology, the choice of the optimum manufacturing technology for chemical sensors is far less evident. For chemical sensors, Si in the sensor often serves no other role than that of a passive substrate. This past decade the following trend emerged: mechanical sensors (pressure, acceleration, temperature, etc.) moved toward more integration (for example, in accelerometers with CMOS-compatible surface micromachining), while chemical sensors and biosensors moved away from integration and from Si as a substrate. For the latter, hybrid technology on plastic or ceramic substrates with silk screening

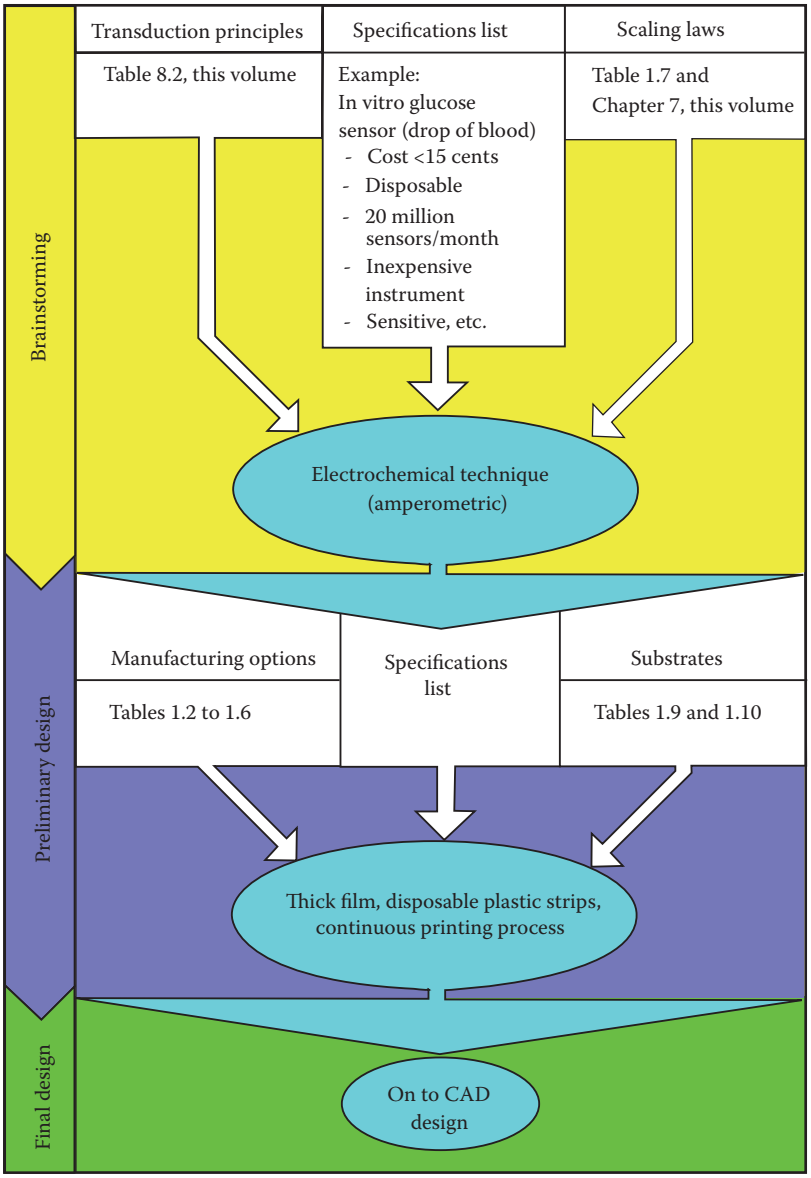

FIGURE 1.17 Confrontation of detailed specification list with sensing/transduction principles and scaling considerations in the brainstorming phase and subsequent searching of manufacturing options by going over a check-off list in the preliminary design phase in the process of developing a disposable glucose sensor (see text).

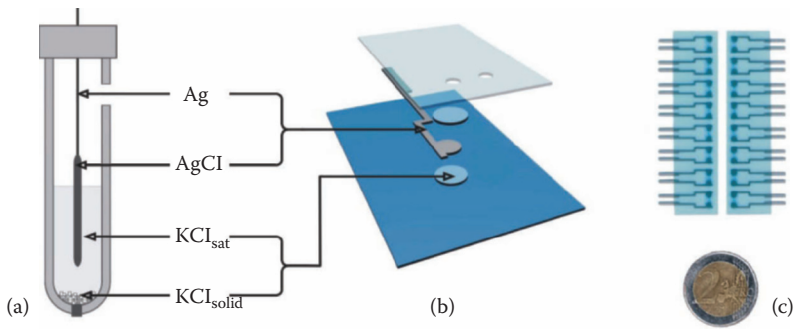

FIGURE 1.18 Structure of a conventional reference electrode of Ag/AgCl/KCl type (a) and design of a planar reference electrode fabricated by means of screen printing (b and c).

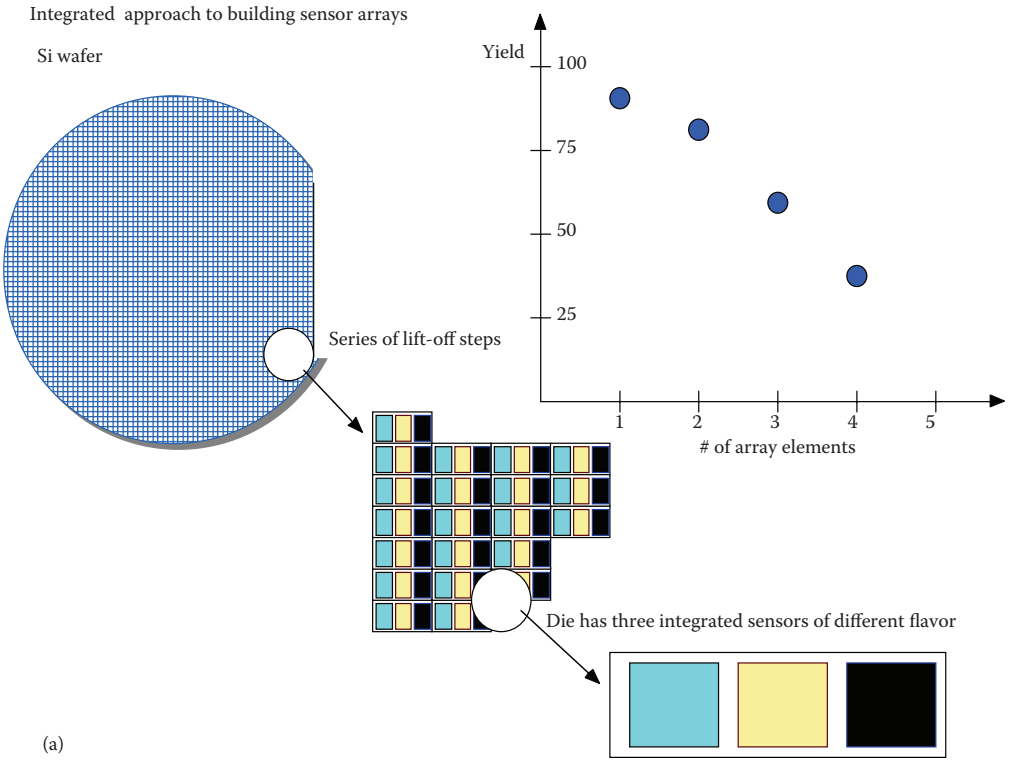

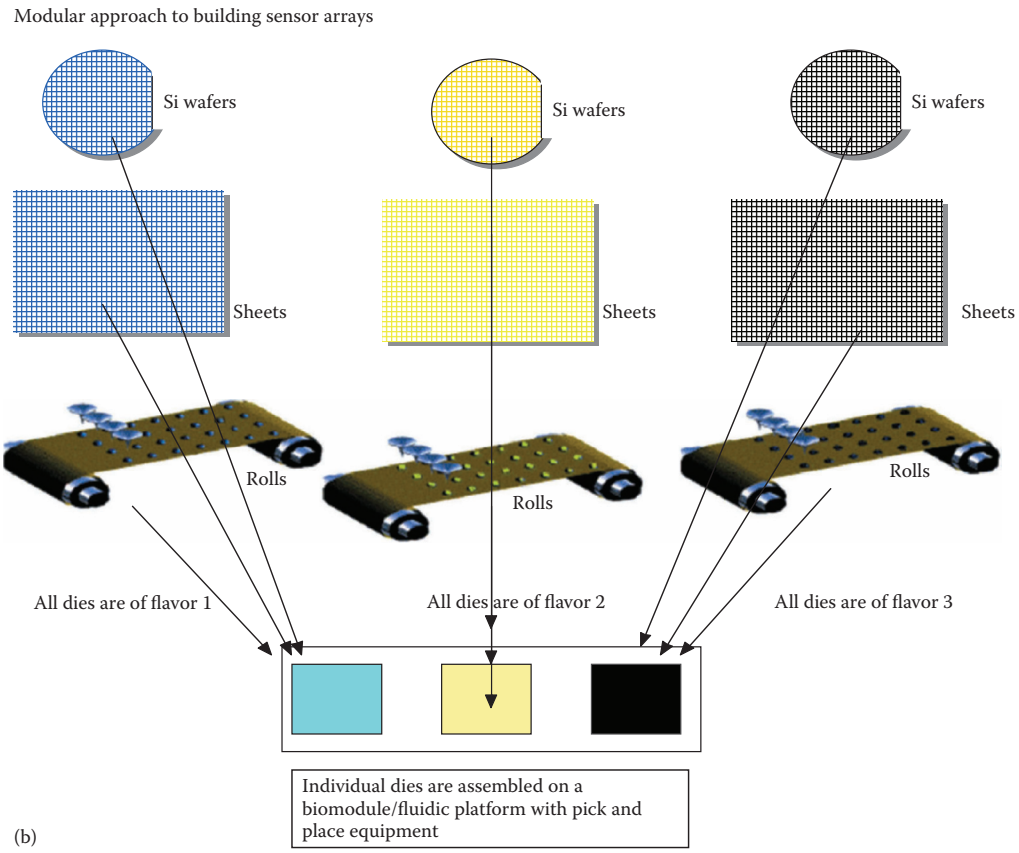

FIGURE 1.19 (a) Integrated sensor array fabrication method. (b) Modular approach to making a chemical sensor array. Wafers, sheets, or rolls of substrate with sensors of one type only are optimized separately to ensure optimum yield. They are then cut out and with pick-and-place equipment put into a biomodule/fluidic platform. Different sensor panels can be put together easily, as there are no compatibility issues to deal with.[63]

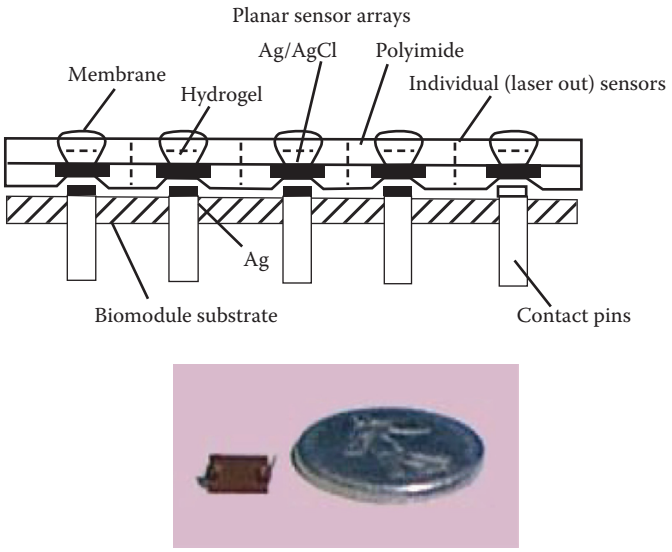

FIGURE 1.20 The individual biosensors [ion-selective electrodes (ISEs)] are combined in a so-called "biomodule" with pick-and-place equipment.[63]

or drop delivery systems for the application of the organic layers became more popular. Microfabrication of Si-based electrochemical sensors, using IC technology, has been especially challenging, mainly due to process incompatibility issues, packaging problems, failure to incorporate a true reference electrode, and the difficulties involved in patterning relatively thick organic layers such as ion-selective membranes and hydrogels [see also i-STAT (Abbott Point of Care, http://abbottpointofcare.com) in Chapter 10 of this volume]. The low cost requirements and the tremendous variety and fragmentation of biomedical sensor applications necessitates a nonsilicon, modular approach. Having addressed materials choice and modularity, various competing manufacturing processes must be compared. Today, in fabricating somewhat larger disposable biosensors, continuous manufacturing processes are used that yield much less expensive devices than silicon batch processes can afford. As an example, consider the mass production of amperometric glucose sensors where the cost per sensor target is 10 cents. Using a Si batch approach, it is very difficult to make a glucose sensor for less than $1 (or any disposable biosensor for that matter). The current process to mass produce glucose sensors involves such proven technology as doctor's blade on a continuous moving web, making a 10-cent cost per sensor quite possible. It is our belief that for disposable microsensors to become an economic reality such continuous or semicontinuous manufacturing processes will have to be further developed and adapted to microsensor construction. In Figure 1.19, we contrast an integrated approach to chemical sensor array fabrication with a more modular manufacturing approach.[63] The integrated sensor array with three types of sensing functions on a silicon substrate, depending on process compatibility, often has a rapidly decreasing yield. The more modular approach shows how one type of sensor might be made on a silicon wafer, a plastic sheet, or a continuous roll. The biosensors fabricated here are electrochemical sensors that can be combined in "biomodules" with pick-and-place equipment after they have been laser-cut from their individual processed sheets (see Figure 1.20). By making sensors of only one type on the same substrate, this approach allows for the fabrication of a sensor array composed of sensors that may otherwise have fabrication incompatibilities, thus increasing the yield of the final array. Since any panel could be put together in a factory upon demand without reconsidering process incompatibilities, more products could be introduced into the market all at once.

The ultimate goal is a manufacturing process for disposable sensors that merges traditional machining options with IC-based manufacturing options and is more akin to packaging processes (e.g., drop delivery, pick-and-place) than to the

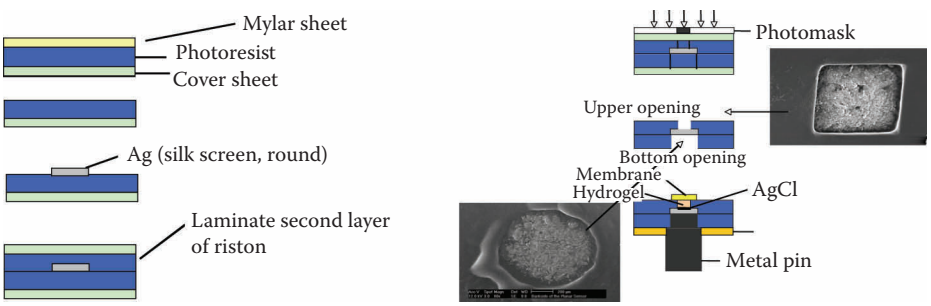

FIGURE 1.21 Schematic illustration of the procedure for fabrication of an individual array element.[63]

Table 1.12 Basic Properties of the Different Photoresist Materials Used to Build Fluidic Elements[63]

Photoresist	XP SU-8	Pyralin PI2721 (Photosensitive Polyimide)	Pyralux PC1025 Dry Resist Film	Riston 4600 Dry Resist Film
Resist tone	Negative	Negative	Negative	Negative
Developer	PGMEA*	DE6180	1% K_2CO_3	1% K_2CO_3
Etching profile	Vertical sidewall	Undercut	Vertical sidewall	Vertical sidewall
Smallest feature	2 μm	2 μm	20 μm	20 μm
Compatibility with plastic substrate in developing	No (surface coating and back cover are needed)	No (surface coating and back cover are needed)	Yes	Yes
Thickness of single layer	Any thickness up to 1 mm	~20 μm	64 μm	30 μm
Bonding to dry resist film	Excellent	Excellent	Excellent	Excellent
Adhesion to substrate	Excellent	Excellent	Excellent	Good
Uniformity	Good	Fair	Excellent	Excellent
Flexibility	Not applicable	Not applicable	Excellent	Brittle
Developing	Vibration needed	Vibration needed	Washing needed	Easy and quick
Multicoating availability	Yes	Yes	Multilayers by lamination	Multilayers by lamination

*PGMEA, propylene glycol methyl ether acetate.

front end part of the IC industry (e.g., lift-off, integration).

As a concrete example, the manufacturing procedure of an individual ion selective electrode array element, say, for sensing potassium, is illustrated in Figure 1.21. These electrochemical planar sensors may be made on a variety of polymer substrates; currently we use 5 × 5 in dry negative photoresist sheets (e.g., Pyralux). Pyralux comes in rolls, so it will eventually be possible to make these types of sensors in a continuous process (as depicted in Figure 1.19). An important simplification in the sensor manufacture depicted in Figure 1.21 is the self-aligned step. By exposing the dry resist from the top through the photomask, both cavities in the photoresist bilayer are made at the same time. The top cavity results from the pattern on the mask while the bottom cavity originates from the silk-screened Ag pattern, which acts as a mask for the lower part of the resist. No expensive double exposure system is required.

Fluid handling for calibration or washing steps may be implemented on the basis of the same dry photoresist technology. Fluidic structures have been made directly in all of the various resist systems listed in Table 1.12. The use of two or more photoresists in combination has enabled the fabrication of photopatternable multilayer microfluidic structures. For example, Madou et al.[63] have sealed photopatterned microchannels of SU-8 with sheets of the flexible photoresist, Pyralux, as shown in Figure 1.22a. Subsequent patterning of the Pyralux allows for the creation of more complex three-dimensional fluidic structures, as seen from Figure 1.22b. The

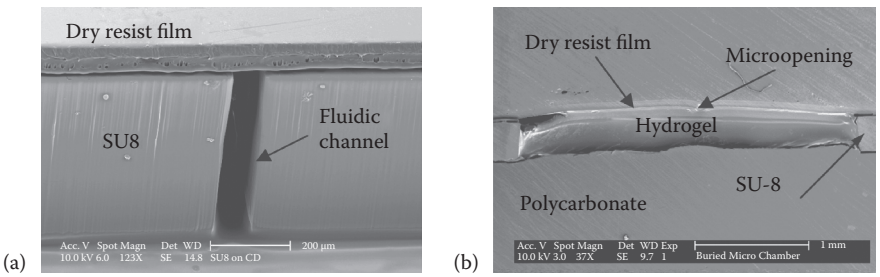

FIGURE 1.22 Buried SU-8 microchannel (a) and multilevel microchamber filled with hydrogel (b) (to be used as an onboard electrochemical reference electrode).[63]

latter structure can be used, for example, to seal liquids or hydrogels such as for an onboard electrochemical reference electrode.

The above "beyond batch" fabrication sequence is generic and applies equally well if optical sensor probes have been selected and will make it possible to fabricate biosensors in an affordable manner. This will lead to a wide variety of additional biomedical products currently impossible to fabricate using silicon technology.

Questions

1.1: List three different methods one can utilize to deposit a thin-metal film on a MEMS structure.

1.2: What do the following acronyms stand for? MEMS, VLSI, DUV, DOF, SEM, NGL, NA, MTF, OAI, OPC, RIE, and CMOS.

1.3: Compare laser-machining (LM) with e-beam machining (EBM).

1.4: The following bulleted list includes examples of micromaching tools:

(a) Classify them according to the applied energy appearance (W: wet chemical and electrochemical machining; M: mechanical machining; E: electrothermal machining) at the workpiece.

(b) Classify them according to machining methods (S: subtractive; A: additive; S/A: subtractive and additive).

- Photofabrication
- Laser beam machining
- Diamond milling
- Chemical and electrochemical milling
- Electron beam machining
- Photochemical milling
- Dry etching
- Ultrasonic machining
- Plasma beam machining
- Abrasive jet machining
- Electroplating and electroless plating
- Stereolithography
- Electrodischarge machining

1.5: Provide a comparison of the economic and technical aspects in the construction of sensors with thin-film technology, IC fabrication (semiconductor substrates), thick film, and classic construction.

1.6: Why use miniaturization technology?

1.7: Get calibrated: What is a mil or a thou? How many microns in a mil? How many thousandths of an inch (thou or mil) are there in a millimeter? Approximately how thick is a human hair? Approximately how big is a virus? A bacterium? A red blood cell? How thick is a standard sheet of paper?

1.8: How small is small? There are many manufacturing processes other than silicon micromachining for making small parts. Do some research to find specifications for various manufacturing processes, small devices, and tools. Search the Internet, call companies, use the Yellow Pages, use a Thomas's Register, ask a machinist, ask your instructor, etc. We're looking for the lower limits on traditional machining or tools that are currently commercially available at a local job shop or a tool distributor. The objective is to get a feel for the boundary between MEMS and traditional machining.

1.9: Reconstruct the decision tree to reach an optimized micromanufacturing option for a given miniaturization problem.

1.10: Explain the statement that MEMS engineers should design from the MEMS package inwards.

1.11: Make a comparison of additive thin- versus thick-film technology.

1.12: Explain the progress from serial to batch to beyond batch manufacturing (R2R).

1.13: Characterize objects made by laser machining, mechanical machining, E-beam machining, and plastic molding using the following criteria:

- Projected versus 3D
- Serial, batch, or continuous manufacturing
- Top-down or bottom-up machining

What then is the vocation of the whole man? So far as I can make out, his vocation is to be a creator: and if you ask me, creator of what, I answer—creator of real values … And if you ask me what motive can be appealed to, what driving power can be relied on, to bring out the creative element in men and women, there is only one answer I can give; but I give it without hesitation—the love of beauty, innate in everybody, but suppressed, smothered, thwarted in most of us …

Watson and Crick with DNA model.

Fall of Icarus. Mimicking nature—biomimetics. The Flemish artist Peter Paul Rubens (1636–1638) depicts Daedalus looking on as his son Icarus is falling from the sky. The picture is sometimes used to illustrate human arrogance. In the current context, the painting illustrates an early attempt at biomimetics: the fixing of bird wings onto human arms with beeswax. When Icarus flew too close to the sun, the wax melted.

Introduction

In biomimetics, one studies how nature, building atom by atom, i.e., through bottom-up manufacturing, through eons of evolution of life, developed materials, structures, processes, and intelligence to inspire and improve the engineering and design of artificial materials, human-made structures and processes (e.g., software). Human manufacturing technology works in the opposite direction, i.e., it builds top-down; in most current manufacturing we tend to start with larger building blocks and use stiff materials (e.g., Si or stainless steel), whereas nature prefers small building blocks and mostly soft, low-Young's modulus materials (e.g., muscle or skin). Throughout history, biomimetics has been attempted but often with less than satisfactory results. Bird flight, for example, did not lead to aircraft, but mathematical expressions from aerodynamics did. As a consequence, from the middle of the eighteenth century to about thirty years ago, engineers were tempted to engineer around nature's obstacles rather than be inspired by nature itself. Today though, in fields ranging from artificial intelligence to microelectromechanical systems (MEMS), nanoelectromechanical systems (NEMS), and smart materials, the perceived advantages of bottom-up designs and manufacturing are convincing many scientists to research natural, biomimetic approaches and manufacturing methods. In this chapter, we first introduce the most important engineering feats of nature and then explain how these are applied in today's biotechnology. It can be argued that molecular scientists and genetic engineers were practicing nanotechnology long before the name became popular with electrical and mechanical engineers. Actually molecular biology or "wet nanotechnology" has been called by some "nanotechnology that works." To be fair, molecular biology discoveries were rarely seen in the light of improved manufacturing techniques, as the discoverers were usually aiming for improved diagnostics and therapeutics. Within this context we introduce the use of natural polymers and their mutants not only for optimized sensing and realizing new drugs but also for the fabrication of actuators and new manufacturing techniques in general.

We start this chapter on a philosophical note, inquiring into the wisdom of biomimetics. We then detail a long list of nature's engineering feats. We try to define life on Earth and other planets, list the many ideas about the emergence of life, introduce DNA and RNA as the software of life and proteins as its hardware, and explain the build of a biological cell and the genetic code. We dwell on how nature generates power, while biomimetic approaches to packaging of nanocomponents are covered in Chapter 4, this volume, on packaging, assembly, and self-assembly, and on implementation of artificial intelligence in Chapter 9, on power and brains in miniature devices.

After introducing a definition of biotechnology we present examples of the use of MEMS and NEMS in biotechnology. We finish this chapter with a comparison of human- and nature-engineered structures.

This chapter is also meant as a bridge from *dry* engineering, in air and with rigid materials (mechanical and electrical engineering), to *wet* engineering, with flexible materials in aqueous solutions (biology and molecular engineering). Miniaturization science in 2011 is still practiced predominantly by electrical and mechanical engineers, but as applications are becoming more and more biological in nature, biologists, materials scientists, chemists, and physicists must work together with electrical and mechanical engineers to develop new miniaturization solutions. We hope that this chapter will further stimulate such collaborations.

Icarus Revisited?

Biomimetic-oriented manufacturing is a hot topic today, but some caution might be in order. As the legend of Icarus reminds us, at least some previous attempts at biomimetics have resulted in failure. The chapter-opening *Fall of Icarus* illustrates an early attempt at biomimetics. Icarus and his father Daedalus fixed bird wings onto their arms with beeswax. When Icarus flew too close to the sun, the wax melted and he fell to his death in the Mediterranean.

Smallness is the ancestral condition of life. Large organisms are built bottom-up from cells rather than divided into cells. Cells are, in turn, fabricated from yet smaller entities. A single *Escherichia coli* bacterium,

for example, is shaped like a cylinder about 1 μm across and 3 μm long. It contains at least 3000 different molecular parts and will divide every 20 min when nutrients are available. No wonder scientists are intrigued by the miniaturization skills displayed by nature! But zoologist Steven Vogel, in his book *Cats' Paws and Catapults*,[1] asks a question very relevant to this chapter: "Who then is the better technologist? Mother Nature or the human engineer?" Natural design and biomimetics are very popular today and, according to Vogel, in danger of being overused or misinterpreted. Vogel presents a balanced view on the relative merits of natural and human mechanical design. He points out that although nature often exemplifies desired features, mimicking it has proved useful on surprisingly few occasions (as the Icarus legend attests). Vogel's explanation is that human and natural mechanical designs are two individually well-integrated technologies, but they are within very separate contexts. Each might be uniquely integrated by its own elements of internal harmony and consistency, but an impressive aspect of one may have little relevance to the other. A prominent example is metallurgy. In human technology, metals enable stamping, forging, casting, grounding, slicing, and sawing. No known organism uses pieces of pure metal for any mechanical purpose; they make stiff materials into artifacts by internal growth and surface deposition. So humanity's diverse array of metal manufacturing techniques is of no value in nature. Nature, on the other hand, does not use steel or favor the production of flat surfaces and sharp corners—all very useful in human manufacturing. Nature builds with proteins and produces mostly curved surfaces and rounded corners, resulting in such masterfully engineered objects as biological cells. Both natural and human manufacturing approaches have their merits within their own proper frame of reference. As a consequence, Vogel maintains, most attempts at mimicking nature have failed; we do not fly in aircraft with flapping wings or use wood to build skyscrapers. Vogel's comparison of human and nature's engineering feats principally deals with large designs, where he finds them competitive.

However, it is at the nanoscale level that nature truly excels, and perhaps Vogel's contention might not hold true in nanoengineering. In the nanoworld, nature is way ahead of human engineering, as it works with much smaller, more versatile building blocks and has mastered the self-assembly and multiparallel construction of those building blocks to create large, hierarchically arranged organisms that are much more complex than even the most complex human machines. Today, using human engineering techniques such as MEMS and NEMS, we are not able to build a single micromachine displaying anywhere near the complexity of even the simplest biological cell.

With biomimetic bottom-up manufacturing techniques, we are able to synthesize natural and mutant nucleic acids and proteins. Using well-established approaches such as recombinant DNA, gene shuffling, and knockout mutations, we can alter the genome of a cell, but there has been little progress made assembling an artificial cell or even the simplest organelle. But all this might be changing soon: at the end of 2007, a team of 20 scientists constructed a synthetic chromosome that is 381 genes long and contains 582,970 base pairs of genetic code, using lab-made chemicals at the J. Craig Venter Institute.[2] Prior to this work, the largest synthesized DNA contained only 32,000 base pairs. The J. Craig Venter team achieved its technical breakthrough by chemically making DNA fragments in the lab and developing new methods for their assembly and reproduction. After several years of work perfecting chemical assembly, the team members found that they could use homologous recombination (a process that cells use to repair damage to their chromosomes) in the yeast *Saccharomyces cerevisiae* to rapidly construct the entire artificial bacterial chromosome from large synthesized subassemblies. This team then started working toward the ultimate goal of inserting a synthetic chromosome into a cell and booting it up to create the first synthetic organism. The artificial chromosome was to be transplanted into a living bacterial cell, and in the final stage of the process, it was anticipated to take control of the cell and in effect become a new life form. The new life form would still depend for its ability to replicate itself and metabolize on the molecular machinery of the cell into which it has been introduced, and in that sense, it would not be a wholly synthetic life form, rather one more in tune with a parasitic

life form. In May 2010, Venter's team did indeed create such a "synthetic cell," i.e., a normal bacterial cell controlled by DNA made in the lab. The Venter team first decoded the genome of the bacterium *Mycoplasma mycoides*. Then they purchased about 1000 bits of DNA about 1000 letters long that make up that bacterial genome. These bits were stitched together in the right order by putting them into yeast cells. The completed synthetic genome, containing almost 1000 genes, was then put into a different kind of bacterial cell, *Mycoplasma capricolum*, where it replaced the native DNA. The man-made DNA booted up the host cell, which began to replicate, making millions of *M. mycoides* cells.[70] Possible applications of this technology are unlimited. For example, in medicine, imagine that synthetic genes could be introduced into individuals suffering from a genetic disease, where they are missing genes or have damaged ones. The ability to correct the original faulty gene could potentially constitute a cure for a number of genetic diseases. Since building large genomes is now feasible and scalable, other important applications, such as biofuels, can be envisioned. Along this line, Venter's team is working already with Exxon Mobil to develop algae that soak up carbon dioxide and convert it into hydrocarbon fuel, and on new vaccines with Novartis. The hope is that many other complex, engineered microbes will be developed to clean up water, produce new forms of food, textiles, pharmaceuticals and industrial chemicals in ways that naturally occurring microbes cannot achieve.

The reason that nature is leading in nanotechnology may be sought in the fact that evolution has worked much longer on developing a single biological cell (3.5 billion years for the first life-forms to evolve) than on the larger life-forms (*Homo sapiens sapiens* first appeared only about 120,000 years ago). In other words, many designs were experimented with over a much longer period of time to come to the optimally designed single-cell life forms than for the larger living creatures such as trees and humans. It will perhaps be through nanochemistry that humans can aspire to reach the same level of sophistication in the manufacture of nanostructures as nature does. Moreover, the flight of birds did inspire the Wright brothers' first successful fixed-wing aircraft. But, as we are cautioned to do, the Wright brothers did not blindly mimic nature: they used fixed-wing aircraft, not the flapping bird wings of Icarus. That is, one should learn from nature's manufacturing techniques and adapt them to human/societal needs rather than blindly mimic king nature's approaches. After all, nature's manufacturing techniques are geared toward maximizing procreation, not toward maximizing speed and efficiency of product manufacturing techniques in a modern human societal context.

As humans learn to build with the same construction set as nature does, we are bound to challenge nature in nanoengineering. Because it uses relatively large building blocks, human manufacturing is rapid, and the expectation is that nature, because it uses much smaller building blocks (for example, atoms with a diameter of 0.3 nm), must be very slow. To offset the time it takes to work with small, basic building blocks, nature, in growing an organism, relies on an additive process featuring massive parallelism and self-assembly, the latter of which is introduced as one of the key characteristics of bottom-up manufacturing, detailed in Chapter 3, this volume.

Nature's Engineering Feats

Life?

The question of how exactly to define life has been a constant dilemma throughout humankind's history. Scientists of the stature of Schrödinger, Fermi, Arrhenius, Hoyle, von Helmholtz, Eigen, Haldane, von Neumann, Urey, Oparin, Monod, Dyson, de Duve, and Crick, to name a few, have been preoccupied with this question. From the plethora of ideas and the many attempts to characterize life that emerged from these thinkers, we select a few that promise the longest staying power. We refer to "ideas" and "characterizations" of life rather than "definitions," as no definition has yet been presented that is accurate enough.[3]

One of the better ideas comes from the book *Life Itself: Its Origin and Nature* by Francis Crick, who describes life as a process that is able to directly replicate its own instructions and indirectly replicate any machinery needed to execute those instructions.[4] Others consider something to be alive if it exhibits a minimal set of features that include,

Table 2.1 Characteristics Associated with Living Things

Characteristic	Remarks
Typical chemistry	Proteins, nucleic acids, fatty acids, sugars and water. Several of these chemicals can also be found in nonliving matter.
Very high degree of complexity	The incredible complexity guarantees the unpredictability of organisms. The weather is also very complex though and few would consider it alive.
Self-organization	Perhaps more important than complexity is organized complexity. Then again, there are also self-assembled monolayers and micelles that we would not call alive.
Chirality	Life on Earth almost exclusively uses left-handed amino acids and right-handed DNA. Experiments show that proteins cannot form if both right- and left-handed DNA are present.
Self-repair	The object is capable of rectifying errors in either its metabolic or genetic machinery.
Autonomy or self-determination	Spontaneity, inner freedom—perhaps the most enigmatic characteristic of life to explain, and one that sets life apart from nonlife.
Decrease in entropy	The increasing complexity of a living organism goes hand in hand with a decreasing entropy. Unfortunately, such a definition also characterizes a refrigerator.
Metabolism and homeostasis	Taking up substances (nutrition) to garner energy and excrete others reaching an equilibrium body shape. But what does this characterization make of a dormant microorganism?
Self-recognition	Distinguish foreign from self and reject foreign.
Sensitivity	Response to environmental stimuli.
Information content	The information needed to replicate an organism is encoded in the genes.
Replication	Identical offspring are generated. Then again, many molecules and crystals form templates for replication.
Evolution (natural selection)	Populations change over time.
Reproduction	Offspring is more than a facsimile; it also must incorporate a copy of the replication mechanism. Slight differences in the offspring are implied. Clays can replicate as well as reproduce (see text).
Growth and development	Growth and gradual evolutionary development, often from a single cell, to more complex structures. Crystals also grow, but there is no actual evolutionary adaptation.
Heredity	Transmit information from generation to generation with some slight changes embedded.

for example, metabolism, self-repair, and replication. A more complete set of characteristics associated with living "things" is summarized in Table 2.1. Not all organisms exhibit all these features all at once, but a combination of some of these characteristics can describe almost anything that can be defined as *alive* on Earth.

From Table 2.1, we learn that thermodynamics offers one of the many descriptions of life. In a living system, materials and free energy (ΔG) flow into the organism, and waste and heat (ΔH) flow out of it. Living things, from the lowly bacteria to the more sophisticated, intelligent humans, all are highly ordered compared with their constituent molecules and seem to violate the law of increasing entropy (second law of thermodynamics). The second law of thermodynamics states that in any spontaneous process, there always is an increase in entropy. Living creatures have spontaneously developed into more ordered and sophisticated systems through evolution with an accompanying decrease in entropy (ΔS). This apparent violation of the second law of thermodynamics is easily explained if one recognizes that the evolutionary process takes place within the broader context of a universe in which chaos keeps on increasing. In more rigorous thermodynamic terms, the argument goes as follows: the entropy of the universe may be expressed as the sum of the system under study (life) and its surroundings, as follows.

$$\Delta S_{\text{universe}} = \Delta S_{\text{system}} + \Delta S_{\text{surroundings}} \qquad (2.1)$$

In life, large molecules assemble from simple, small ones into those that are increasingly complex; that is, ΔS_{system} is negative. To reconcile this with Equation 2.1, we must remember that $\Delta S_{universe}$ must be positive, which can be achieved only if $\Delta S_{surroundings}$ is large and positive.[5*]

To illustrate how weak some of these "definitions" of life are, just consider a thermodynamic definition, often presented in the literature: a living system is one that can maintain itself in a state of low entropy. However, a definition in which a system reducing its entropy through interaction with its environment is considered alive would also qualify your refrigerator—or the weather, for that matter.

Computer science (through modeling of artificial life), mathematics (through complexity theory), and information theory all contribute their own definitions. The following are some of the basic tenets. In artificial life, or a-life, computer-virus-like entities are created in an artificial computer world (e.g., Tom Ray's *Tierra* and *Network Tierra*);[6] these creatures reproduce, mutate, evolve, and die. Some scientists actually have considered these digital entities alive. Critics of a-life are skeptical because of the many simplifications and the arbitrariness of its rules. Independent of the issue of a-life being alive or not, important information about what life is and how it evolved might be gathered in days rather than over millions or billions of years. Indeed, because of the simulation power of today's computers, Darwinian evolution scenarios, involving creatures of varying complexity and different degrees of environmental pressures, can be played out over short periods of time.

The continuing study of complex systems may result in a better definition of *life*. Complexity scientists suggest that life is an "emergent" or "self-organizational" property that arises spontaneously when a broth of different chemicals reaches a certain level of complexity.[3] Others are adamant that it is the principle of information economy in self-developing systems that provided the guiding principle of biological evolution. Artificial life and complexity theory is touched upon in Chapter 9, on power and brains in miniature devices, and in "Emergence of Life: Biogenesis" below. Some artificial life Web sites can be found at http://alife .org and http://www.alcyone.com/max/links/alife .html. It is perhaps best at this point to admit that, today at least, because of its complexity, we cannot define what life really is and that describing life obviously is easier than defining it.

Life on Other Planets?

To garner a better understanding of what life is, we might look for it on other planets. The search for extraterrestrial intelligence (SETI) (http://setiathome.ssl.berkeley.edu) is privately funded and kept somewhat at arms' length by NASA out of fear of criticism by overzealous politicians, who would rather spend tax dollars finding weapons of mass destruction. Use of miniaturized systems figures prominently in this quest, and NASA is an important funding source for miniaturization science. It is beyond the scope of this book to dwell on SETI, but a brief introduction of the Drake equation, which predicts the probability of finding intelligent life on other planets, might motivate interested readers to explore the topic further. The Drake equation has been a starting point for almost all theoretical speculation on the existence of extraterrestrial intelligence since 1960.[7] The equation is a product of a large number of elements, most of which are only vaguely known:

$$N = R^* \times \underbrace{f_p \times n_e}_{\text{Physical}} \times \underbrace{f_l \times f_i}_{\text{Biological}} \times \underbrace{f_c \times L}_{\text{Cultural}} \qquad (2.2)$$

The elements forming the Drake equation are as follows.

Physical Elements

R^* = the rate at which stars are formed in our galaxy per year; f_p = the fraction of stars, once formed, that will have a planetary system; n_e = the number of planets in each planetary system with the right environment suitable for life.

* But where did the order of the universe as a whole come from? The second law of thermodynamics must have been violated during creation! Pointing out that the expanding universe allows increasing room for order to form could deflate this point, but then one may further ask where did the energy and mass of the universe originate? The first law of thermodynamics (conservation of energy) must have been violated at creation. This point may perhaps be refuted as well since the positive energy of the universe is exactly balanced by the negative gravitational potential energy: E = k(inetic) + mc^2 (matter/energy) – V_g (gravitational) = 0. So perhaps no energy was required to produce the universe?

Biological Elements

f_l = the probability that life will develop on a suitable planet; f_i = the probability that life will develop to an intelligent state.

Cultural Elements

f_c = the probability that intelligent life will develop a culture capable of communicating over interstellar distances; L = the time (in years) that such a culture will spend trying to communicate.

We know that *N* is no less than 1, as manifested by life on Earth. Beyond that, the widest range of *N* values has been proposed—from 1 all the way up to >100 million! *Paradigms Lost* by John Casti (1989)[7] presents an excellent treatise on the subject. Casti revisited the topic in 2000[8] and points out that, since his *Paradigms Lost* of 1989, the evidence for planetary systems outside our own solar system has become overwhelming, increasing n_e in Equation 2.2.

Most of the "life" sensors that NASA has developed so far are based on the assumption that life on other planets is similar to that on Earth and are based on sensors for flow of typical Earth-type feed materials (e.g., oxygen) and Earth-type waste materials (e.g., carbon dioxide), or they may be heat flow detectors. A few such "life" detectors were tested on Mars. Oyama, for example, in a Mars *Viking* experiment, wetted a soil sample with amino acids and other nutrients and then monitored common metabolic gases, such as carbon dioxide, oxygen, and hydrogen.[9] Perhaps too many experiments designed to find life on other planets are based on the expectation of Earth-like life and a specific molecular structure rather than on an abstract system featuring properties such as adaptability, flexibility, reproduction, and self-organization. Life elsewhere might well involve molecules other than DNA.

Crick, in his 1981 *Life Itself: Its Origins and Nature,*[4] details the Panspermia theory, quite controversial at the time, in which life on Earth came from somewhere else in the universe. This, of course, puts the question about what life is, or how it emerged, on another planet and does not answer the underlying question. Interestingly, the Panspermia theory has found new supporters. In August 1996, it was announced that features that were explained as life forms more primitive than those on Earth were found in a 4-pound meteorite retrieved on Earth but originating from Mars* named ALH84001[8] (Figure 2.1). A mineralogical study concluded that the temperature of the rock never rose much above that of boiling water, and a living microbe or spore deeper inside would have survived the voyage. There have also been new suggestions that extremely sturdy life forms might reach Earth unscathed via dust or small objects such as comets.[10,11] We do, indeed, know now that some types of meteorites contain carbon and organic chemicals, including amino acids.[11] In this context, the amino acid glycine was found inside the galactic cloud Sagittarius B2 in 1994.[8] An issue that the cosmic seed theory does address is how life on Earth could get off to such a quick start; it might have arrived nearly fully developed!

FIGURE 2.1 ALH84001. A rock from Mars retrieved on Earth.

Emergence of Life: Biogenesis

Introduction

Religious debates aside (Genesis with creationism, vitalism, reincarnation, etc.), and ignoring earlier suggested life forces such as psyche, air, lifeblood, phlogiston, electricity, and radioactivity, the question about the "emergence" of life has been even more controversial than the question about what life itself is. The two questions, as suggested in the preceding section, are intertwined: if we knew how

* The 1996 NASA announcement of potential proof for life on Mars is still mired in controversy relating to life originating from inorganic or organic sources.

life evolved, we might be able to define it better. There are several schools of thought on the issue. We briefly review the most prominent ones.

DNA, RNA, and Proteins: Who Was on First?

Four billion years ago, there was so much cratering on the moon and on Earth's surface that no life could have taken hold. The oldest fossilized bacteria date the start of life on Earth to 3.8 billion years ago. The starting point of "life," in a "narrow" window between 3.8 and 4 billion years ago, might have been a simple molecule with the ability to catalyze its own formation from raw materials found in its immediate surroundings—*replication through autocatalysis*. The period of "competing chemistries" before terrestrial life developed is known as the *prebiotic* phase. One or several self-replicating "mother molecules" must have led to the molecules of life we have come to know: deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and proteins. In Table 2.2 we summarize some of the most common terms/definitions used in the context of the emergence of life (biogenesis) and genetics.

Many of the debates have focused around the primacy of DNA versus RNA versus proteins. We discuss life's functional polymers—DNA, RNA, and proteins—and the genetic code in more detail below. For now, it will suffice to expose the purported roles of DNA, RNA, and proteins in the emergence of life.

1. *DNA first.* DNA is the repository of genetic information and would seem like a logical candidate to be the first molecule of terrestrial life to follow one or more of the mother molecules of prebiotic times. However, this is not so. It is widely accepted that the carrier of the genetic code could not have been at the cradle of life, as it cannot replicate without the presence of certain proteins. To be specific, it needs enzymes unzipping its double helix structure before it can replicate. Some theories have RNA emerging first, others proteins, and yet others have both of them arising separately and developing a symbiotic relationship. In all instances DNA would have emerged later as a more reliable repository for genetic information.
2. *RNA first.* RNA is involved in the copying of the DNA genetic code and the assembly of amino acids into proteins on the basis of the copied DNA blueprint. As told by Casti, Eigen et al., in 1974, showed that from a broth containing the four RNA bases and an enzyme, RNA could self-assemble.[8] Thomas Cech (1989 Nobel Prize winner for Chemistry for the codiscovery of ribozymes, and now director of the Howard Hughes Medical Institute), when at the University of Colorado, demonstrated that RNA exhibits enzymatic properties and can catalyze the replication of other RNA molecules (i.e., ribozymes).[8] According to Matt Ridley, RNA was Greece to DNA's Rome, Homer to its Virgil.[12]
3. *Proteins first.* Proteins are the basis of a wide variety of functions (e.g., catalysis of reactions and immunoreactions to combat disease) and structural elements (e.g., in skin and hair). There is also evidence for the protein-first model. Reza Ghadiri, for example, showed that in homogeneous solutions, certain small peptides can catalyze the formation of other peptides, form symbiotic relationships, and spontaneously develop error-correcting mechanisms that prevent mutant forms from replicating.[8] In 1997, Lee et al.[13] published results in *Nature* on a helical peptide that is able to replicate itself, so the debate of what came first, RNA or protein, remains unsettled.
4. There also are serious problems with the pre-DNA models. The RNA-first model, for example, is thought to be too prone to errors. Coding errors are induced by mutations, and they are quite frequent in RNA, as there is only one strand of the molecule, and there would have been no "proofreading" enzymes available. As we will see below, DNA features two strands and special enzymes that repair coding errors before the code is translated into proteins. The RNA error rate explains why nature eventually switched to the more secure DNA molecule in order to protect its software. In the case of the proteins-first model, it is not easily understood how proteins could have passed on their heritage. An example of a symbiotic relationship theory is the one postulated by

Table 2.2 Common Terms Used in Biogenesis and Genetics

Term	Definition
Allele	Slight variant of the same gene in a given species.
Archaea	Archaeans are single-celled creatures that join bacteria to make up a category of life called the prokaryotes (pronounced "pro-carry-oats").
Chromosomes	A complex structured set of DNA with proteins inside the cell nucleus. It stores genetic information.
DNA	Biological chain molecule built from four kinds of building blocks, the nucleotides. DNA, normally found as a double helix spiral of two complementary strands, is the carrier of genetic information in all cellular life forms and many viruses.
Eukaryotes	Creatures whose cells have a nucleus, which contains the genetic information (pronounced "ew-carry-oats").
Gene	A segment of DNA containing the necessary information to produce a particular protein.
Genome	All of the DNA possessed by an individual member of a species.
Genotype	The particular collection of various possible gene alleles present in the genome of a given individual.
Germ cells	The cells of the body involved in reproduction; i.e., the sperm of the male and the eggs of the female are formed from germ cells.
Heterozygous	If there is more than one allele of a given gene within the population, an individual might have two different alleles for a given gene, in which case that individual is said to be heterozygous for that gene.
Homologous chromosomes	Chromosomes containing the same gene sequence.
Homozygous	Having the same alleles at a particular gene locus on homologous chromosomes.
Mutation	Modification of a DNA sequence extending from a single base change to the addition or elimination of an entire DNA fragment.
Phenotype	The physically discernible features resulting from a particular genotype.
Polymorphic genes	Genes that have allelic forms.
Prokaryotes	Prokaryotes' genetic material, or DNA, is not enclosed in a central cellular compartment called the nucleus. Bacteria and archaea are the only organisms of this class.
Protein	Molecules made up of long chains of amino acids. They build tissues, organs, etc., and carry out many critical functions in the body.
RNA	A nucleotide chain that differs from DNA in having the sugar ribose instead of deoxyribose and having the base uracil instead of thymine. RNA helps translate the instructions encoded by DNA in order to synthesize proteins.
Single-nucleotide polymorphisms	Differences (polymorphism) of individual bases within a genome from different individuals.
Somatic cells	All of the cells in the body except the germinating cells, such as those in the eggs and sperm.

Freeman Dyson. In this attractive model, a vesicle or cell (the hardware) metabolizes proteins but has no genome (the software) until a primitive nucleic acid replicating molecule invades the vesicle and finds it advantageous to replicate not only itself but also all the helpful proteins it finds in the cell.[8]

Made from Clay?

A rival theory to the DNA-, RNA-, or proteins-first models has life originating from inorganic materials such as clays. (Life originating from clay! Where have we heard this before?) This concept was first advanced in 1982 by Cairns-Smith,[8,10] a chemist at the University of Glasgow, Scotland. In a test tube,

small clay plates (platelets), less fragile than nucleic acids, given the right feed stock, will replicate—that is, identical offspring are generated (see Figure 2.2a). In a natural, more challenging setting in which a small change might induce the platelets to change shape (evolution), they may even reproduce—that is, their offspring become somewhat different, and these offspring may in turn replicate (identical offspring) or reproduce (offspring changed in shape). Microcrystals of clay, typically flat platelets with two large plane surfaces exposed to the surrounding medium, consist of a silicate lattice with a regular array of ionic sites but an irregular distribution of metal ions (e.g., Mg^{2+} and Al^{3+}) occupying these sites. The precise arrangement of metal ions in the clay may be capable of catalyzing specific reactions of organic molecules on the clay surface. These organic molecules in turn can bestow certain benefits onto the clay crystals: perhaps a more advantageous platelet shape or cementing the crystal planes together better—anything that protects them against the environment and speeds up (catalyzes) their replication. During crystal growth, silicate and metal ions from the surrounding medium will tend to carry the same pattern of ionic charges as the clay layer below it. In this way, the metal ion patterns, the carriers of information, are replicated and selected by environmental pressures. Replication and reproduction of clay are illustrated in Figure 2.2a. In a clay such as kaolinite, many cross-sectional shapes of crystallites are possible. The electron micrograph of the structure of kaolinite in Figure 2.2b illustrates the basic idea. The distribution of metal ions on these platelets, in association with organic molecules from the surrounding medium, helps favor one platelet out-replicating another. Physical aspects of the crystal act as the phenotype (what an organism—in this case a crystal—looks like as a consequence of its genotype) and cause selection to choose among the genotypes (the genes that an organism possesses).

Cairns-Smith suggests that clays came first, enzymes second, cells third, and genes fourth. After natural clay *learned* to direct synthesis of organic molecules, clay and organics *learned* to make a cell membrane. These cells containing clay as the hereditary unit eventually *discovered* RNA, which "piggybacked" at first on clays as they fitted snuggly into clay lattices. Clays might then have found a way of fabricating these self-replicating organics and, consequently, they would have quickly out-replicated other clays. By piggybacking on clays, RNA could have existed for a long time before becoming self-replicating. Once the organic molecules on the clay started replicating faster and faster by absorbing organic material from their surroundings, "organic life" might have taken over from "inorganic life." The latter is called a genetic takeover. For Cairns-Smith's bibliography and work, see http://originoflife.net/cairns_smith/index.html. There was not much experimental evidence for the Cairns-Smith's model until 1996, when Ertem and Ferris discovered that long strands of RNA, given the right feedstock, form spontaneously on the surface of montmorillonite (a type of clay).[14]

Life's Origin beneath the Earth's Surface?

The Archaea (also Archaeabacteria) constitute the earliest and most basic life form: relatively simple single-celled organisms that are chemotrophic; i.e., they do not need light, as they make biomass via chemical energy rather than light. Today, these organisms are still often are found in "extremophiles" living in harsh, toxic environments. Archaea use

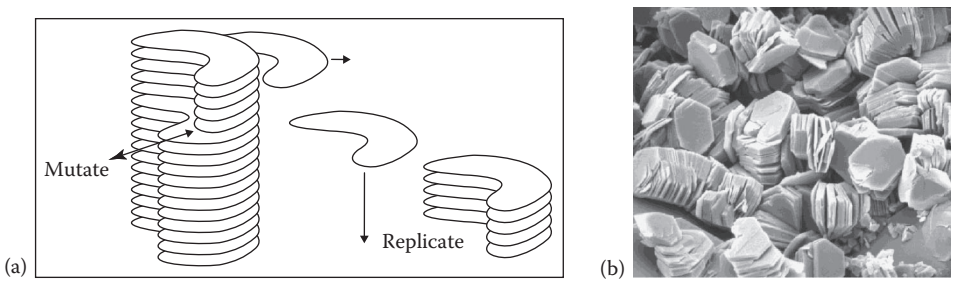

FIGURE 2.2 Replication and reproduction. (a) Replication and reproduction in a stack of clay platelets. (b) Electron micrographs of the structure of kaolinite clay.

a remarkable diversity of metabolic tricks and adaptations to survive under apparently impossible conditions. A lot of information has been gathered on these "superbugs" in the last twenty years; they have been found in oil wells, the Dead Sea, the Antarctic, near volcanic deep-sea vents, and deep down below the Earth's surface. From the Archaea two quite different groups developed, namely, the Eubacteria (bacteria) and the Eukarya (eukaryotes). Archaeans and Eubacteria (bacteria) make up a category of life called the prokaryotes. In prokaryotes, the genetic material, or DNA, is not enclosed in a nucleus, a central cellular compartment. The Eukarya include all organisms made up of cells with nuclei; that is, their DNA is walled off in a separate compartment of the cell (see also below under "Cells," Figure 2.20). It should be noted that extremophiles also include bacteria, and these hardy organisms can be grouped as acidophiles (acid loving), halophiles (salt loving), thermophiles (heat loving), hyperthermophiles (the present record is 121°C), psychrophiles (cold loving), alkaliphiles (thriving at high pH), barophiles (surviving under high-pressure levels, especially in deep sea vents), osmophiles (surviving in high-sugar environments), xerophiles (surviving in hot deserts where water is scarce), anaerobes (surviving in habitats lacking oxygen), microaerophiles (surviving under low-oxygen conditions), endoliths (dwelling in rocks and caves), and toxitolerants (able to withstand high levels of damaging agents, for example, living in water saturated with benzene or in the water core of a nuclear reactor).

Carl Woese, from the University of Illinois, in 1977, had a hard time convincing the world about the existence of Archaeans.[15] Woese found that Archaeans clustered together as a group well away from the usual bacteria and the eukaryotes. Because of their vast differences in genetic makeup, he proposed that life be divided into three domains: Eukaryota, Eubacteria, and Archaebacteria (Figure 2.3). Craig Venter, in 1996, completed the genome sequence of the first Archaean, *Methanococcus jannaschii*. The genome data of this hardy bacterium, thriving at a balmy 85°C and 200 atm of pressure,

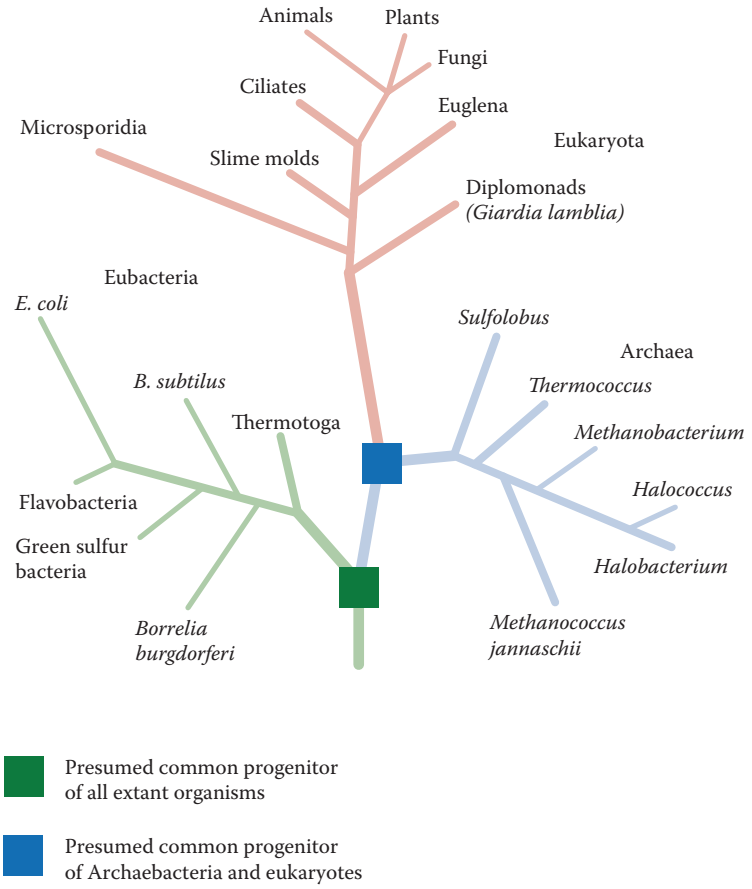

FIGURE 2.3 The tree of life.

includes the sequence of more than 1700 extremely heat-stable proteins never before sequenced.

The idea that chemicals beneath the Earth's surface produced these prebiotic replicators is attractive to many researchers. Early Earth, with high concentrations of $CO_2/H_2S/H_2$ etc., low oxygen levels, and high temperatures, was largely inhospitable to life as we know it today. Life forms that could evolve in such an environment needed to adapt to these extreme conditions. Many hyperthermophiles and Archaea are H_2 oxidizers. Thus, it is widely held now that extremophiles represent the earliest forms of life, with nonextreme forms evolving after cyanobacteria had accumulated enough O_2 in the atmosphere.

The recognition of life in those harsh environments on Earth makes the prospect of life on a harsh planet like Mars a bit more likely, and Archaea are favorites of the adherents of the Panspermia theory. A Web site with good information on extremophiles is http://www.astrobiology.com/extreme.html.

Extremophiles present a tremendous opportunity for more robust biotechnology processes and nanochemistry. Ordinary natural macromolecules cannot withstand extreme environments, making the prospect of widely used bottom-up, biomimetic devices less bright unless proteins from these superbugs are used to implement more robust nanochemistry. A well-known example of this approach is that of the hyperthermophile *Thermus aquaticus* used as the DNA polymerase in the very useful polymerase chain reaction (PCR) technique, which amplifies DNA samples by heat cycling the DNA sample together with the required chemistry cocktail (see "Polymerase Chain Reaction"). In Appendix 2A, we list other applications of extremophiles.

Complexity Theory

A groundswell of opinion has it that the difference between life and nonlife is only one of degree of organization, not of the type of components involved, and that life is how things behave, rather than of what they are made. Along this line, complexity scientists suggest that life is an "emergent" or "self-organizational" property that arises spontaneously when a large set of chemicals reaches a certain level of complexity (see also Chapter 3, "Self-Organization"). The background here is quite profound: humans are reasonably capable of calculating behavior of inorganic materials and the structures built from them, but we have had much less success with the more complex organic systems. This is where the science of complexity comes in—just like scaling and artificial life, complexity is a subdiscipline of biomathematics and represents a general attempt to elucidate fundamental biological principles on the basis of mathematics.

The Belgian Nobelist Ilya Prigogine (1917–2003) models complex systems that are far removed from thermodynamic equilibrium and describes their self-organizing* properties. These self-organizing properties have a tendency to reach critical "bifurcation" or "indecision points," where their behavior may leap into chaos or greater complexity and stability.[16] The latter scenario, Prigogine envisions, is how life might have started, that is, on the precipice between order and chaos.

An outstanding example of work in complexity is the theoretical work by Kauffman, from the Santa Fe Institute, who showed that an autocatalytic set of reactions leads to "emergent" and "self-organizational" behavior when a certain level of interconnectedness is reached between the reactions.[17] Kaufmann's Web site can be found at http://wn.com/Stuart_Kauffman. There is plenty of experimental evidence gathering for his theory in the laboratory. We described Ghadiri's protein work already (see "DNA, RNA, and Proteins: Who Was on First?"). In similar work, Rebek has demonstrated that synthetic chemicals can also reproduce, mutate, evolve, and combine with other reproducing chemicals.[18] Skeptics not only point to the simplifications and the arbitrariness of the rules of complexity theory but also point out that life is actually not an example of self-organization but one of genetically directed or specified organization. In other words, in life there is a software code directing the organization that emerges from complexity; in the complexity theory, on the other hand, there is no underlying software. In complexity theory, the physical boundaries of the system lead to the

* In Chapter 3, we clarify the distinction between self-assembly (near equilibrium) and self-organization (far removed from equilibrium) (see "Self-Assembly and Self-Organization").

emergence of organization. Despite the skeptics, this discipline is proving itself. We need to know how the system's software came about before we can understand how life emerged.

A Model from Information and Communication Theory

Yet another way of looking at the emergence of life comes from the theory of information and communication. Considering that DNA stores the information needed to construct and operate an organism, noise, a form of disorder, may then be regarded as the encroaching entropy. One then has to explain the creation of information (negative entropy) from noise, which again seems to violate the second law of thermodynamics until we realize that we are dealing with an open system (see above). Mutations in this model generate the noise, and it is the environment, via natural selection, that selects which information out of that noise ends up in the genetic message. The ultimate question in this model is, from where did the information content of the universe come?[10] The above considerations can be expressed in some simple mathematical formulations. There is a direct connection between information content (I) in a system and its entropy (S); an increase in entropy implies a decrease of information, and vice versa. Boltzmann linked entropy, S, to the computed probability of sorting objects into bins—a set of N into subsets of sizes n_i as follows:

$$S = -k\sum_i p_i \ln p_i \qquad (2.3)$$

where p_i is n_i/N, and k is the Boltzmann constant ($3.2983\ 10^{-24}$ calories/°C). On Boltzmann's tombstone, Equation 2.3 is written out as follows:

$$S = k \log W \qquad (2.4)$$

where W is the probability of a given state. One of the classic equations of information, derived by Claude Shannon in the 1940s, is formally similar to Equation 2.3.

$$I = \sum_i p_i \log_2 p_i \qquad (2.5)$$

Information, I, is a dimensionless entity, but its partner entity, entropy, has a dimension; comparing Equations 2.3 and 2.5, one notices that S and I have opposite signs and otherwise differ only in their scaling factors, and to convert from one to the other expression, one may write $S = -(k \ln 2)I$, or an entropy unit equals $-k\ln 2$ bits. Information is thus a concept equivalent to entropy, and "life" can be described in terms of one or the other.* Lowenstein promotes the idea that the first molecular mutants that came about were those that made the most efficient information loops, an information loop where the product promoted its own production.[19] As with digital computers, it is in the resetting of the memory register where the unavoidable thermodynamic price is paid. Each time a molecule has been produced on its template, the molecule needs to be reset for spinning out the next "clone."

For further reading on the origins of life in general, good starting points are http://www.seti.org/seti and http://www.panspermia.org/.

DNA and RNA: The Software of Life

In all known life forms on Earth, heredity, or genotype, is encoded by deoxyribonucleic acid (DNA). This molecule first appeared on Earth more than 3.5 billion years ago. Sections of DNA, called genes, constitute the chemical recipe expressed in the actual form of an organism or its phenotype. DNA—a master "read-only" memory—guides, records, and passes on every evolutionary development of all carbon-based life on Earth. Its building blocks are sugar (deoxyribose), phosphate, and four different nitrogen-containing bases, namely guanine (G), cytosine (C), thymine (T), and adenine (A). A unit of a base, sugar, and phosphate is a *nucleotide*, and since there are four different bases in DNA, there are also four different nucleotides in DNA. A model of a DNA molecule is shown in Figure 2.4b.

In 1953, James Watson and Francis Crick (see photo on chapter-opening page), building on experimental results by Rosalind Franklin (Figure 2.5), Maurice Wilkins, and many others, elucidated the

* William Dembski, a proponent of intelligent design, has claimed that natural causes are incapable of generating information. He calls this the *law of conservation of information*. From Equations 2.3, 2.4, and 2.5, information gain is equivalent to loss of entropy, and Dembski is confusing entropy and energy: entropy is not a conserved quantity like energy.

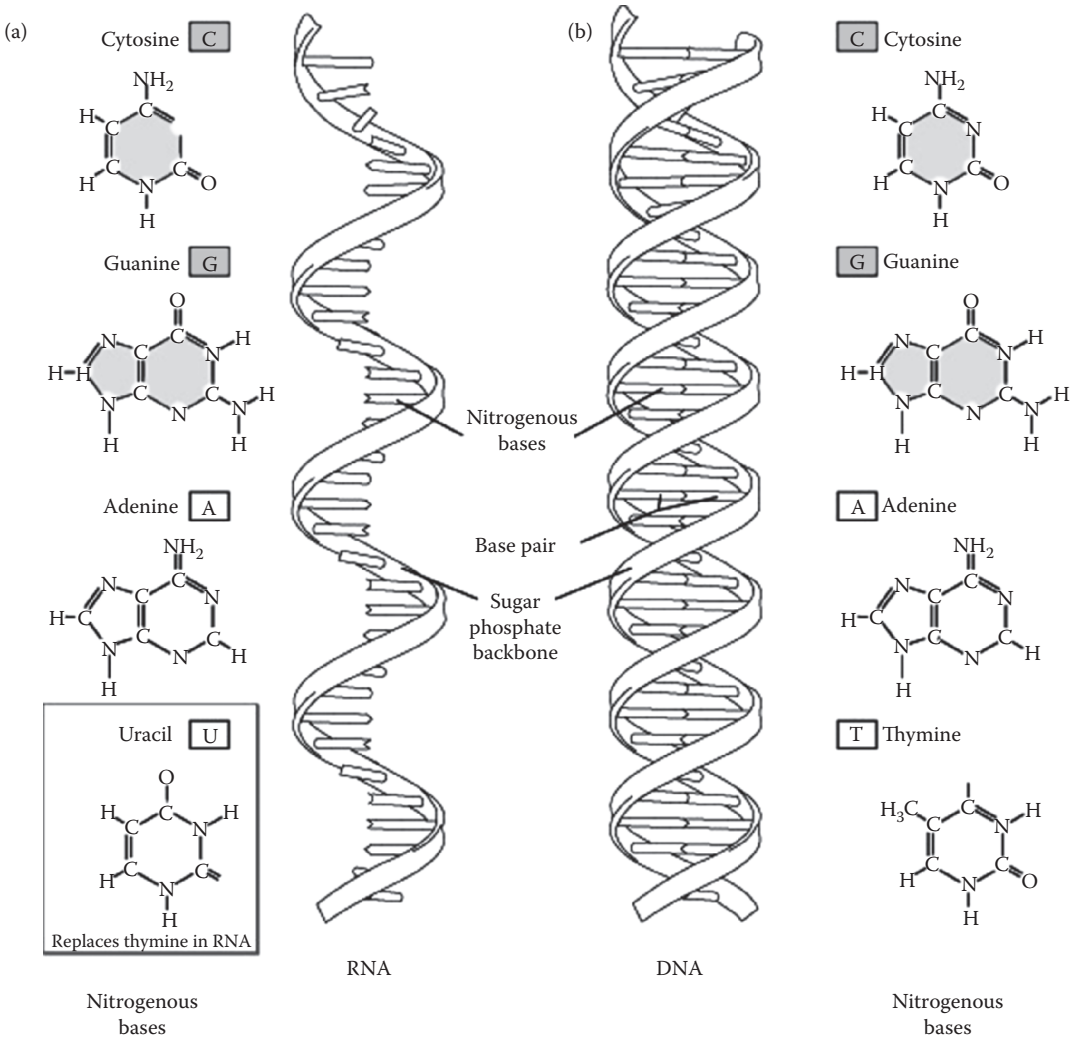

FIGURE 2.4 (a) Single-stranded RNA. (b) Double-stranded DNA.

double helix motif of DNA. Within a few years, it became clear how DNA, with the help of some other more or less complex molecules, is able to store and pass on hereditary information. This insight, among others, earned a Nobel Prize for Watson, Crick, and Wilkins in 1962. A fascinating historical, scientific, and ethical perspective on the discovery of the human blueprint is that of Robert Shapiro, *The Human Blueprint: The Race to Unlock the Secrets of Our Genetic Script*.[20] While scientific, Shapiro's book manages an entertaining account of the personalities involved in this greatest of scientific discoveries. Watson's autobiography *Double Helix* reads like a detective story and has become a classic bestseller.[21] Contrasting it with Crick's autobiography, *What Mad Pursuit*,[22] reveals how differently these two Nobel laureates measured their own contributions and that of others leading to that same monumental discovery (Crick passed away in July 2004).

The double helix DNA molecule consists of a right-handed spiral coil of two linked strands and is about 20 Å in diameter. Watson, during a dinner talk, perhaps after a bit too much wine, could muster only, "It is beautiful."* A model of the molecule as shown in Figure 2.4 is a bit misleading, since DNA is in reality a very narrow but extremely long molecule. From an

* It has been noted that the height of one unit of the DNA helix is related to its width in a proportion equal to the *Golden Ratio*. Throughout history, the ratio for length to width of rectangles of 1.61803398874989484820 has been considered the most pleasing to the eye. The Greeks named this ratio the Golden Ratio. In the world of mathematics, the numeric value is called "phi," named for the Greek sculptor Phidias. Many artists who lived after Phidias have used this proportion. Leonardo Da Vinci called it the "divine proportion" and featured it in many of his paintings. Long before Phidias, the Great Pyramids were proportioned based on the Golden Ratio.

FIGURE 2.5 Rosalind Franklin.

engineering point of view, DNA is a highly asymmetric molecule, with a width on the atomic scale and a length on the macroscopic scale, that is, from millimeters to centimeters and up to meters for a human.

This asymmetry makes DNA quite susceptible to breakage by shearing forces. The winding staircase of the DNA molecule in Figure 2.4 has railings made up by alternating molecules of sugar and phosphate; the steps are made up by pairs of bases. The four bases guanine (G), cytosine (C), thymine (T), and adenine (A) form only two types of pairs. An A base always joins to a T base via two hydrogen bonds (in shorthand, A = T), and a G always joins a C via three hydrogen bonds (G ≡ C). Walking up the staircase of the double helix, staying close to one side of the steps, the climber might read at his or her feet a base sequence such as AGCTAT; coming back down, on the other side of the steps, the descending person will read TCGATA. DNA often operates in conjunction with another nucleic acid, namely, ribonucleic acid (RNA). RNA is involved in the copying of the DNA genetic code and the assembly of amino acids into proteins based on the copied DNA blueprint. RNA uses a base called uracil (U) in place of thymine (T) and also employs a slightly different sugar ring (ribose instead of deoxyribose) (Figure 2.4a). Apart from these two differences, the components of RNA are identical to those of DNA.

The joining of two single-stranded DNA (ssDNA) strands into one double-stranded DNA (dsDNA) is called *hybridization*. The Watson-Crick pairing or hybridizing of DNA bases is shown in Figure 2.6.

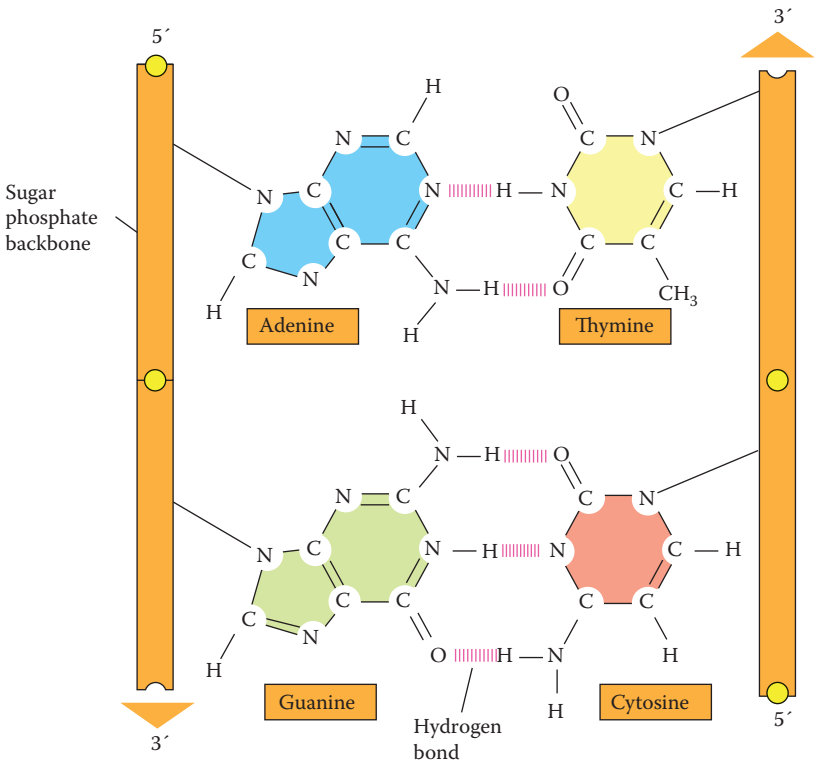

FIGURE 2.6 Base pairing in DNA.

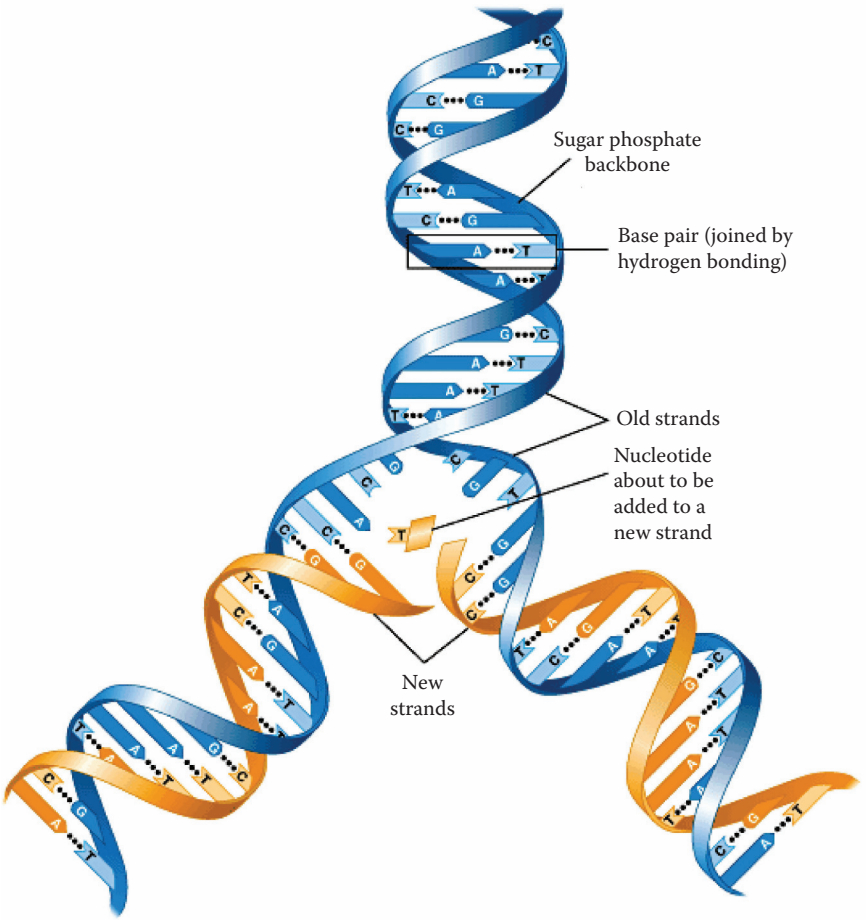

FIGURE 2.7 The DNA replication process.

To pass on information, a DNA molecule simply splits apart down the middle and then rebuilds matching parts to each half. The two strands in the ladder are complementary to one another, and, if the strands separate, each is fully capable of recreating the base sequences of the other with the help of a specialized enzyme. The enzyme, DNA polymerase, links up the appropriate nucleotides to make two daughter strands. The replication process is demonstrated in Figure 2.7. From this figure, we see that once the original double helix "unzips," the two separated strands act as templates (molecular molds), directing the production of new matching strands. If a double-stranded DNA is heated above its so-called "melting temperature," T_m, the two strands separate into two single strands. The melting temperature is a function of the ion concentration of the solution and the G-C content in the specific DNA sequence. When the temperature is reduced again, the two strands will eventually pair again by diffusion, and consequently "rehybridize" or "renature." The process just described is the one taken advantage of in PCR to replicate DNA (see above).

As mentioned earlier, one must distinguish between DNA replication as shown in Figure 2.7 and reproduction. Reproduction involves making modified copies of itself that can reproduce in return. If reproduction were flawless, evolution would never have occurred. DNA not only replicates and allows for reproduction, it also is the blueprint* for the synthesis of proteins. Further below, we introduce

* Not everyone sanctions the blueprint analogy. Ian Steward in *Life's Other Secret* correctly points out that genes are actually more like recipes in a cookbook rather than engineering blueprints; they tell us what ingredients to use, in what order, and in what quantities, but they do not provide a complete, accurate plan of the final result. Matt Ridley in *Genome* prefers the analogy of an immense book, a recipe of extravagant length; he also considers the term *blueprint* a poor analogy for a one-dimensional digital code. Then again, Robert Shapiro titled his book *The Human Blueprint: The Race to Unlock the Secrets of Our Genetic Script*.

some important characteristics of proteins, but we must first learn how a reading of the DNA blueprint results in their synthesis or production; i.e., we need to understand the mechanism of the genetic code.

Proteins: Hardware of Life and Nature's Robots*

Introduction

Virtually every process and product in an organism depends on proteins. In addition to their roles as enzymes (catalysts), messengers between cells, and defenders against infection, they are the principal constituents of cell membranes, tendons, muscles, skin, blood, bone, silk, hair, and other structural materials. The human body alone contains more than 100,000 distinct types of proteins, and all are synthesized in the same basic way. Just like nucleic acids, they are macromolecules, long polymeric chains. In the case of proteins, the chains are composed of just twenty different types of amino acids that are always joined in the simplest possible manner: linearly, in long chains (see Appendix 2B for a listing of their names and chemical formulas). There are many more amino acids, but nature only uses the twenty listed.

Biomolecules can process electrical and/or optical signals, but what proteins excel in is at recognizing and reacting to three-dimensional shapes. Proteins have twenty letters in their alphabet rather than the four of DNA, and they have the ability to adapt an endless number of three-dimensional (3D) shapes, making them much more versatile molecules than DNA. Information in biology, we shall see, is stored in the 3D shape of molecules.

Making Proteins

Amino acids are the basic components that make up all proteins. They are left-handed chiral molecules (except for the simplest, glycine) containing both a carboxylic acid group and an amine group. Chiral molecules are molecules that come in two forms, enantiomers, which are structurally identical except that one is the mirror image of the other. Like left- and right-hand gloves, these molecules cannot be superimposed (Figure 2.8). All chiral amino acids, forming proteins, in nature are "left-handed," and nucleotides, forming the genetic material, are "right-handed." It is one of the great unifying principles of biochemistry that the key molecules of life have the same hand in all organisms. The twenty common amino acids can be combined in an almost infinite number of ways to produce proteins. The reaction involved is the formation of a peptide bond (amide bond) in a so-called "condensation reaction" between the amine group of one amino acid and the carboxylic acid of another amino acid. In this reaction, a water molecule is released, as shown in Figure 2.9.

Each type of protein differs in its sequence and number of amino acids; therefore, it is the sequence of the chemically different side chains that makes each protein distinct. The two ends of a polypeptide chain are chemically different: the end carrying the free amino group (NH_3^+ or NH_2, depending on pH) is the amino, or N, terminus, and the one carrying the free carboxyl group (COO^- or COOH, depending on pH) is the carboxyl, or C, terminus. The amino acid sequence of a protein is always presented in the N to C direction, reading from left to right.

When only a few amino acids are linked, the product is called a *peptide*, the difference between a peptide and a protein being one of size. A protein with a molecular weight of 50,000 is also referred to as a protein of 50,000 daltons or 50 kilodaltons (kD). One dalton is equal to one atomic mass unit.

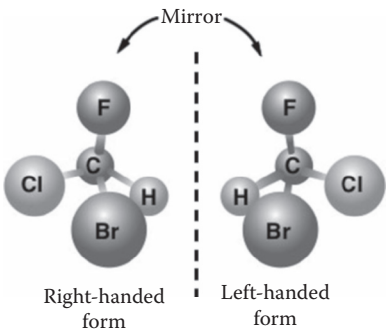

FIGURE 2.8 Right- and left-handed bromochlorofluoromethane. The left-handed form of a chiral molecule rotates a beam of polarized light to the left, while the right-handed form rotates it to the right. The example shown in this figure is the CHFClBr molecule.

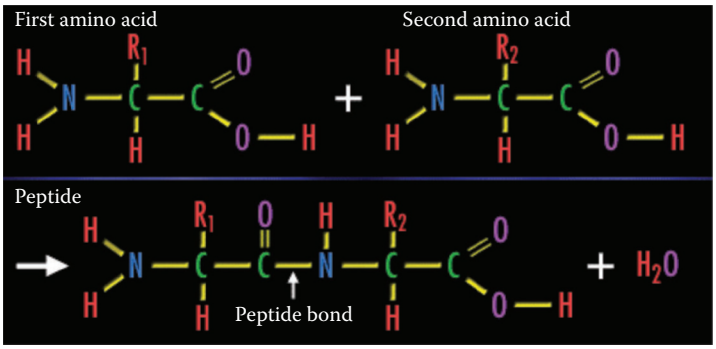

FIGURE 2.9 Water release in protein formation: proteins consist of a polypeptide backbone with attached side chains.

In Table 2.3, example proteins and their function are reviewed.

The Odds against the Emergence of Proteins

All models of the emergence of life eventually rely on the theory that a chance combination of chemicals leads to increasingly complex molecules and eventually to "life." Some simple organic molecules were already present in Earth's primeval atmosphere, as first demonstrated in 1953 in the now famous Miller-Urey experiments.[7] Miller, inspired by a suggestion of his advisor, Urey, reproduced a potential primeval atmosphere in laboratory glassware. When heating methane (carbon source), ammonia, and hydrogen with water, and passing an electrical discharge, to simulate lightning, through the mixture, he produced significant quantities of organic compounds, including some amino acids (e.g., glycine and alanine). He obtained this result after running the experiment for one week. Earth's early atmosphere was at first believed to have been reducing. Although Miller used hydrogen, ammonia, and methane, today it is believed that the atmosphere was more of a neutral mixture, consisting mainly of carbon dioxide and nitrogen and only small amounts of methane and ammonia. Since 1953, the Miller-Urey experiments have been reproduced with different simulated environments, such as the electric spark being replaced by a furnace, an ultraviolet lamp, shock waves, and energized chemicals. It turns out that amino acid synthesis is rather easy; as we saw before, they actually have been found even in meteorites.[3,7,10] The issue is not so much how to make individual amino acids but how to string them into the three-dimensional complicated proteins that life needs. The odds are stacked against making even the smallest protein this way. Take a small protein of 100 amino acids; with 20 different amino acids, the number of differently arranged proteins corresponds to 20 multiplied by itself 100 times (which corresponds to 1.26×10^{130}). Even the total number of stars in the observable universe, on the order of 10^{21}, is trivially small compared with the gigantic odds of stitching together a simple protein properly.[10] The latter is the major reason why scientists such as Crick and Davies came to believe that life on Earth was seeded from interstellar space, as there was not enough time to reach that degree of complexity on Earth in such a short amount of time.[23]

TABLE 2.3 Examples of Proteins

Structural	Functional
Collagen (found in bone and skin)	Hormones (control body functions)
Keratin (principal component of hair and nails)	Antibodies (fight infections)
Fibrin (helps blood clot)	Enzymes (catalyze chemical reactions)
Elastin (major part of ligaments)	Hemoglobin (carries oxygen and carbon dioxide in the blood)
	Myoglobin (transports oxygen in muscles)

Protein Structure

Proteins begin their life as linear chains of linked amino acids; however, most of them do not stay that way long, as is clear from Figure 2.10. The floppy protein chains quickly fold to minimize free energy. This minimization involves hydrophilic groups (groups that like water) orienting themselves toward the aqueous environment and hydrophobic groups (groups that dislike water) orienting themselves inward, that is, away from the aqueous or hydrophilic environment. Similarly, there are groups attracted to one another and groups that repel one another. The sequence of amino acids constitutes the primary structure of the protein. The secondary protein structure can follow several motifs—an α-helix (a right-handed spiral), a β-pleated sheet, or a ribbon. The tertiary protein structure describes how secondary structural motifs are packed together to give the molecule its three-dimensional shape. The tertiary structure of an enzyme molecule creates cavities and grooves on the molecule surface into or onto which only selected partner or ligand molecules fit. Those select ligand molecules, while bound to the enzyme, may in turn react as they present the right functional chemical groups to the immediate environment. The quaternary structure refers to the grouping of individual proteins into protein clusters that carry out a task collectively. The final assembly of any protein or protein group is all programmed by the original amino acid sequence in the linear primary structure. The seamless differentiation of proteins into different components results in one smooth and uniform manufacturing process. Every living body is thus a unique molecular machine in which function at the nanoscale dictates the cellular and whole organ behavior at the macroscale.[24] The various protein structural organizational levels are illustrated in Figure 2.11.

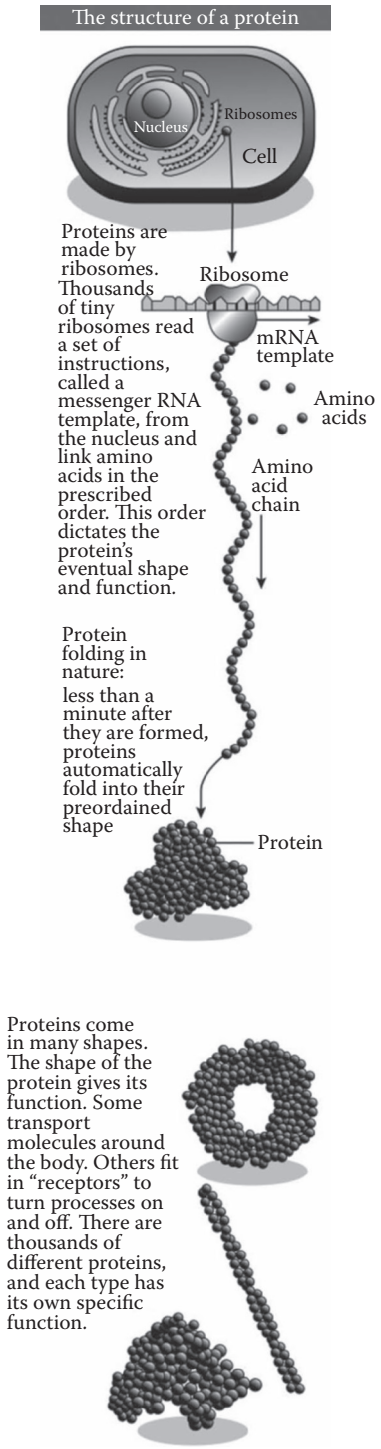

FIGURE 2.10 A protein emerges from a ribosome.

Today's computers can barely simulate a fraction of the fascinatingly complex protein-folding process. With that task in mind, IBM developed a computer called Blue Gene. Blue Gene is 500 times faster than other supercomputers. It was the first petaflop computer (10^{15}), and it is able to simulate interactions of certain proteins with their natural ligands and potential drug candidates and thereby potentially aid in the design of more efficient and potent drugs.

Protein Self-Repair and Recycling

Proteins and derived structures (e.g., tissues such as skin) are of use only in a small operational range of temperature and pH. Despite this narrow dynamic

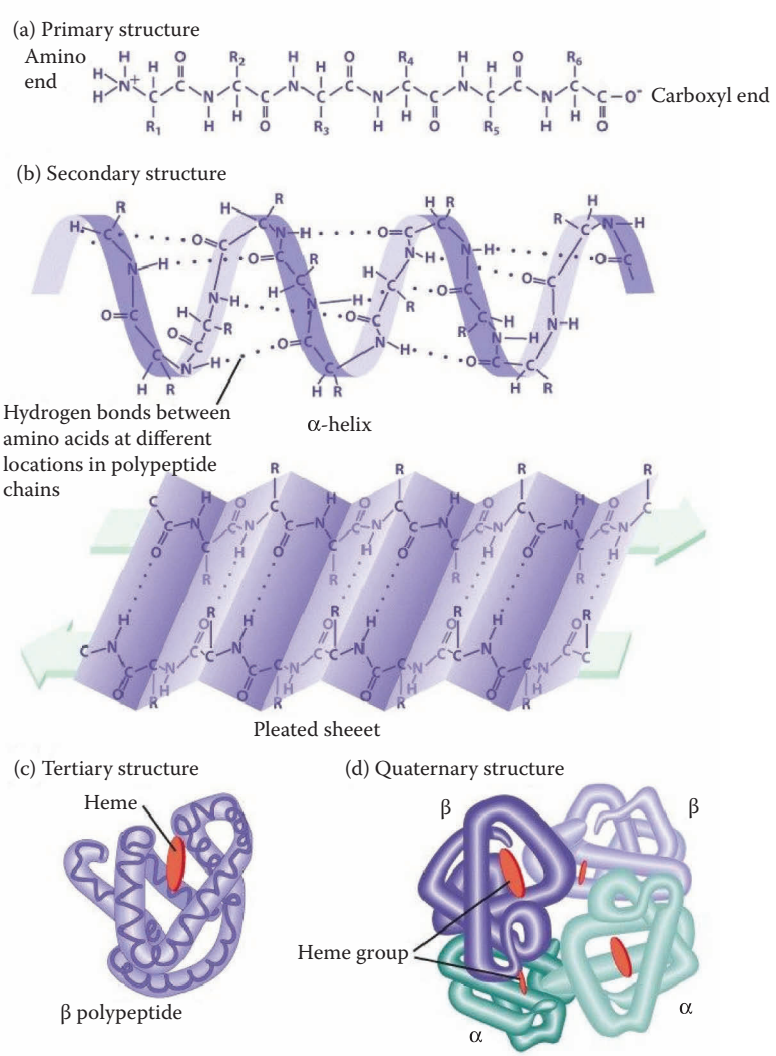

FIGURE 2.11 The various protein structural organizational levels.

range, the synthesis of natural organisms—starting with atoms and molecules, through intermediate structures such as fibers and grains, to components such as skin, bone, and teeth, has led to marvels of enduring engineering such as trees, birds, and humans. Humans usually use stronger (higher Young's modulus) building materials than proteins (say steel or aluminum), but nature has another major advantage, namely, self-repair. The external physical observable form, function, and behavior of living organisms (i.e., the phenotype) are not permanent constructs; they derive from the entire genetic information (i.e., the genotype). Some structures, such as skin and brain, are in a state of constant regeneration; proteins are continually synthesized de novo. Other structures, such as the eyes, are made up by proteins with some of the slowest turnover rates. This type of self-repair compensates for many of the deficiencies of life's construction materials. In human engineering, we have nothing of this kind yet, and together with self-assembly, self-repair is a must for the bottom-up approach in human engineering to succeed.

Cells of nearly all life forms possess systems for recycling proteins that have been damaged or are no longer needed. Ubiquitin tags proteins for degradation in a complex protein system, the proteasome, a molecular abattoir, in which only those proteins that are unfolded and marked with ubiquitin are destroyed. The proteasome also plays an important role in the immune system as it cuts foreign proteins down into chunks that the immune cells then present on their surfaces to signal the start of the attack by antibodies.[25]

The Genetic Code

In this section, we address the question of how nature, using DNA as a template, builds a plethora of different proteins from just twenty different amino acids. From our description of DNA, we learned that there are four different bases and four different nucleotides in DNA. All cells contain the same DNA, but different genes are expressed depending on the local need for an enzyme, a muscle cell, a neuron, or a bone. In this process, DNA is the repository for the construction blueprint, but it is not responsible for building the proteins. This hard work is done by another nucleic acid, namely, RNA. RNA uses a base called uracil (U) in place of thymine (T), and it also employs a slightly different sugar ring (ribose instead of deoxyribose). Apart from these two differences, the components of RNA are identical to those of DNA.

The details of the protein-building process are sketched in Figure 2.12. The process of protein manufacture (e.g., of insulin) may be compared to that of the manufacture of a car (such comparison was first made by Casti).[7] It all starts with copying the car's blueprint at headquarters, corresponding to transcription or copying of DNA in the cell nucleus. Next is a quality control step in which the copy of the blueprint of the car is inspected, a process that has its analog in the editing, or snipping out, of introns in protein manufacture. This step is followed by mailing of the copies to the various manufacturing plants—the ribosomes in the case of a cell. After a new car, or protein, is finished, it is packaged and shipped, and, finally, if the car or protein is no longer needed, it is disassembled and recycled.

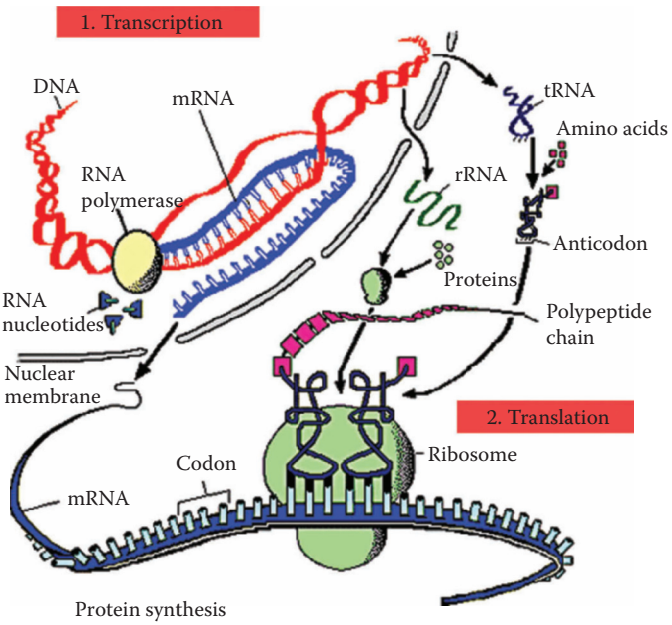

FIGURE 2.12 Protein manufacture: transcription and translation.

A bit more slowly, and in more detail, the story unfolds as follows. In protein manufacture, an enzyme first unzips a section of DNA, and the gene (DNA segment) that codes for the protein (in this case insulin) is freed for expression. All genes use the ATG codon to serve as the marker to start protein synthesis and TAA to stop it. Expression of a specific gene is switched on and off by proteins physically attaching themselves to promoter and enhancer sequences near the start of the gene text. In other words, the blueprint is unfolded for reading and copying one specific part of the original only (one car or protein is copied). Messenger RNA (mRNA) interprets the freed construction blueprint from the DNA inside the nucleus of the cell in a process called *transcription*. In transcription, an mRNA strand is synthesized by complementary base pairing between the nucleotide bases of the DNA and the mRNA. In Detroit lingo, this translates to the photocopying of the blueprint for a certain type of car. In eukaryotic cells, the mRNA now leaves the nucleus and acts as a template for protein synthesis in ribosomes. In our car analogy, copies of the car's blueprint are being distributed to different factories in Ohio and Indiana. The code to make proteins on the mRNA template is a triplet code—a sequence of three bases, or a *codon*, describes one amino acid.

If each individual base is coded for only one amino acid, then the four bases would only code for four amino acids. A pair of bases could code for sixteen different amino acids (4^2), and a triplet could handle sixty-four (4^3). It is the latter code, the one with the largest bandwidth available to call on the twenty amino acids, that nature has chosen to build proteins (see Appendix 2C for a list of the twenty amino acids). Actually, an amino acid may be encoded by between one and six codons, several different triplets may code for the same amino acid, and three triplets are assigned to the instruction for

a stop. In 1967, Har Gobind Khorana and Marshall Nirenberg were able to correlate each one of the twenty amino acids with the sixty-four possible codons. The resulting universal decoder chart is presented in Appendix 2C.

In many cases, stretches of DNA coding for polypeptide chains are not continuous but are interrupted by large stretches of "nonsense" sequences. Even within genes, there are stretches of nucleotides, called *introns*, that don't code for anything; Casti calls them *commercial breaks*.[8] Exons within the gene are the only segments where protein coding occurs (see Figure 2.13). In humans, there is only about one gene per 100,000 base pairs, and the mean gene extends over 27 kilobases, whereas the mean transcript is 1.3 kilobases.

The validity of the mRNA copy is checked by verifying the integrity of all base pairs (also called *editing*). A team of enzymes snips out the introns and reconnects the parts that contain useful information called *exons*, which are the expressed genetic sequence. This editing process reduces the error rate to about one in 1 billion base pair replications. Although most editing is done by enzymes, some RNA molecules can do it unassisted. These are called *ribozymes*, reflecting the

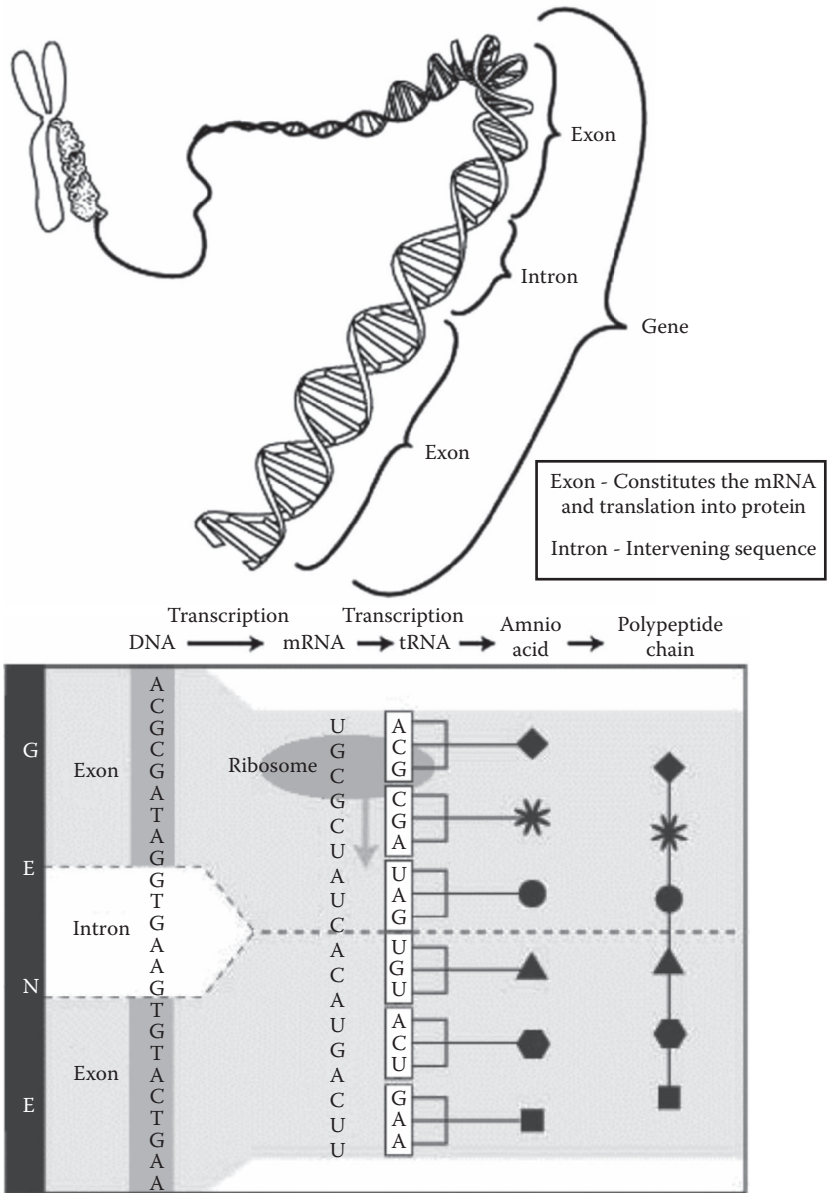

FIGURE 2.13 In the expanded gene, only the exons actually code for the protein corresponding to the gene.

fact that they show -enzyme-like tendencies. The nonsense DNA—perhaps up to 95% of the human genome—has been called *junk* DNA in the past but more recently has been upgraded to *selfish* DNA, as scientists recognized that it might play some role in heredity after all. Crick speculated that this selfish DNA might be involved in the rapid evolution of some of the complex genetic control mechanisms essential for higher organisms (lower organisms have none or much less of this selfish DNA). Crick believed selfish DNA might be there for its own sake rather than that of the organism itself. The same claim is made by Richard Dawkins[26] in his book *The Selfish Gene*.*

We continue now our story about the genetic code and car manufacture and study the process that follows transcription and editing—that is, translation of the blueprint into proteins, or how to go from a blueprint copy to a car.

Living organisms feature armies of three-dimensional protein construction sites called *ribosomes* (see also Figure 2.12) in which any conceivable protein can be manufactured. Small RNA molecules called *transport RNA* (tRNA) transport the proper amino acids to the ribosomes, which are cell organelles located in the cytosol outside the nucleus, to build new peptide chains on the mRNA template in the so-called *translation* process. Each of the twenty amino acids has its own tRNAs equipped with a codon, complementary to the triplet of bases that encodes the tRNA's amino acid on the mRNA template. In the car analogy, individual car components are being shipped to the car assembly plant. The ribosomes bind together the amino acids, docked in place by the tRNAs, in a growing protein chain at a rate of five amino acids per second. Many ribosomes can be lined up on one mRNA strand so that a full copy of a new protein—for example, insulin—can be delivered every few seconds. The insulin protein just fabricated in the ribosome contains a short sequence specifying the part of the cell to which it should be sent. This is the equivalent of a bar code on a new car. When this signal sequence (the bar code) has emerged from the ribosome, the cell's transport mechanism is activated, the bar code is read by a signal recognition particle, and in the case of an emerging insulin it is, together with its ribosome, directed toward the membrane of the cell's shipping dock, the endoplasmic reticulum (ER). The ribosome attaches to the ER membrane, and the protein is threaded through a pore in the ER. Once inside the ER, the signal sequence or bar code is removed, the protein—assisted by molecular chaperones—folds into its native shape and is packaged into a small sphere (vesicle) that buds out of the ER membrane. The vesicle then transports the insulin to the Golgi apparatus. The Golgi apparatus, similar in appearance to and perhaps continuous with the ER, is a region of smooth, stacked membranous sacs. Cell biologists have shown that the Golgi apparatus modifies proteins, which it receives from the ER in vesicles, and prepares them, in a series of steps, for excretion to the exterior. Just as a letter is taken to the post office to be mailed to another location, proteins are transported to the Golgi apparatus for shipment to other locations in the body. Within the Golgi apparatus, the proteins and lipids are labeled with sequences of molecules (an address), which tells the body where the product should be delivered.

The French biochemists Francois Jacob and Jacques Monod showed in the 1960s that genes regulate one another, switching each other on and off via the proteins they encode. For example, some genes that encode proteins used in the cell (called *structural genes*) are partnered with regulatory genes that encode repressor genes. With the regulatory gene switched on, the repressor protein is synthesized and binds to the structural gene, preventing it from being *expressed* (transcribed and translated into its protein). Jacob and Monod called these regulated stretches of DNA *operons*.

The fact that information flows from DNA to RNA to protein is called the *central dogma* of molecular biology. This "dogma" also implied that there was only one protein per gene. A first serious attack on the first part of this central dogma came in 1970 when David Baltimore and Howard Temin discovered an enzyme that does just the opposite: it transforms the RNA genome of a group of RNA viruses, now called *retroviruses*, into a DNA copy that can be

* *The Selfish Gene* is an elegant account of neo-Darwinism in which Dawkins argues the view that DNA rules.

inserted into a genome. The family of retroviruses includes HIV. The enzyme in question is a reverse transcriptase. In comparison with DNA polymerase that replicates DNA chains, reverse transcriptase is very error-prone. The latter is what makes it so difficult to make an HIV vaccine. Baltimore and Temin received a Nobel Prize in 1975 for this discovery.

Gene Copying Errors: The Error Catastrophe

A higher organism has about thirty thousand genes capable of storing about one hundred million bits of information, each of which may be subject to copying errors. Too many copying errors can cause the reproduction machine itself to come to a halt. The German biochemist Eigen called this the *error catastrophe*.[27] Eigen, who believed in an RNA-first world, introduced a simple mathematical formulation for characterizing this error catastrophe. He assumed that a self-replicating system is specified by N bits of information and that each time a single bit is replicated from parent to offspring the probability of making and error is given by ε. He also accepted that natural selection penalizes copying errors by a selection factor S. In other words, an error-free replication has a selective advantage of S over a system with one error, and so on. Then according to Eigen the criterion for survival of a replicating organism is:

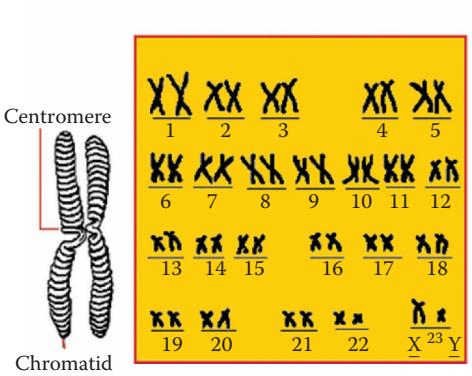
$$N\varepsilon < \log S \qquad (2.6)$$

If the above condition does not hold, the species will die out, but with the inequality satisfied, the selective advantage of the error-free system is great enough to maintain a population alive with few errors. To understand the deeper meaning of Equation 2.6, we may look back to the information theory of life (see above) for some further insights. The left side of the inequality represents the information loss through copying errors in each generation. The right is the number of bits supplied by the selective action of the environment. If the information supplied is less than the information lost in each generation, a progressive degeneration is inevitable. The selective advantage of an error-free system cannot be too large, so that log S is probably not much greater than 1 (life always survives on the edge of chaos). The greater the number of genes an organism possesses, the lower the error rate must be to avoid error catastrophe. Human beings accumulate about 100 mutations per generation, with N of the order of 10^8, to satisfy Equation 2.6, ε must be of the order of 10^{-8}. In other words to avoid error catastrophe, the copying error in human DNA should be less than one in a hundred million per replication. In human cells, an editing process weeds out errors, and the remaining error rate is actually one in a billion. Bacteria with considerably fewer genes than humans can get away with many more errors (they can tolerate up to one in a million), and a virus can survive an even greater number of errors. The latter is the reason why drug-resistant mutations emerge with such rapidity, always keeping researchers one drug behind. This will continue to challenge chemists and the pharmaceutical industry, keeping the latter happy and rich for a long time to come.

Genes and Chromosomes

A gene, as we learned above, is a segment of DNA with a unique sequence of nucleotides that encodes information—the genetic code—for assembling amino acids into a particular protein. Genes are located on chromosomes and humans have twenty-three chromosome pairs (Figure 2.14). Genes are isolated from chromosomes through purification of RNA molecules. Since RNA is not very stable, this purified material is first converted back into DNA known as *complementary DNA* (cDNA). To store and make copies of genes, the cDNA is stitched into a small circular bacterial chromosome. Whenever more of the gene is needed, the bacterial colony containing the gene of interest is grown, and the required amount of cDNA is isolated.

The biggest surprise of the rough analysis of the first sequencing of the human genome (see below) was the low number of genes it contains. For years scientists had been predicting that human DNA would contain somewhere between 100,000 and 140,000 genes. It turns out we may have as few as 26,000—a genome about the size of a rat or a corn plant, with roughly a third more genes than the fruit fly. We are coming to the somewhat uncomfortable conclusion that there is no relation between the complexity of an organism and the number of chromosomes or genes or the length of the DNA strand. *Lysandra atlantica* (a butterfly) has 250 chromosomes



Organism	Genome Size (Bases)	Estimated Genes
Human (*Homo sapiens*)	3 billion	30,000
Laboratory mouse (*M. musculus*)	2.6 billion	30,000
Mustard weed (*A. thaliana*)	100 million	25,000
Roundworm (*C. elegans*)	97 million	19,000
Fruit fly (*D. melanogaster*)	137 million	13,000
Yeast (*S. cerevisiae*)	12.1 million	6,000
Bacterium (*E. coli*)	4.6 million	3,200
Human immunodeficiency virus (HIV)	9,700	9

FIGURE 2.14 Human chromosomes and genome size (bases) and estimated number of genes for some different organisms.

versus our meager 46. Nor is there a correlation with the number of genes; the fruit fly has 13,700, whereas *Caenorhabditis elegans* (a 1-mm nematode worm) has 20,500. Despite the fact that the eye of the fruit fly is composed of more cells than are found in the entire *Caenorhabditis* worm (profoundly more complex in structure and behavior than the microscopic roundworm), the fruit fly has 5000 fewer genes! Finally, there is also no correlation with the length of the DNA, with, for example, the *Amoeba dubia* at 670,000,000,000 bases and *Homo sapiens* at 3,000,000,000. Obviously, the complexity of organisms is not reflected in the complexity of its genes. Some people are referring to this dilemma, the lack of correlation between the genome and the complexity of the organism, as the cosmic joke. The cosmic joke violates a second tenet of the central dogma, i.e., one gene to one protein. Ron Evans, Michael Rosenfeld and others clearly demonstrated that the same RNA gene transcript can be spliced in many ways to encode multiple proteins.[28] This discovery shed much-needed light into the low number of genes–large number of proteins paradox.

Only 40% of a chromosome consists of DNA. The rest is made up of packaging protein materials. Figure 2.15 illustrates an exploded view of a chromosome as well as some other important cell components. The total human genome, that is, the full set of chromosomes, comprises about 3 billion DNA base pairs. One strand of human DNA stretched out would measure up to 5 cm. Since there are forty-six chromosomes in a human cell, this means we have about 230 cm, or 6 feet, of DNA for each cell. Within the chromosome, the DNA is obviously very well coiled and packed. This remarkable feat of packaging is described in more detail in Chapter 4 on packaging (see Figure 4.1). In this packed state, the DNA is so tightly bundled that it is entirely inaccessible to gene-activating enzymes. Only as stretches of chromosome move out of this condensed state are genes exposed and available for expression. Inside the nucleus of each cell there are two complete sets of the human genome. Egg and sperm cells contain only one copy, and red blood cells do not have any DNA.

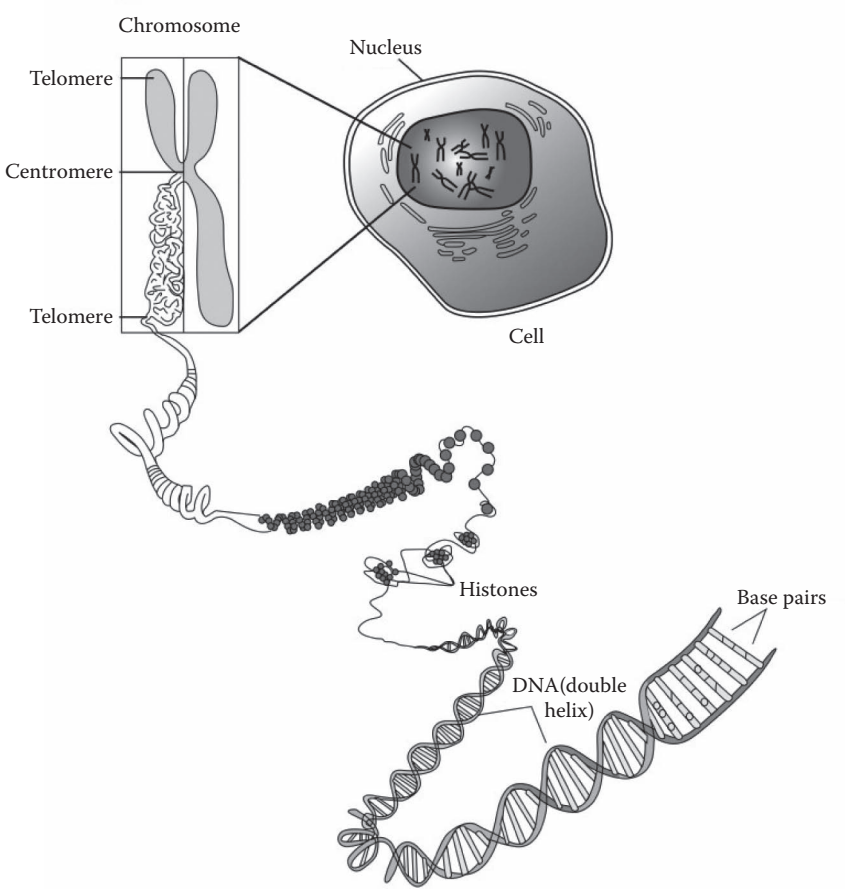


FIGURE 2.15 From chromosome in the nucleus to DNA.

Evolution

The driving force for the sequence of events that led to the plethora of life forms we know today comes from the ever-changing challenges presented by the environment to living organisms in a process called *evolution* or *natural selection*. Evolution theory tells us that over long periods of time, life forms change. Perfect replication of DNA would only have led to a planet with very little diversity among its life forms. Errors during DNA replication do occur, and when errors occur, they can manifest themselves as mutations in the organisms that inherit them. Mutations not only arise from copying errors but may also be caused by physical damage to the DNA in the genes, such as that caused by radiation and certain chemicals. If an alteration of a gene results in an observable change in some aspect of an individual's phenotype, and if this change is passed on to his or her offspring, then we say that a mutation has occurred or a new allele of a gene was created. Only mutations in germ cells are passed on to the offspring: mutations in somatic cells (all the cells of an organism except for the germ cells) do of course occur, but they are not passed on. An allele is defined as one of the two alternative states of a gene that occupy the same locus on homologous chromosomes (chromosomes containing the same gene sequence) and that are responsible for alternative traits. Not all genes have alleles; many genes within a given species are invariant among individuals. If there is more than one allele of a given gene within a population, an individual might inherit two different alleles for a given gene (one from the father and one from the mother), in which case that individual is said to be heterozygous for that gene. Some alleles are dominant over others, and with a heterozygote the dominant allele will be the one that is expressed in the phenotype. With two identical alleles, the individual is called monozygotic. Random errors in the DNA coding are mostly disadvantageous, sometimes neutral, and very rarely beneficial, conferring

an advantage on the mutant. Over long periods of time, favorable traits will be transmitted more efficiently to the offspring, and unfavorable ones will occur with decreasing frequency, until they are eliminated. For any two unrelated individuals, there is roughly one alteration every 1000 bases, or 3 million sequence variations altogether. These sites of sequence variations are called single-nucleotide polymorphisms (SNPs, pronounced *snips*). Those "snips" are critically important in the development of new molecular diagnostics (see applications in Chapter 10).

The concepts of evolution and inheritance were introduced in the second half of the nineteenth century with Charles Darwin's *On the Origin of Species* (1859). Gregor Mendel published in *Transactions of the Brunn Natural History Society* on heredity of peas in 1865, but his work was not widely known until 1900, when it was rediscovered. Darwin had predicted a continuous variation within a species with gradual change over long periods of time. The perpetuation of any life form requires a fine balance between fidelity of replication and variation from generation to generation. A slight imbalance, and extermination certainly follows. Among Mendel's pea plants, a more discrete variation manifested itself, with the plants exhibiting either white or purple flowers with no continuous variation in between. In the early twentieth century, evidence pointed toward gene mutations having a big step effect rather than a continuous effect. Only later did it become apparent that although the units of heredity—genes—are discrete, many mutations do have small-scale effects, and that combinations of genes can produce continuous variations, such as height in humans. The mathematical foundation of Darwin's theory was on solid footing by the 1930s. Mendel's very discrete heredity results were found to be coincidental, because the traits he studied were controlled by single genes only. If this had not been the case, he would not have obtained such clear-cut results.

There is some controversy as to whether natural selection explains all features of evolution. One extreme position is that of Dawkins, who, in his books *The Selfish Gene*[26] and *The Blind Watchmaker,*[29] contends that everything is shaped by natural selection alone. The opposite extreme, much more controversial, is represented by, for example, Micheal J. Behe with his intelligent design who claims that Darwin's mechanism—natural selection working on variations—can explain small changes but does not explain how complex molecular systems, such as vision, might have been gradually produced (for an introduction visit http://www.talkorigins.org/faqs/behe/review.html). Intelligent design is a criticism of Darwinism, not a theory, as it does not logically follow from experimental evidence. In between, there are scientists such as the late Stephen Jay Gould, who believed that there must be other factors involved and that selection alone is not capable of explaining all patterning forces in the history of life (http://www.stephenjaygould.org/library/gould_structure.html). This view supports complexity theory, which sees evolution as a complex system, not to be studied by its individual parts alone. This implies that self-organizational properties typical of complex systems would go hand in hand with selection. Artificial life simulations also have the potential to solve some of the major problems that evolutionary biologists have struggled with for decades. The first one has to do with the concept of predeterminism in evolution. Evolution is not supposed to have purpose or a predetermined goal in mind—mutations are random, which makes it difficult to explain how life organized itself into increasingly complicated organisms. However, computer simulations of artificial life do suggest a tendency for systems to organize themselves into increasingly complex forms for purely mathematical reasons. A second problem is that of mass extinctions, which computer simulations suggest are the norm, not the exception.[6]

Transposomes

It is estimated that less than 5% of the DNA in a human contains gene sequences that code for proteins. Noncoding DNA is assumed to consist of structural elements and repetitive sequences such as transposons. Transposons, also called *jumping genes*, are stretches of DNA that jump from site to site within one genome or "catch a ride" with a virus and move from species to species in so-called horizontal transmission.

Barbara McClintock won the 1983 Nobel Prize for her work on transposons in Indian corn; she postulated transposons as far back as the 1940s. It is now widely accepted that genes operate as parts of networks almost like those formed by neurons in the brain, and individual genes may either inhibit the action of another gene or cause it to be more likely to express itself (translate into proteins). Because of this additional complexity, it seems increasingly likely that a traditional reductionist approach will not be able to solve all of the issues involved in the expression of the 30,000 or so human genes. Answers may come from the science of complex systems instead, and, as a result, nonlinearity and complexity mathematics may become the most important contributors to the understanding of life and evolution. Along this line of thinking, Roy Britten at Caltech and many others believe that evolution cannot be explained by single-point mutations only.[30] Britten's position is that transposons are a much larger source of natural variation. To make his argument, he has focused on the Alu transposons that are unique to primates. Alus make up more than 5% of our DNA and could conceivably be responsible for the diversity of primates. Alus, for some unknown reason, seem to have started spreading widely around 30 to 50 million years ago. Wanda Reynolds discovered that Alus have the power to alter which sets of genes are expressed, by which hormone, and when they are triggered, thereby elevating or reducing gene expression in certain tissue so that the evolution of a species can gradually be changed (see also http://www.ncbi.nlm.nih.gov/pmc/articles/PMC38434/). This process might have been an important factor in creating diversity in primates. Despite the fact that the genetic distance separating us from pygmy chimps is only 1.6%, it is possible that not all our differences are the result of this (the chimp-human split occurred not much more than 10 million years ago, possibly even less than 5 million). The proximity of Alus might have regulated which sets of genes were triggered, enabling *Homo sapiens* to appear around 40,000 years ago. Transposons can be regarded as an internal environmental challenge to the evolution of life forms rather than the more familiar external environmental factors. Transposons, by posing a continuing challenge to increasingly complex genomes, have helped evolution along and might even be the reason why more complicated organisms such as humans could emerge at all. The reason for the dense packing of chromosomes in more complex living systems is probably to keep transposons better hidden within them. As a consequence, only 0.2% of all spontaneous human mutations are caused by transposons, although they make up a large portion of our genome. By contrast, fruit fly transposons constitute only 10–20% of the genome, yet they are responsible for as much as 85% of spontaneous fruit fly mutations. The chromosomes of the fruit fly hide the transposons much less than our chromosomes do.

In 1998, Schatz and coworkers at Yale University identified yet another major role that transposons might have played in evolution, namely, the development of a powerful immune system in vertebrates.[31] A powerful immune system is created by mixing gene fragments to create a vast array of antibody genes in millions of B cells.* Schatz's group has demonstrated that the mechanism for the creation of these antibody cocktails involves the RAG1 and RAG2 genes, which produce the proteins used to "cut and paste" the gene fragments into new combinations. RAGs have lost their ability to reinsert themselves at random in our genome, and as a result, they are not only harmless but actually beneficial. Transposons also might be dangerous, as their presence near or on a functional gene may damage or destroy it; they have been associated with diseases such as leukemia, hemophilia, and breast cancer.

Human Genome Project

The aim of the $3 billion Human Genome Project, started in the mid-1980s, was to decode the details of the software running the genetic code machinery depicted in Figure 2.12 by 2005.[32] Scientists working on the project located, mapped, and identified the ~30,000 individual genes carried on our twenty-three pairs of chromosomes by 2001. If the

* B cells develop from stem cells in the bone marrow. Each B cell is programmed to make one specific antibody. For example, one B cell will make an antibody to block a virus that causes the common cold, while another produces an antibody to attack a bacterium that causes pneumonia.

human genome is compared to a book, the twenty-three chromosomes may be considered the chapters, with each chapter containing many stories, or genes. Each story contains many paragraphs, called *exons*, interrupted by advertisements called *introns*. The words are *codons*, and each word is written in letters, or *bases*.[12] One of the project's approaches involved cloning fragments of DNA, inserting them into *E. coli* bacteria, and looking for shared sequences of DNA that could be identified chemically. The Human Genome Project stressed free access, including via the Internet, to all the information resulting from this multinational project (http://genomics.energy.gov). On the other hand, Celera, a competing private company, had already applied for patents on 6500 different gene sequences. In elucidating the genome, Celera used an approach in which the genetic material was shredded into tiny pieces and, after analysis, a supercomputer tried to put the pieces back together. In September 1999, Celera succeeded in mapping the genome of the fruit fly (*Drosophila melanogaster*), which contains "only" 180 million base pairs. The Human Genome Project announced the elucidation of the map of human chromosome 22, the second smallest, on December 2, 1999.[33] Although this chromosome holds only 1.6–1.8% of the human genetic code, it is believed to contain genes that play a role in at least thirty-five diseases, including congenital heart disease, mental retardation, leukemia, and schizophrenia. By June 26, 2000, Bill Clinton, president of the United States and Tony Blair, prime minister of the United Kingdom, simultaneously announced that the rough draft of the Human Genome was complete. We can now only hope that humankind has it in its genes to exploit the results for the benefit of humanity rather than for making a very few very rich individuals yet richer at the cost of their own country and especially to the detriment of third world nations.

Identification of the DNA sequence is only the beginning; the real payoff is still to come; molecular biologists worldwide that wrote down the 3.5-billion-bit genetic code are now trying to link specific genes and the proteins for which they code. It is becoming apparent that the expression of genes and the folding of proteins might better be solved by complexity theory than with a reductionist approach because of the extreme interconnectedness of the subcomponents.

Death and Aging

With the aging of the population in the industrialized countries, research funding for the study of death and aging is rapidly increasing. Some things about aging are known, but more needs to be learned, and plenty of controversy surrounds the topic. Here are some generally accepted facts. The simpler the life form, the easier it is to prolong its life or to regenerate parts of itself. Bacteria, for instance, continue to grow and produce progeny as long as they have food and a nontoxic environment. They do not die because of aging. Aging becomes increasingly important as a species acquires more sophisticated, specialized cells and organs. In these more complex life forms, there are two types of cells, namely germ cells and somatic cells. Germ cells are potentially immortal (like bacteria, they can reproduce the whole living entity forever); somatic cells are there for the greater efficiency of particular functions but cannot reproduce the whole organism. If a worm is cut in half, the tail, which contains germ cells, can reproduce a whole worm; the head, which only contains somatic cells, dies. The higher the ratio of somatic cells to germ cells, the more prone an organism is to aging. Mutating the genes that control how worms respond to hormones resembling insulin enable worms to live two to five times longer.[34,35]

Chromosomes are capped and protected by special DNA pieces called *telomeres*, in the same way that shoelaces are prevented from becoming frayed by aglets. These telomeres in mammals consist of thousands of TTAGGG repeats and act somewhat as an internal clock for the aging of cells: each time a cell divides, the telomeres on the chromosomes get shorter, and when they are short enough, they signal the cell to stop dividing. By adding telomerase, an enzyme that rebuilds telomeres, cells cultured in a dish become immortal (the patent rights for telomerase are owned by Geron in California). Cancer cells keep on dividing in part because they reactivate their telomerase! It is not yet clear how telomeres relate to death and aging in humans, since so many

other factors play a role. It is reasonable to expect, though, that some cells and tissue—especially those that divide quickly—become crippled by shortened telomeres. Short telomeres in old people might weaken the immune system and the capability of regenerating bone and skin, all of which contain rapidly dividing cells. The more times DNA is replicated, the more likely it is that errors are introduced. This link between age and mutation frequency is clear from parental-age-dependent genetic disorders such as Down's syndrome. Dolly, the cloned sheep, died in 2003, at age seven, very young for a sheep (see Figure 2.18). It has been speculated that Dolly started off life with a telomeric "clock" set already at her mother's age. This has put somewhat of a damper on cloning enthusiasm.

Many factors are claimed to influence average lifetime. Free oxygen radicals decrease the average life span (Linus Pauling's vitamin C is an antioxidant, and he claimed that it increased lifetime!).[36] Mutant forms of the enzyme catalase decrease the average life span; food restriction and less sexual activity (or more sex later in life—figure that one out!) will make you live longer. Cooler temperatures and an efficient glucose metabolism also prolong life (goodbye Florida). Although we can expect to live longer and healthier in the new millennium, Hayflick discovered in 1961 that normal human cells, when grown in a culture dish, divide a limited number of times (mean value is 61) and then die. This ultimate ceiling for life has been dubbed the Hayflick limit. Hayflick believes that our maximum life span is fixed by our genes at about 125 years.[37–40] Evolutionarily, there is no reason for human life to go on after the reproductive years are over (just look at the Rolling Stones).

Cloning

Introduction

The last decade of the twentieth century brought one of the most important milestones in molecular biology: the creation of the cloned sheep Dolly in 1996,[41] an event that made unprecedented headlines, both in scientific journals and in the popular press. The result was that suddenly the entire world was introduced to cloning. Cloning has become a household term, but most people are still unacquainted with the scientific processes involved in cloning and how cloning is actually executed. In this section, the cloning process and its implications from a molecular biology point of view is introduced. As shown below, there are three different types of cloning: 1) DNA cloning or recombinant DNA technology, 2) reproductive cloning, and 3) therapeutic cloning.

DNA Cloning, or Recombinant DNA Technology

First, we should mention that the terms cloning, gene cloning, recombinant DNA technology, and molecular cloning are used interchangeably to denote the same genetic engineering method. The term *cloning* denotes the process by which genetic material from one species is transferred to a self-replicating genetic element, such as a bacterial plasmid or a virus. A plasmid is an extrachromosomal circular piece of DNA distinct from the normal bacterial genome that contains genes and that is capable of producing multiples copies of itself when introduced into a host organism (i.e., bacteria, yeast, mammalian, or plant cells). Thus, plasmids replicate desired genes; in nature, these genes are from the plasmid's same organism (bacteria, yeast, etc.), but in recombinant DNA technology, scientists introduce foreign genes and use the plasmid to copy said genes. For example, in genetically modified foods, a gene encoding for a natural pesticide can be incorporated into a corn cell, giving rise to corn that now can produce its own pesticide.

Of all the terms used to denote cloning, *recombinant DNA technology* is perhaps the one that best defines what the procedure entails. As explained, the method involves taking a gene that encodes for a desired protein and introducing it within a bacterial plasmid, thereby recombining this foreign DNA with that of the plasmid. More specifically, the gene to be cloned first is isolated or cut out from chromosomal DNA by employing restriction enzymes, a type of enzymes that cleave DNA when they encounter a specific sequence of DNA bases that they recognize, leaving a distinct sequence of bases at both ends. The resulting DNA fragment

containing the gene is then isolated and purified from the mixture of chromosomal DNA, so it is ready to be inserted into the plasmid. Likewise, the plasmid is also cut open, or cleaved, with the same restriction enzyme, leaving the same sequence of bases at each end of the open plasmid as those present in the isolated gene. In that manner, when the gene fragment and the open plasmid are mixed together in the presence of another enzyme—ligase, whose function is to bind or "glue" together DNA sequences—they recombine like two pieces in a puzzle. After the plasmid is constructed, it is ready to be inserted into a host—most commonly a bacterium—where it will take advantage of the host's cell machinery to replicate in large amounts. The plasmid then expresses the gene that was inserted, thus producing the protein encoded by the desired gene. Figure 2.16 depicts a generic cloning procedure performed in bacteria.

Reproductive Cloning

The process of reproductive cloning is different from DNA cloning as described above. Its goal is to create an animal from the nuclear DNA of an existing one. The principle of this method involves the removal of the nucleus of an egg containing all the DNA of the cell and replacing it with that from another cell. In the laboratory, the newly created egg is then treated with chemicals or electrical stimulation so it can divide. Once the embryo reaches a certain cellular stage, it is inserted into the uterus of a female host, or "surrogate mother," where it grows and develops until birth (see Figure 2.17). It is important to note that cloned animals are not

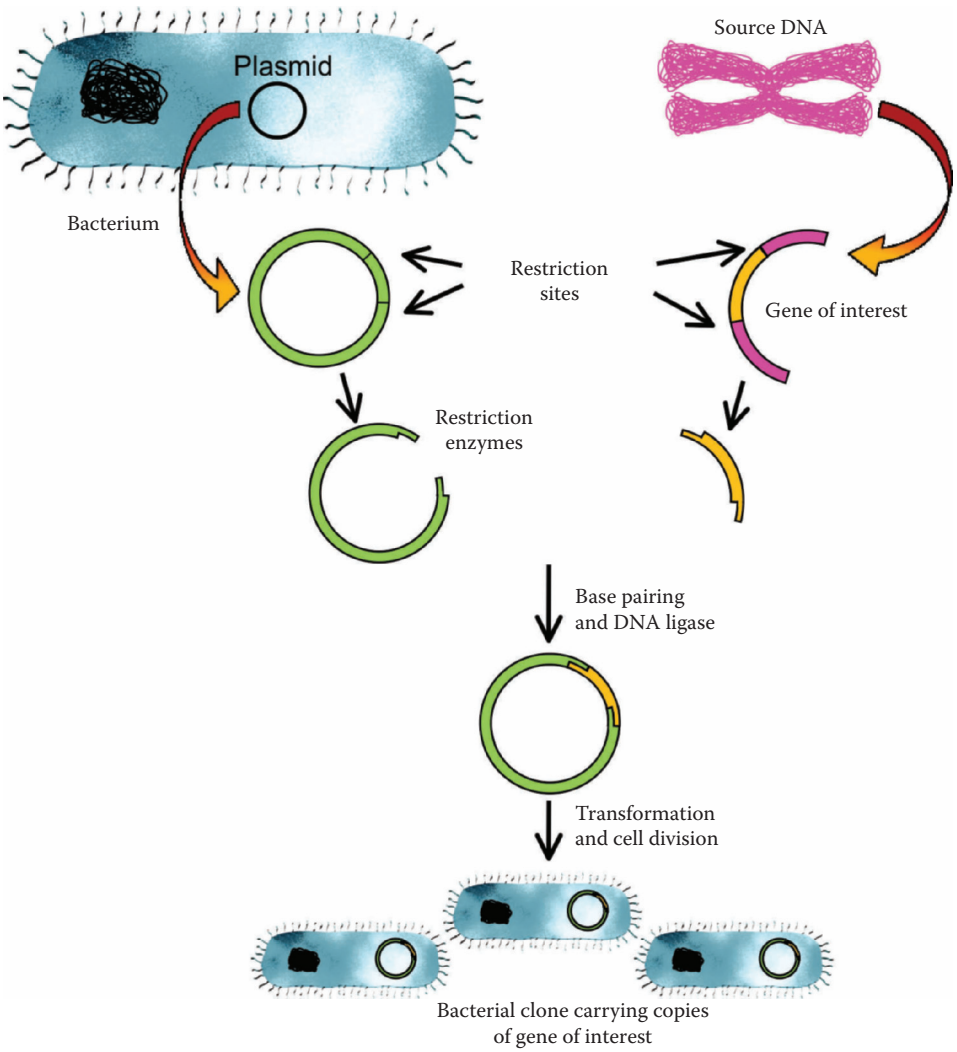

FIGURE 2.16 A generic cloning procedure performed in bacteria.

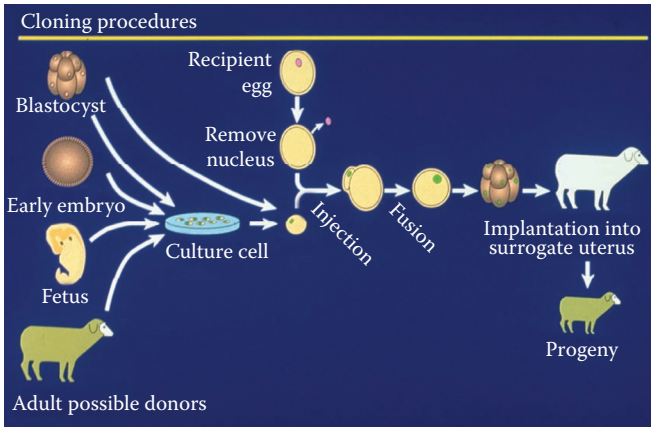

FIGURE 2.17 Reproductive cloning.

FIGURE 2.18 Dolly with her firstborn lamb, Bonnie. All of Dolly's offspring were bred the old-fashioned way. (Roslin Institute Image Library, http://www.roslin.ac.uk.)

exact replicas of their progenitors because the clones, in addition to the nuclear DNA from the progenitor, have mitochondrial DNA that is derived from the original egg. Mitochondrial DNA plays a role in the aging process, an important consideration when choosing the egg donor.

Reproductive cloning is not as effective as DNA cloning, where virtually any gene can be cloned into a suitable host, with the exception of a few incompatibilities. Reproductive cloning methods, although continuously improving, still are inefficient, with more than 90% of the embryos failing to produce viable offspring. To date, not enough data are available to allow one to predict the long-term effects of cloning, partly because a large number of the cloned animals produced are dying at a premature age. The first example of reproductive cloning, performed in 1952, resulted in a tadpole.[42]

Although other examples of cloned amphibians and other animals exist,[43] the most notable example of this type of cloning involves the creation of Dolly the sheep (named after the country singer Dolly Parton). Dolly (Figure 2.18) was cloned by a team of Scottish scientists led by Dr. Ian Wilmut,[41] currently at the Queen's Medical Research Institute at the University of Edinburgh. Dolly's cloning was exemplary in that she was the first large mammal to be cloned, thus bringing to reality the possibility of cloning other large animals, including humans. Unfortunately, Dolly's life was not easy; she suffered from crippling arthritis and lung cancer in addition to having to deal with paparazzi following her at all times—she was a Dolly Parton kind of celebrity! As a result, Dolly had to be euthanized when she was only six years old, a rather short life span compared to the eleven to twelve years of life of regular sheep.

Therapeutic Cloning, or Biomedical Cloning

The goal of this type of cloning is to produce an artificial organ or tissue that can be transplanted back into the individual who supplied the original DNA. The procedure, in its first stages, is almost identical to that of reproductive cloning, and it involves first removing the nucleus of an egg and then replacing the genetic material by inserting the nuclear DNA of the individual for whom a new organ or tissue is needed. The egg is allowed to develop until it has produced a large number of stem cells. After that, the stem cells are harvested from the embryo. This procedure results in the destruction of the embryo. The stem cells are allowed to reproduce in vitro and are chemically treated so as to develop in different types of stem cells that will give rise to the desired organ or tissue type. Once the artificial tissue or organ has been produced, it can be implanted into the patient (see Figure 2.19). The fact that the embryo is being destroyed during the cloning process brings up a number of ethical issues (see discussion in the section below). Nevertheless, the potential benefits of therapeutic cloning are tremendous, and researchers believe that these cells will be invaluable in the treatment of all sorts of diseases, among others, those of neurological origin

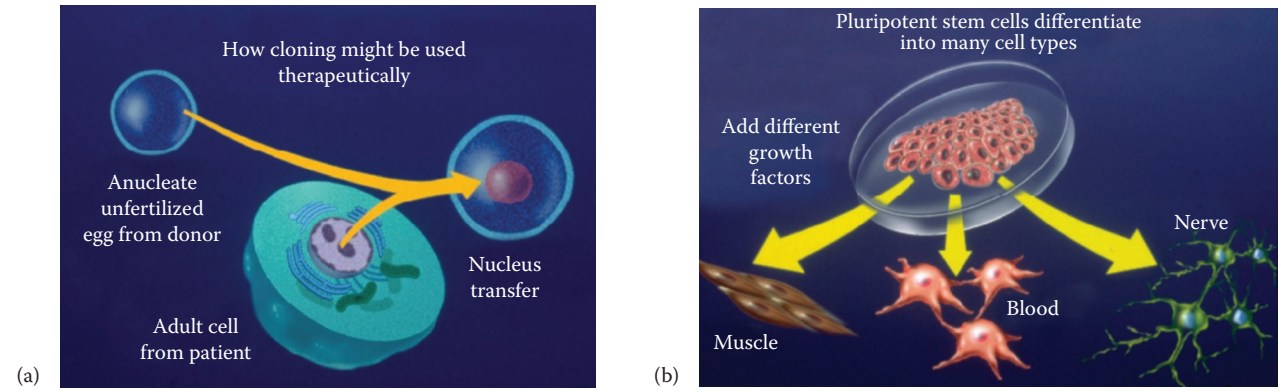

FIGURE 2.19 Therapeutic cloning.

(e.g., Parkinson's, Alzheimer's), cardiac diseases, and autoimmune diseases.

Stem Cells

The human body has more than 200 different types of cells, all derived from the same original stem cells. These stem cells are capable of reproducing themselves and transforming into different kinds, depending on what type of signal they receive while growing. This results in the production of a large number of diverse specialized cells responsible for organ and tissue formation in animals. Much research has been devoted to understanding the signaling events and pathways that lead to the transformation of a pool of identical unspecialized stem cells into this distinct very specialized cells originators of organs and tissues. Embryonic stem cells can develop into all different types of cells, whereas adult stem cells (present in fully developed adult individuals) are limited to the production of only certain types of specialized cells. In addition to embryonic and adult stem cells, rather recently, stem cells have been identified in placenta and in umbilical cord blood. The latter two types can develop into various types of blood cells. The characteristics and differences between embryonic and adult stem cells are shown in Table 2.4, below.

There is much to be learned about stem cells, but undoubtedly, the knowledge gained thus far already shows the vast number of applications and benefits that their manipulation and production will have in medicine, agriculture, and in the environment. A clear example of the potential of embryonic stem cells in medicine involves the preparation of active functioning nerve cells in mouse brains. In order to realize all the benefits of stem cells, protocols and methods will need to constantly be improved and simplified. In that regard, in 2006 researchers demonstrated the feasibility of producing embryonic stem cells from the morula (i.e., solid mass of cells that develops about six days after fertilization of an egg cell) of a mouse, thus showing that stem cells can be made without animal products in a culture. In November 2007, two separate teams of researchers were able to reprogram skin cells and turn them into stem cells.[44,45] The teams, led by James Thomson of the University of Wisconsin-Madison and by Shinya Yamanaka of Kyoto University in Japan, first identified four genes that confer the ability to reprogram certain types of cells. They then introduced these genes into skin cells from different sources and individuals by employing a retrovirus to essentially infect the skin cells and carry these genes into the nucleus of the cells. Once the new genes were part of the skin cells, they reprogrammed them, converting the skin cells into pluripotent stem cells. Because the original cells came from different types of tissue (i.e., facial skin, connective tissue, fetal skin, and baby foreskin) and from a variety of individuals (i.e., a 36-year-old woman, a 69-year-old man, a fetus, and a baby), the researchers are confident that the method will be able to be generalized and employable in most individuals. While the efficiency of the method was not the best—the Japanese team reported that 1 in 5,000 cells treated turned into a stem cell, and the US team, 1 in 10,000—both methods still result

Table 2.4 Stem Cell Overview

Characteristics of Stem Cells			
	Embryonic Stem Cells		
	In Vitro Fertilization	Nuclear Transfer	Adult Stem Cells: Adult Tissues
Properties	Produce all cell types Easy to manipulate and grow in the laboratory Can obtain embryos from in vitro fertilization clinics	Produce all cell types Easy to manipulate and grow in the laboratory Stem cells are genetically matched to patient	Successful in certain treatments Stem cells are genetically matched to patient
Limitations	Limited number of cells available for federally funded research Risk of creating tumors from transplanting undifferentiated cells	Not achieved with human cells yet Risk of creating tumors from transplanting undifferentiated cells	Results in limited numbers of cell types Not found in all tissues or organs Difficult to manipulate and grow in the laboratory
Ethical issues	Destruction of human embryos Require informed consent from embryo donor	Destruction of human embryos Require informed consent from embryo donor Possible misapplication in reproductive cloning	No ethical issues have been raised

Source: Adapted from the National Academies of Sciences, http://dels.nas.edu/dels/rpt_briefs/Understanding_Stem_Cells.pdf.

in a good number of cell lines that are viable. The implications of this discovery are vast, as this is the first real demonstration of conversion of cells from mature adult individuals into stem cells. The major downfall of these cell-reprogramming experiments is that they use a retrovirus to carry the reprogramming genes into the skin cells to be transformed. Retroviruses are known to cause tumors in human cells, and thus, the risk of inducing tumors cannot be trivialized. However, at this moment the possible positive outcomes of this new breakthrough technology outweigh the negative. Perhaps the most interesting application stemming from the work of these groups is the possibility of regeneration of organs and tissues of a patient from his/her own cells. Moreover, since the methods developed bypass the use of embryos or oocytes, the ethical dilemmas and controversy associated with their use will be avoided.

Finally, it is important to note that stem cells are also useful in studying human development, for testing new drugs and screening of toxins, and for testing gene therapy methods.

Reproductive Cloning and Stem Cell Research: Implications in Bioethics

Dolly's creation and life led to controversy, and as a consequence, reports regarding the ethics of cloning were drafted in the European Union (EU), the United States, and a number of other countries, including Canada and Australia. Specifically, in 1997, after Dolly's creation, President Clinton responded quickly to the prospect of human cloning, banning the use of federal funds for human cloning in the United States. Having considered the scientific and moral implications of said research, he also asked privately funded researchers to implement a temporary moratorium on human cloning research until the Bioethics Advisory Committee set up guidelines regarding this matter. Moreover, in 2001, then President George W. Bush created The President's Council on Bioethics (http://www.bioethics.gov/topics/cloning_index.html), whose mission is to advise the President on bioethical issues that may emerge because of advances in biomedical science and technology. Currently, there are no federal

laws in the United States that prohibit human reproductive cloning. To date, federal regulations on most human biotechnologies are not adequate, and more comprehensive regulatory policies are needed. Regarding stem cell research, in 2001, President Bush imposed a limitation on federal funding earmarked to embryonic stem cell research. This policy decision has been a source of controversy and debate, with many members of Bush's own Republican Party regretting this limitation and siding with the more progressive Democratic members of Congress. Also noteworthy are some of the most outspoken supporters of stem cell research, Republican public figures Nancy Reagan, former First Lady, and Arnold Schwarzenegger, the California governor. In that regard, then Governor Schwarzenegger led the country by proposing a bill, Proposition 71, in his state to fund stem cell research. Californians voted to pass the bill in 2004, which authorized up to $3 billion over 10 years for embryonic stem cell research in California. With this funding, the California Institute for Regenerative Medicine was created to foster stem cell research and appropriate the funds provided by the state of California. Other states have followed suit with the creation of stem cell research programs, albeit not as ambitious or comprehensive as the California one.

In 2005, the National Academies of Sciences of the United States published the Guidelines for Human Embryonic Stem Cell Research, which provide a common set of scientific and ethical guidelines aimed at aiding scientists from both the public and private sectors to establish new protocols in stem cell research. These guidelines state the need for the monitoring of all human embryonic stem cell research and outline specific methods for the derivation of new stem cell lines; for example, experimenting on human embryos by inserting stem cells into them is not allowed. Furthermore, the rapid advances in stem cell research prompted the National Academies to create a panel composed of experts in the field to monitor and review scientific developments; to change ethical, legal, and policy issues; and to prepare periodic reports to update the guidelines. More information on this can be found at http://www.nationalacademies.org/stemcells.

Within the EU, the European Convention on Human Rights and Biomedicine has prohibited human cloning in one of its protocols; however, only a few countries—namely Greece, Spain, and Portugal—have ratified this protocol. Furthermore, the ambiguity continues in the EU with regard to any kind of legal standing on reproductive human cloning despite the fact that the Charter of Fundamental Rights of the European Union has prohibited its practice. The United Nations decided to introduce debate on this issue among the country members of its General Assembly; as a result, in March 2005, the United Nations Declaration on Human Cloning was adopted.

For information on National Polices Governing New Technologies of Human Genetic Modification in a large number of different nations, see http://geneticsandsociety.org/article.php?id=304. For readers interested in the topic of bioethics, information can be found at http://ethics.sandiego.edu/Applied/Bioethics/index.asp. In addition, a good source of information and interesting reading can be found on the Web site of Professor Lee Silver of Princeton University, an expert in bioethics, http://www.leemsilver.net/challenging/index.htm. Dr. Silver's views are provocative as well as entertaining, and interested readers will enjoy his written work and audiovisual pieces.

Biological Cells and Their Machines

Prokaryotes and Eukaryotes

Earlier, we learned how cells might have emerged from a soup of chemicals, and their more detailed construction and operation will be instructive for the future of miniaturization science. Living cells and their organelles have dimensions in the micrometer and submicrometer range and constitute the first truly autonomous micromachines. There is much more membrane area (99%) surrounding the internal organelles than there is outer membrane surface (1%).

Microscopic sizes are the normal working size for the biological world, a biological cell of about 5–10 μm being one of the larger components. The human body contains approximately 100 trillion of these cells. Some of the simplest organisms, such as

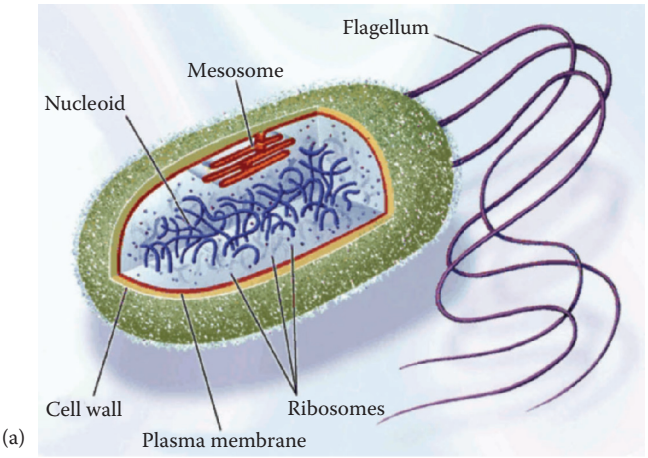
bacteria and algae, have no cell nucleus, and their genetic material is mixed in with the aqueous cytoplasm. These life forms are known as *prokaryotes*, a designation used to convey their relatively simple status as protocells, and they are the forerunners to multicellular organisms. Most multicellular organisms have their genetic material in a separate chamber within the cell, the *nucleus*, and are called *eukaryotes*, literally, "true nucleus." These two types of cells are compared in Figure 2.20.

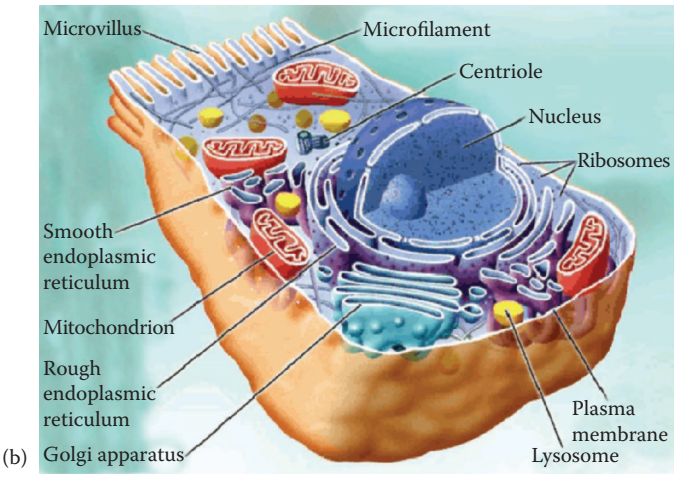
Prokaryotes (from bacteria to blue-green algae) took about 500 million years to evolve, but the evolution of the first eukaryotic cells took 2500 million years. Clearly the development of this more elaborate construction was a crucial step in the evolution toward more complex life forms; early eukaryotic cells began the evolutionary path that led to complex multicellular animals and plants. The more complex a multicellular organism, the more different types of cells it has; a blue whale, for example, has approximately 120 types of cells, whereas a mushroom has fewer than 10. Eukaryotic cells come in a very wide variety of shapes and sizes, but on average a cell has a volume of about 3.4×10^{-9} ml and weighs roughly 3.5×10^{-9} grams. Cell size, on the upper end (400 μm^3), is limited by the ability of diffusion to bring nutrients to the appropriate parts inside the cell and to dispose of waste products. The smallest size for a free-living organism (0.02 μm^3) most likely is set by the catalytic efficiency of enzyme and the protein synthetic chemistry machinery.

Organelles

Introduction

Organelles, visible in the eukaryotic cell in Figure 2.20b, are specialized structures. The functions of several of these cell organelles are described in the following sections. As depicted in Figure 2.21, a cell might be compared to a city, with the corresponding functions listed below the images. The high degree of spatial/temporal organization of molecules and organelles within cells is made possible by protein machines that transport components to various destinations within the cytoplasm. These different tiny motors are specialized for specific tasks, such as cell division, cell movement, crawling, maintenance of cell shape, movement of internal organelles, synthesis of ATP, RNA synthesis, DNA synthesis, etc.





Prokaryotes	Eukaryotes
No nucleus—have a nuclear "area"	Nucleus present
No membrane-bound organelles	Have membrane-bound organelles
DNA present usually as 1 large chromosome	DNA in nucleus
Primitive cells usually quite small	"Modern" cells, can be quite large
Archebacteria, Eubacteria	Plants, Animals, Fungi, Protists

Mitochondria and Phylogenetic Trees

The nucleus contains the genetic material (library), and the mitochondria (power plants), through utilization of pyruvate and oxygen, produce ATP (adenosine triphosphate), a compound that provides energy for cellular activities. There is convincing evidence that these mitochondria used to be independent structures with a life of their own that became incorporated into eukaryotic cells over time—very much like bacteria that permanently colonize more complex cells.[46] Mitochondria, for example, contain DNA that uses a slightly different code for amino acids than does the same DNA in the nucleus of the cell. As in bacteria, the length of DNA is closed into a loop and the mitochondria reproduced by splitting in two. These are amazing findings, as the DNA code for amino acids is otherwise the same for species as different as humans and fish (see under "The Genetic Code"). While each of us necessarily has two parents, our mitochondria and mitochondrial DNA come from the ovum and hence from our mothers. Our mothers, in turn, got their mitochondrial DNA from their

mothers, and so on. Thus, while our nuclear DNA is a mish-mash of the DNA of our four grandparents, mitochondrial DNA (mtDNA) is an almost exact copy of the DNA of our maternal grandmother. The match is not exact because of mutations: mtDNA has a pointwise mutation substitution rate 10 times faster than nuclear DNA—so it is a better record of evolutionary change.

Evolutionary trees or phylogenies can be reconstructed by comparing mtDNA (Figure 2.22). In fact, the mutations in the mitochondrial DNA provide the molecular clock that allows us to determine how much time has elapsed since the *mitochondrial* Eve lived. University of California Berkeley's Allan Wilson, in 1987, compared mtDNA of many racial groups.[47] Knowing the average mutation rate, he figured out that we all derive from a single version of mtDNA that existed 200,000 years ago in the cells of an African woman—the common ancestor of all of humanity. This work is now seen as overly simplistic. Construction of an exact phylogenic tree is indeed still controversial: for example, it is not necessarily true that the molecular clock is constant; i.e., mutation rates may change, and environmental pressure may change (http://www.sciencemag.org/feature/data/tol). Moreover, the mathematical descriptions and algorithms that may lead to a historically correct phylogenetic tree remain to be developed (http://tolweb.org/tree).

Mitochondria and Power

Here we dwell for a moment as we consider the operation of the cells' power stations—the mitochondria—in more detail (Figure 2.23). We study how cells derive their power from the sun by relying on mitochondria. Energy is required for mechanical work, transportation, and chemical work. When considering building artificial cells, powering the micro- or nanounits is one of the first priorities. This might mean, in human engineering terms, capturing radiant energy (e.g., sunlight) with a solar cell

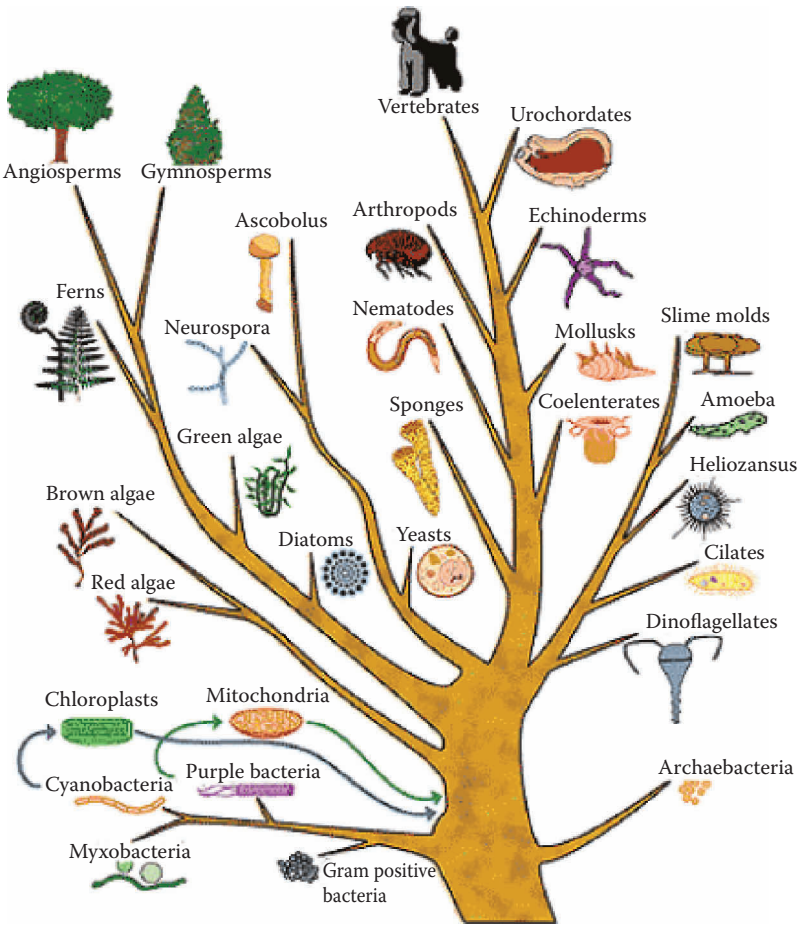

FIGURE 2.22 Evolutionary trees or phylogenies can be reconstructed by comparing mitochondrial DNA.

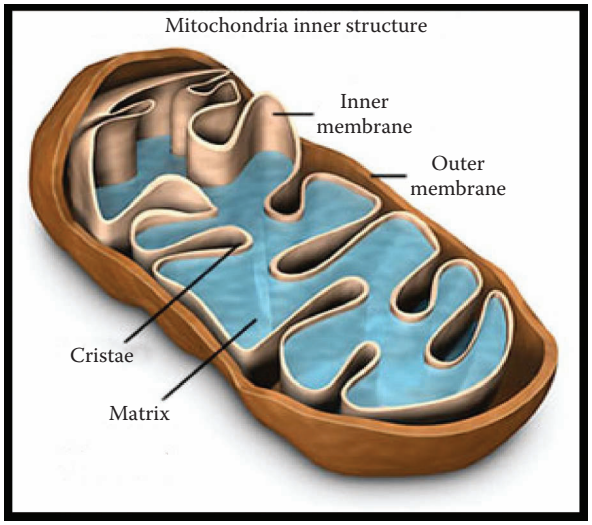

FIGURE 2.23 Mitochondria.

and converting it to a fuel that can be stored for later use (e.g., hydrogen through water electrolysis).

In Figure 2.24a we show the molecular structure of the energy currency of a biological cell, i.e., adenosine triphosphate or ATP, the immediate source of energy in all cells of all living organisms on Earth. The structure of an ATP molecule contains three molecules of phosphate linked to each other; at the pH of normal biological fluids, they have a negative charge. When energy is required, ATP is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate (P_i). Back in the mitochondria, ADP is recycled back to ATP almost immediately, so that the energy is again available to do needed work (recharging of the batteries) (Figure 2.24b). The production of ATP is due to three different cell processes, namely photosynthesis, fermentation, and respiration. In photosynthesis, nature uses stacks of thylakoids in a chloroplast, a plant organelle as shown in Figure 2.25. We will detail the photosynthesis process, the conversion of carbon dioxide and water into glucose with the help of sunlight, shortly.

For now it suffices to say that through photosynthesis, plants, algae, and some bacteria store solar energy in the form of the high-energy chemical bonds of glucose. In that process carbon dioxide and water are consumed, and some leftover oxygen is released in the air. This energy consuming process is said to be anabolic; i.e., large molecules are synthesized from smaller ones in a scenario schematically illustrated in Figure 2.26a ($\Delta G > 0$). Most living organisms (including plants and animals) then reverse photosynthesis by taking glucose apart and releasing energy to power their own growth and development. In this second process, oxygen is consumed, and water and carbon dioxide, the original ingredients consumed by the plants, algae or bacteria, are released. This energy producing process is said to be catabolic, i.e., breaking down complex

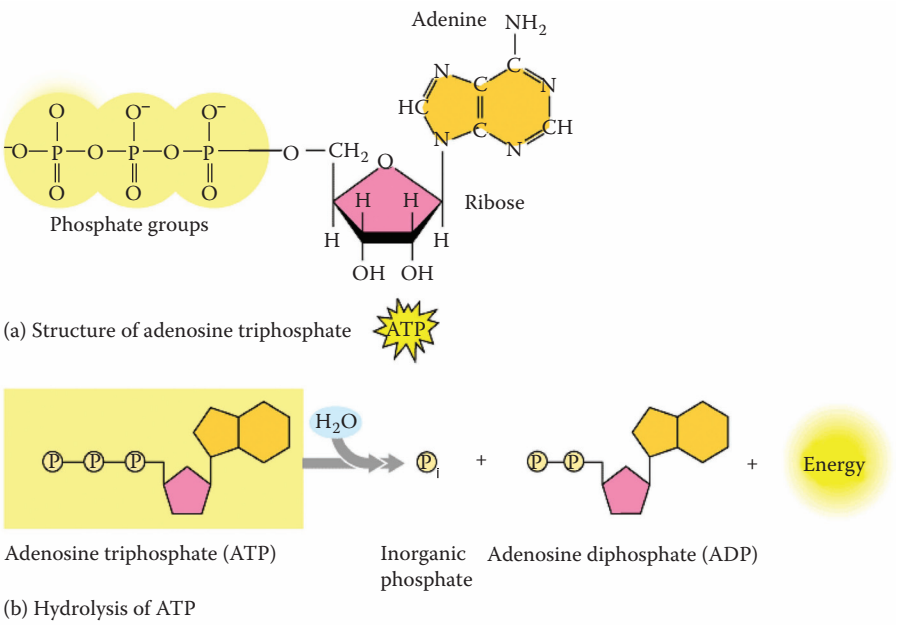

FIGURE 2.24 (a) Molecular structure of adenosine triphosphate (ATP). (b) Hydrolysis of ATP to ADP.

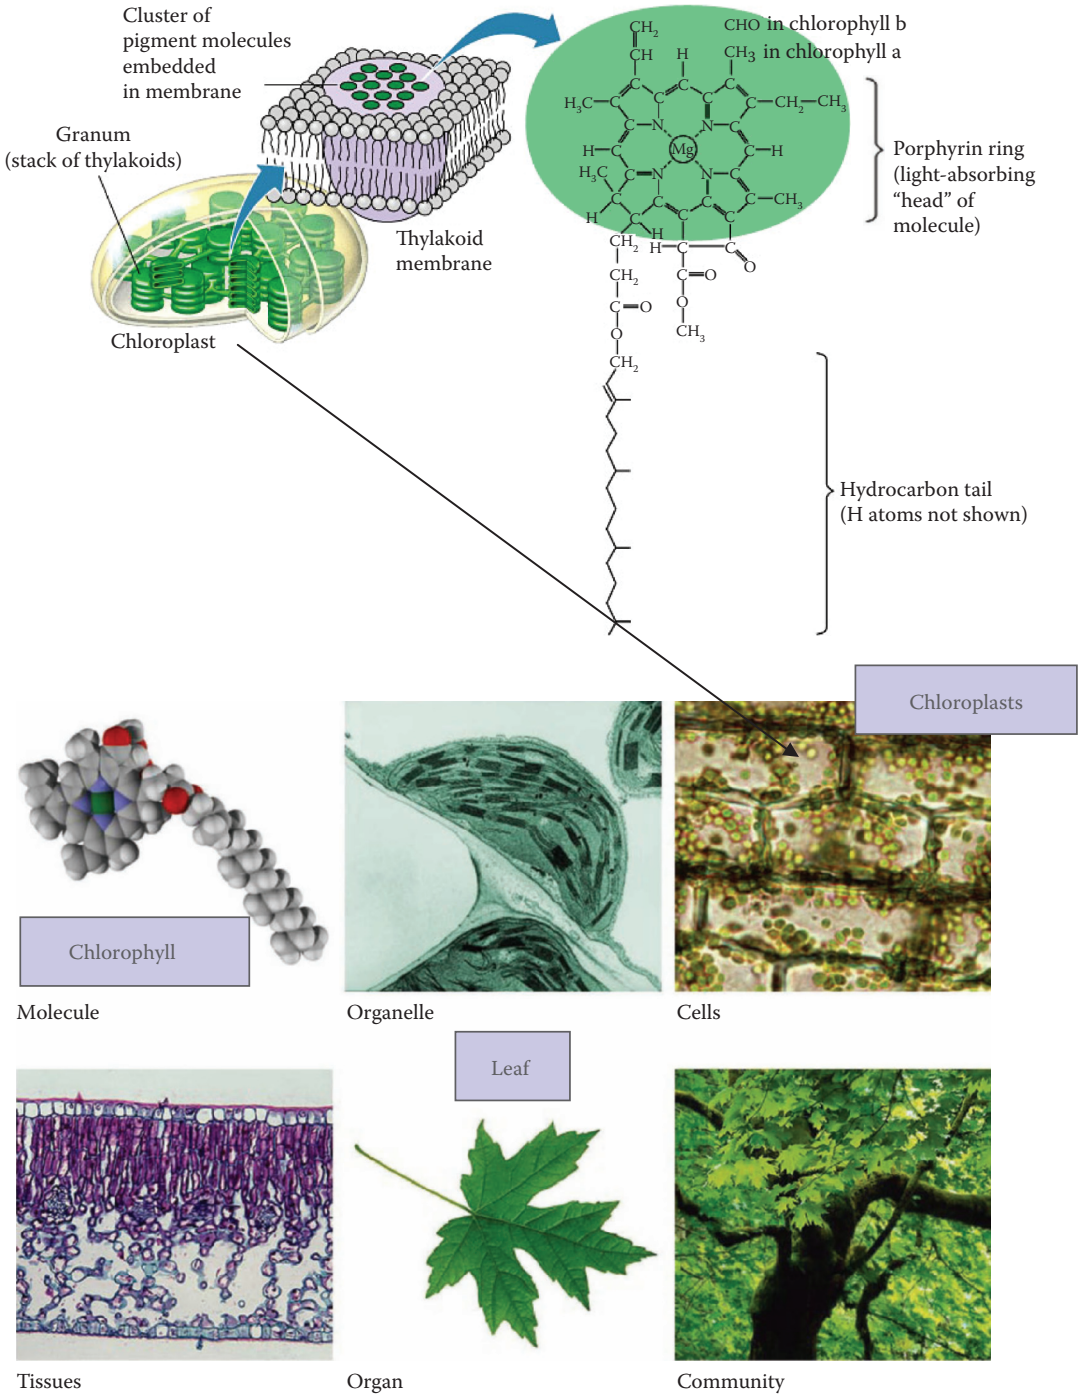

FIGURE 2.25 Photosynthesis in plants: from trees to pigment molecules in the thylakoids in chloroplasts.

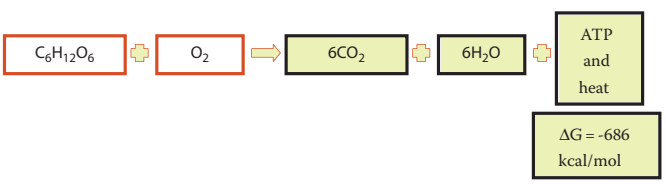
molecules into smaller, simpler ones. This is illustrated in Figure 2.26b ($\Delta G < 0$).

Direct oxidation of glucose with oxygen would release 686 kcal/mol ($\Delta G = -686$ kcal/mol) (Reaction 2.1), but cells cannot use the energy stored in glucose directly.

In the cytoplasm of a cell, first, nine different enzymes must help convert the glucose (a chain of six carbons with twelve hydrogen atoms and six oxygen atoms) in nine successive chemical reactions



Reaction 2.1

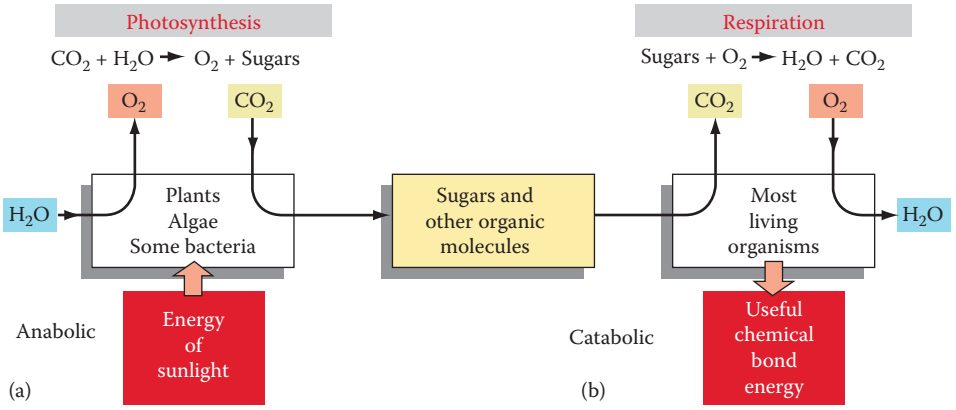


FIGURE 2.26 (a) Anabolic process: use of energy to conduct unfavorable/uphill reactions (from small to large molecules). (b) Catabolic processes: fuel breakdown to deliver energy (from large molecules to small).

to two molecules of pyruvate (a three-carbon chain with three hydrogens and three oxygens). This complicated process is called *glycolysis*. After glycolysis, it is the pyruvate that carries on as the energy source originally produced with the solar energy input, and transports it to the mitochondria. The mitochondria takes the energy garnered during photosynthesis (in the case of plants) or the digested food (in the case of animals) and stored as pyruvate and converts it to ATP. This conversion in the mitchondria occurs at a very high surface inner membrane in a complex set of reactions, including the famous Krebs cycle. The Krebs cycle is an aerobic process (i.e., it involves the use of oxygen) that is responsible for cellular respiration. Hydrolysis of the ATP result in the release of one of three P_i groups, along with 7 kcal/mol, and the formation of ADP (Figure 2.24b). ATP thus packs a wallop of concentrated solar power. These tiny solar batteries are released by the mitochondria into the cell to power all types of uphill reactions ($\Delta G > 0$). In releasing their power, ATP battery molecules shed instantly one phosphate (P_i) and are discharged to become ADP (ATP minus one P_i). In biochemistry, phosphorylation is the addition of a P_i group to a protein or a small molecule. Beyond doubt, protein phosphorylation is the most important regulatory event in eukaryotic cells. Many enzymes and receptors are turned on or off by phosphorylation and dephosphorylation. Phosphorylation is catalyzed by various specific protein kinases, whereas phosphatases dephosphorylate. The discharged ADP solar battery, in need of recharging now, diffuses until it finds a mitochondria power station, where it will regain its lost phosphate. Cells obviously recycle the ATP batteries they use for work.

To make ATP from pyruvate, as we show in Figure 2.27, the most prevalent and efficient pathway is cellular aerobic respiration. In cellular aerobic respiration, the conversion of 1 mol of glucose yields up to 36 mol of ATP; therefore, the energy efficiency is 36×7 kcal/mol divided by 686 kcal/mol = 252/686 = 36.7% (compared with about 3% efficiency in the burning of oil or gasoline). In the absence

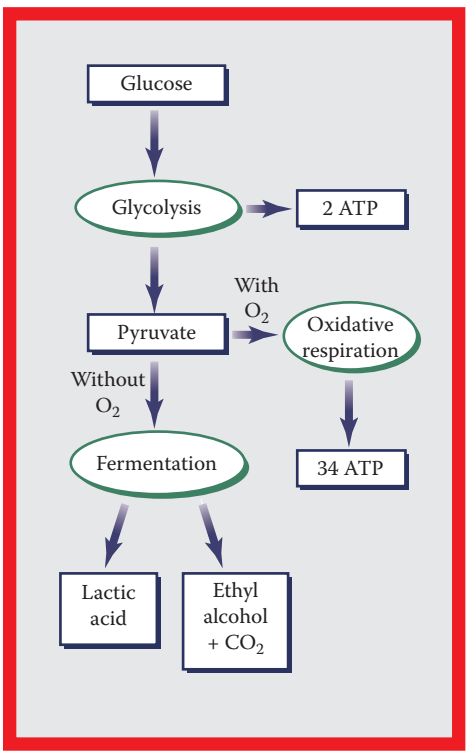

FIGURE 2.27 Various pathways to making of pyruvate, the food source for mitochondria.

of oxygen, certain cells are still able to make ATP, albeit in a less efficient matter. This can be accomplished through fermentation and anaerobic respiration. Fermentation is the breakdown of sugars in the absence of oxygen to release energy, carbon dioxide, and alcohol (or lactic acid). Yeast cells produce ethyl alcohol by fermentation.

Some prokaryotes are able to carry out anaerobic respiration, respiration in which an inorganic molecule other than oxygen (O_2) is the final electron acceptor. For example, certain bacteria known as sulfate reducers can transfer electrons to sulfate (SO_4^{2-}), reducing it to H_2S. Other bacteria, called nitrate reducers, can transfer electrons to nitrate (NO_3^-), reducing it to nitrite (NO_2^-). Other nitrate reducers can reduce nitrate even further, to nitrous oxide (NO) or nitrogen gas (N_2). The total energy yield per glucose oxidized is less than with aerobic respiration, with a theoretical maximum yield of 36 ATP molecules or fewer.

Cellular respiration, fermentation, and anaerobic respiration are catabolic, energy-yielding pathways. The totality of an organism's chemical reactions is called *metabolism*. Metabolism manages the material and energy resources of the cell. In Figure 2.28 the various processes that ATP energizes are summarized.

Since animals cannot make food directly from water and CO_2, chloroplasts and mitchondria work in tandem, as illustrated in Figure 2.29. Photosynthesis and respiration are complementary processes in the living world. Photosynthesis uses the energy of sunlight to produce sugars and other organic molecules. These molecules, in turn, serve as energy sources or food. Respiration is a process that uses O_2 and forms CO_2 from the same carbon atoms that had been taken up as CO_2 and converted into sugars by photosynthesis. In respiration, organisms obtain the energy that they need to survive. It is the cycling of molecules between chloroplasts and mitochondria that allows a flow of energy from the sun through all living things. Photosynthesis preceded respiration on the Earth by, probably, billions of years before enough O_2 was released to create an atmosphere rich in oxygen. Ultimately, the process of photosynthesis (Reaction 2.2) can be considered one of the most, if not *the* most, important chemical reaction on Earth.

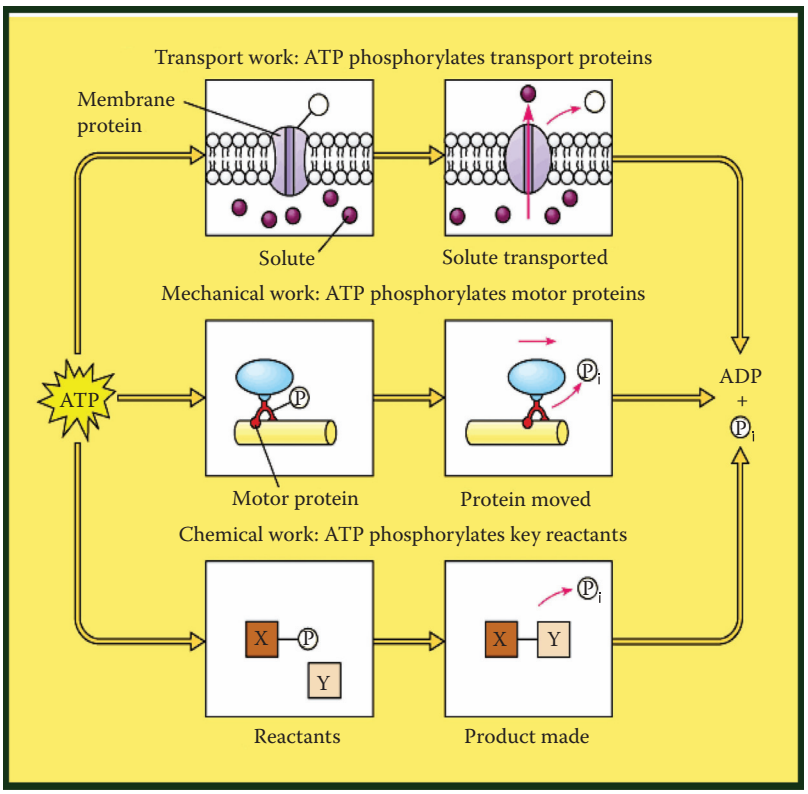

FIGURE 2.28 The various processes that ATP energizes: ATP at work.

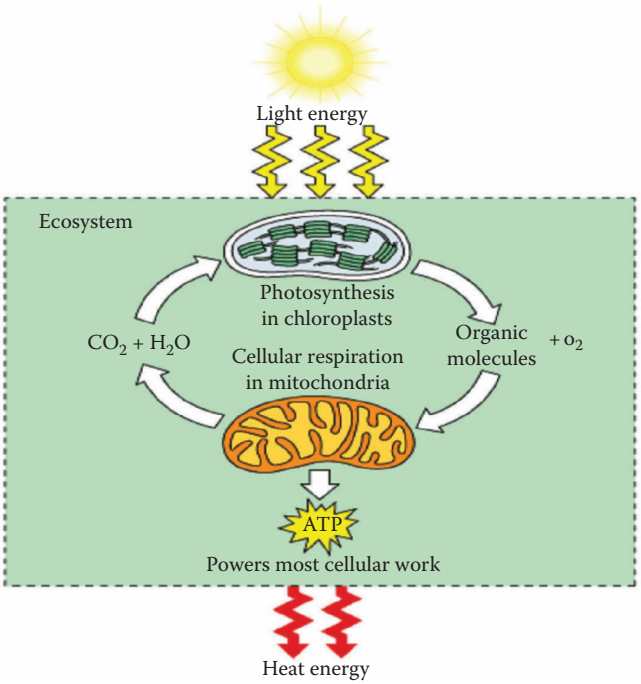

FIGURE 2.29 From light to photosynthesis to cellular respiration and heat energy.

$$6CO_2 + 12H_2O + \text{light energy} \Rightarrow C_6H_{12}O_6 + 6O_2 + 6H_2O \qquad \text{Reaction 2.2}$$

For building artificial cells, we would be better off building plant like-cells, as the source for fuel is in the atmosphere (water and/or CO_2) and harvesting energy from the sunlight is relatively simple. So let us take a more detailed look at how the chloroplasts in plant leaves do it (Figure 2.25).

Pigments in the leaves of plants absorb sunlight, principally through chlorophyll in the chloroplasts. Chloroplasts are found mainly in mesophyll cells forming the tissues in the interior of the leaf (Figure 2.25). Chlorophyll comes in two slightly different forms, called chl a and chl b. Most leaves contain at least two additional types of pigments, carotenes and xanthophylls, that are capable of absorbing light of different wavelengths. The more abundant chlorophylls usually mask the latter two types of pigments. There are about half a million chloroplasts per square millimeter of leaf surface. The color of a leaf comes from chlorophyll, the green pigment in the chloroplasts. Oxygen exits and carbon dioxide enters the leaf through microscopic pores, stomata, in the leaf. Veins deliver water from the roots, and carry off sugar from mesophyll cells to other plant areas (Figure 2.30).

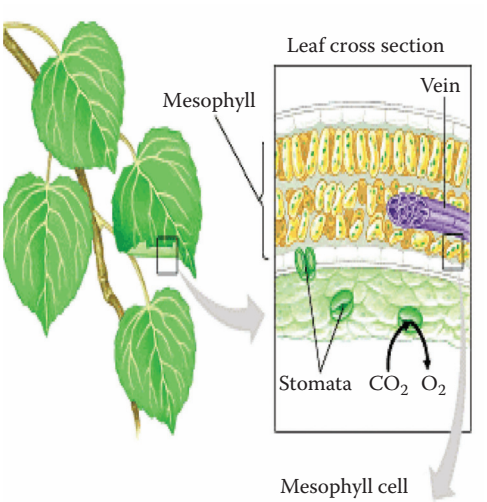

FIGURE 2.30 Stomata and veins in a green leaf.

Only chl a can participate directly in the light reactions. Other pigments in the thylakoid membrane (e.g., chl b, carotenoids) can absorb light and transfer the energy to chl a. These pigments thus broaden the spectrum of solar light (wavelengths) that can drive photosynthesis. Plants only use a narrow range of frequencies from sunlight between 400 and 700 nm. Light reactions on the thylakoid membrane convert solar energy and produce oxygen, and dark reactions fix CO_2 in the Calvin-Benson cycle to make sugar, as shown in Figure 2.31.

Molecular Motors

Other subcomponents of biological cells exhibit equally fascinating feats of nanoengineering. For illustration, consider molecular motors, composed of a discrete number of atoms that produce molecular or supramolecular motions. Molecular motors derive energy from ATP that is present in the cytoplasm and nucleoplasm of every cell and is the universal energy currency for all biological processes (see Figure 2.24). Living things can use ATP like a battery. Molecular motors are in a sense nanomachines that do mechanical work through the hydrolysis of ATP, the energy source of the cell. During hydrolysis of ATP, a shape change occurs within the motor protein (a mechanochemical process), and mechanical work is performed. This mechanical work is used to move the motor along a track in order to perform a load transport function or to apply forces to the filament for cell motility and cell

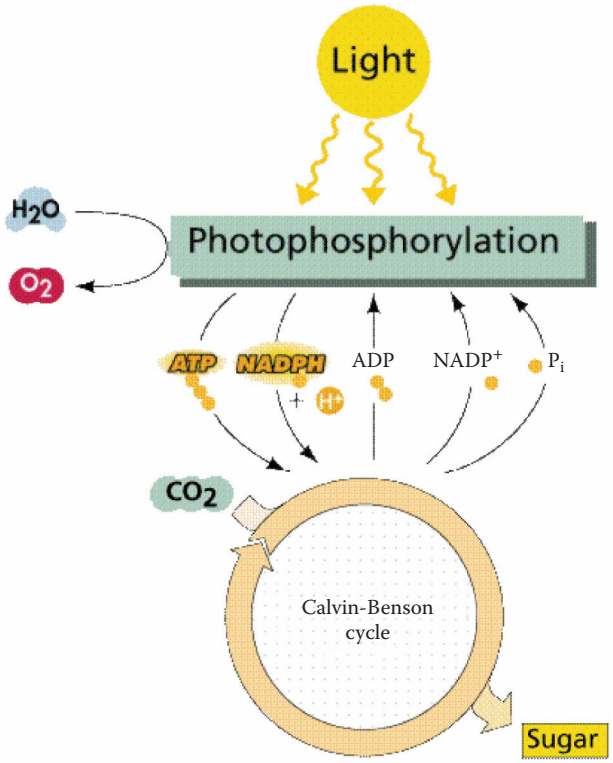

FIGURE 2.31 Photosynthesis with light reaction and dark reaction in the Calvin-Benson cycle.

division. Three types of motors can be distinguished, i.e., linear motors (such as myosin, dynein, and kinesin), rotary motors (F_0-F_1 ATP synthase) and polymerization motors (RNA, ssDNA); their tracks and functions are summarized in Table 2.5. Many of proteins can be considered nanoactuators, not only rotary or linear motor proteins. In some cases, even a simple binding of a protein and a specific target molecule—a chemical reaction—results in definite shape change—a mechanical effect. A conformational change might be put to good use in genetically engineered nanoactuators or biosensors (see calmodulin example, below).

Kinesin is a linear motor protein that steps along the microtubuli, the tubelike fibrils of the cell's skeleton, and is responsible for carrying organelles over a long distance within the cell (Figure 2.32). Most kinesins "walk" toward the plus ends of microtubules. A single kinesin molecule can drag along relatively large things like chromosomes and other organelles. Svoboda et al. demonstrated that kinesin can even work in vitro on a microscope slide.[48] This was demonstrated by gluing kinesin on microtubuli and observing it drag along a little ball of silica gel. Its strength is about 5 piconewtons (the force a laser pointer makes on a screen). Optical tweezers are well suited for studying molecular motors because of their low spring constants. Using optical traps, this same group determined that kinesin moves in individual steps that are 8 nm (80 Å) in length, a size consistent with its dimensions (Figure 2.33).[48] Microtubules can also move themselves on a glass slide surface containing bound kinesin (a single molecule bound to glass can move a microtubule). For the latest on kinesin research, visit the kinesin homepage at http://www.proweb.org/kinesin.

Noji et al. discovered that the γ-subunit of the hydrophilic F_1 portion of ATPase rotates in response to the synthesis/hydrolysis of ATP (Figure 2.34).[49] The moving part of an ATPase is a central protein shaft (or rotor, in electric-motor terms) that rotates in response to electrochemical reactions with each of the molecule's three proton channels (comparable to the electromagnets in the stator coil of an electric motor). The ubiquitous ATPase was the first rotary motor enzyme ever found, and the force generated by this motor protein (>100 pN) is among the greatest of any known molecular motor. The enzyme puts out a very large torque, comparable

TABLE 2.5 Molecular Motors and Their Tracks and Functions

Type	Track	Function
Myosin	F-actin, filament	Cell crawling, cell division, muscle contraction
Dynein	Microtubules	Eukaryotic cell (produces the axonemal beating of cilia and flagella and also transports cargo along microtubules toward the cell nucleus)
Kinesin	Microtubules	Organelle transport, chromosome segregation, moves cargo inside cells away from the nucleus along microtubules
Polymerase	RNA, single-stranded	Nuclear processes (transcribes RNA from a DNA template)

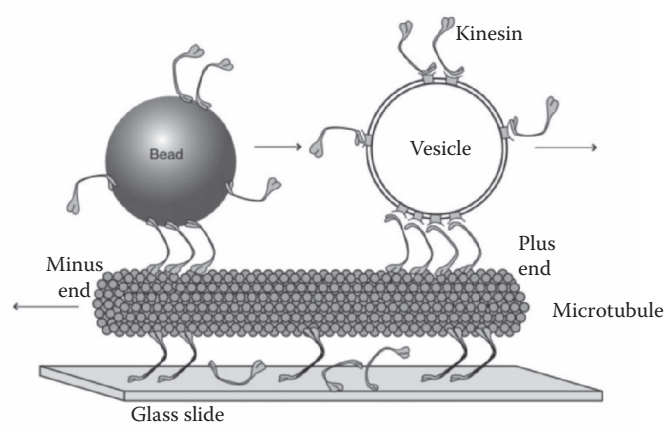

FIGURE 2.32 Kinesin motor. Schematic diagram showing movements mediated by kinesin, an ATP-driven motor, on microtubule tracks. Vesicles and beads containing kinesin molecules on their surface move toward the plus end of microtubules. Microtubules can also move themselves along a glass slide containing bound kinesin.[48]

to a person rotating a 150-m rod. The enzyme can spin such a long filament because it automatically ratchets down the rotation rate. A no-load rotational velocity of 1020 rpm was calculated, and the motor has a diameter of less than 12 nm. Montemagno et al.,[50] then at Cornell University, integrated these genetically engineered motor proteins with NEMS, for example, by attaching the protein nanomotors to arrays of nickel posts and attaching nickel rotor blades to the protein molecules.[50] The "handle" for attaching the ATPase motor to the nanofabricated metallic substrates is a synthetic peptide composed of histidine and other amino acids. The histidine peptide allows the molecular motors to adhere to nanofabricated patterns of gold, copper, or nickel—the three standard contact materials in integrated circuits.

The researchers attached fluorescent microspheres (~1 μm in diameter) to the ATPase molecule's rotor and observed the microsphere movement with a differential interferometer and with a charge-coupled device camera.

The authors envision that F_1-ATPase motors will be used to pump fluids and open and close valves in nano- and microfluidic devices and provide mechanical drives for a new class of nanomechanical devices.[50] This work was cited by *Discover* magazine as one of the most promising new technologies of 1999. Today, twelve years later, that promise remains unmet.

Bacteria swim in viscous liquid environments by rotating helical propellers known as flagella, shown in Figure 2.35 (see also Volume I, Chapter 6, "Mixing, Stirring, and Diffusion in Low Reynolds Number Fluids"). The bacterial flagellum is a nanomachine made of about twenty-five different proteins, each of them in multiple copies ranging from a few to tens of thousands. It is constructed by self-assembly of these large numbers of proteins, each into a different

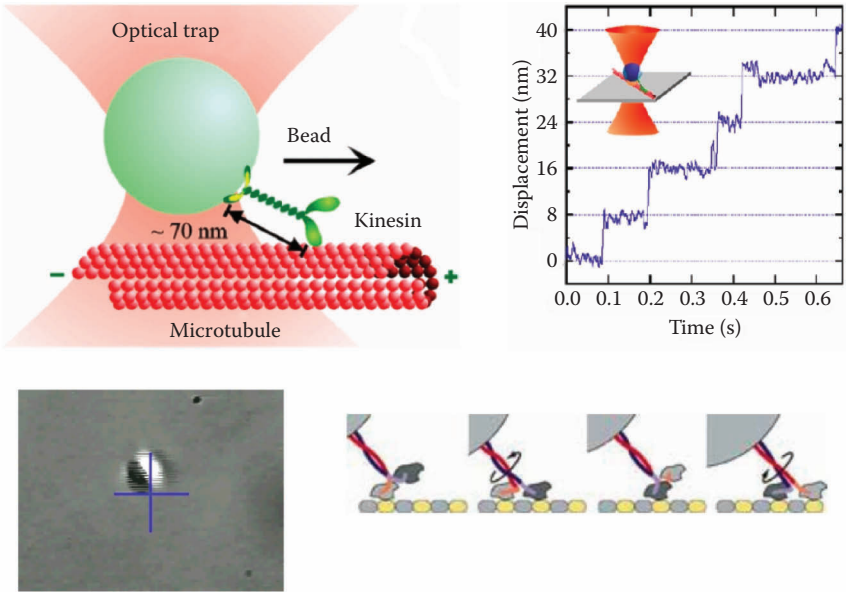

FIGURE 2.33 Laser tweezers were used to study kinesin motors with the kinesin molecule attached to a bead traveling over a microtubule. (From http://www.stanford.edu/group/blocklab.)

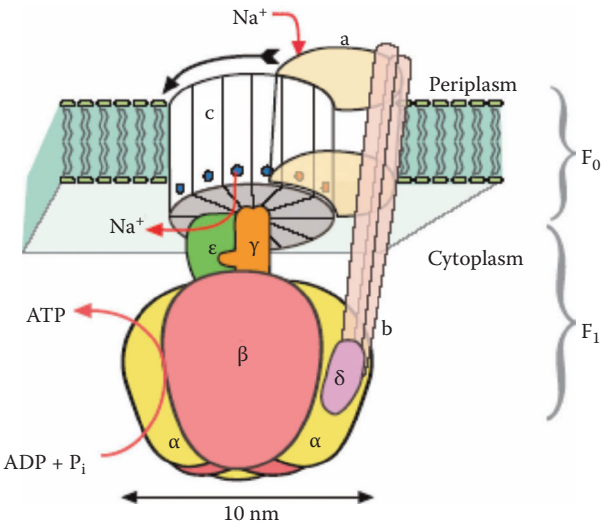

FIGURE 2.34 ATPase motors. A single molecule of F_0F_1-ATPase acts as a rotary motor—the smallest known. A central rotor of radius ~1 nm, formed by its γ-subunit, turns in a stator barrel of radius ~5 nm formed by three α- and three β-subunits.

part that exerts a different function, such as a rotary motor, bushing, drive shaft, rotation-switch regulator, universal joint, helical propeller, and rotary promoter for self-assembly. The rotary motor, with a diameter of only 30–40 nm, drives the rotation of the flagellum at around 300 Hz, at a power level of 10–16 W, with energy conversion efficiency close to 100%. These protein motors appear to be fueled by a flow of protons across a pH gradient and can push an average-sized cell at 30,000 nm/s or 15 body-lengths per second—and can also run in reverse![51] In comparison, the surface micromachined motors of Volume II, Chapter 7, are hopelessly impractical.

The structural designs and functional mechanisms revealed in the complex machinery of the bacterial flagellum could provide many novel technologies that may become the basis for future nanotechnology, from which we should be able to find many useful applications.

Mammalian muscle, nature's ubiquitous actuator for larger organisms, is another chemomechanical actuator. Muscle cells are long and cylindrical and made up of thick myosin filaments surrounded by thin actin filaments. A central myosin filament and surrounding actin filaments form a sarcomere unit, which has a length of 2.5 μm and a thickness of 10–20 nm. The thin and thick filaments are interdigitated, and upon muscle contraction, the thick filaments are pulled along the thin filament in a ratchet-like manner (Figure 2.36). The linear motion is effected by the myosin head, which is attached to the thick filament via a flexible hinge and binds to the actin filament (Figure 2.37). This linear protein motor again uses chemical energy released in the conversion of ATP to ADP and a phosphate ion (P_i). The hydrolysis of 1 mol of ATP releases about 10 kcal of energy (i.e., 6.96×10^{-20} J per molecule).

The maximum static muscle force generated per unit cross-sectional area (i.e., tension, stress) is about 0.350 MPa, a constant number for all vertebrate muscle fibers. In vertebrate muscle, the maximum force generated can be held only for short periods of time because of muscle fatigue. The maximum sustainable force usually is about 30% of the peak value. For this reason, the maximum static sustainable stress generated by muscle is about 0.100 MPa. The maximum power per unit mass (in W/kg) is an important figure of merit for robotic and prosthetic actuators. For human muscle, it typically measures

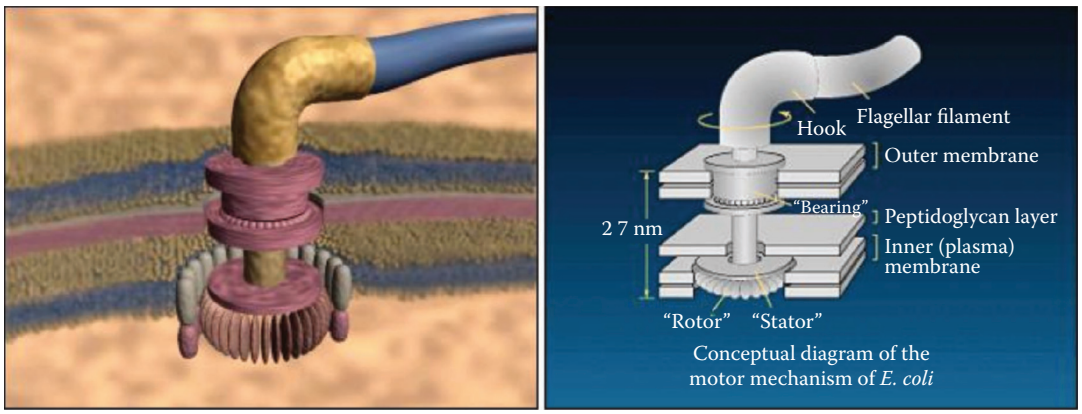

FIGURE 2.35 Bacteria swim in viscous liquid environments by rotating helical propellers called flagella.

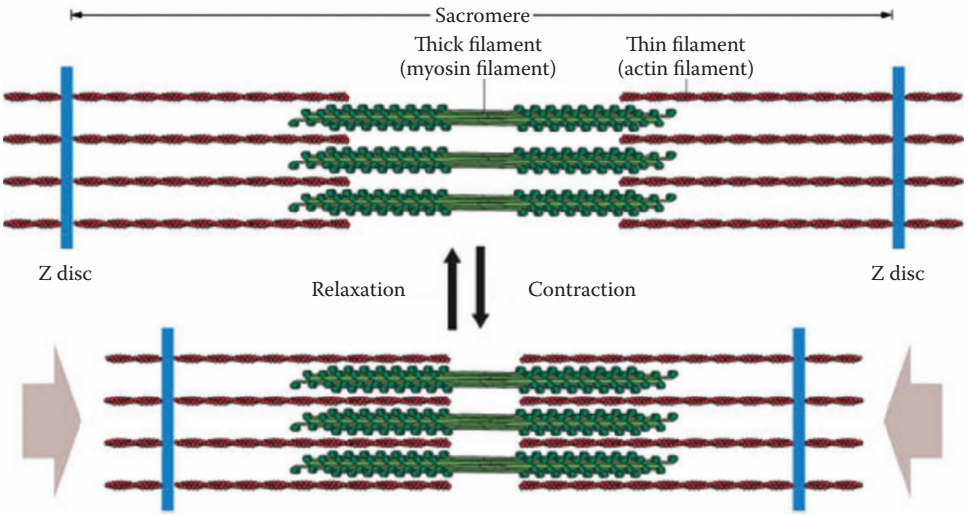

FIGURE 2.36 Muscle cells: the linear motion of muscles, which results in muscle contraction, is driven by chemical energy as ATP is hydrolyzed.

about 50 W kg^{-1} but can be as high as 200 W kg^{-1} for some muscles for a brief period of time. To illustrate the excellent cycle lifetime of a muscle, we need only look at cardiac muscle. The heart beats more than 3×10^9 times in the lifetime of an average person; an excellent lifetime compared with any artificial actuator. When trying to mimic a muscle with an artificial actuator, one of the most difficult properties to emulate is the extreme change in stiffness occurring between resting muscle and maximally activated muscle. Stiffness can increase as much as 5 times from rest to a 100% contraction.[52] On the basis of these observations, researchers preparing artificial muscles are now shifting from using stiff inorganic materials with a high Young's modulus, such as Si, to low-Young's modulus organic materials, such as hydrogels and redox polymers.

The beating motion of hair-like cilia on cells and of flagella depends on an interplay of a pair of proteins, dynein and tubulin (see Figure 2.38). Dyneins walk toward the minus ends (the microtubule part with less expand and shrink activity) of microtubules, causing sliding of microtubules, which leads to a beating motion. This protein pair is equivalent to the myosin and actin pair in muscle tissue (see Figure 2.37).

Unlike the cells of plants and fungi, animal cells do not have a rigid cell wall. This feature was lost in the distant past by the single-celled organisms that

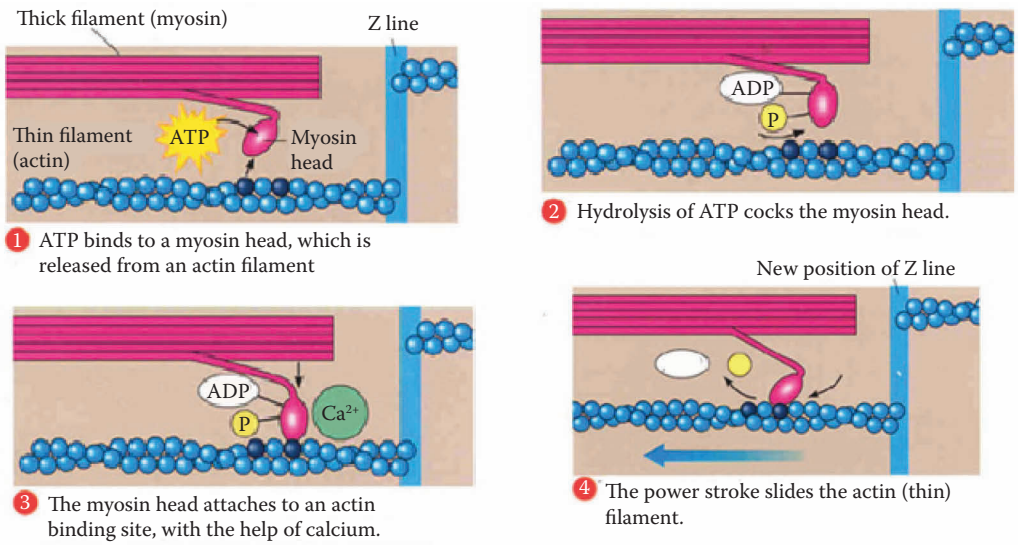

FIGURE 2.37 The linear motion is effected by the myosin head, which is attached to the thick filament via a flexible hinge, and binds to the actin filament.

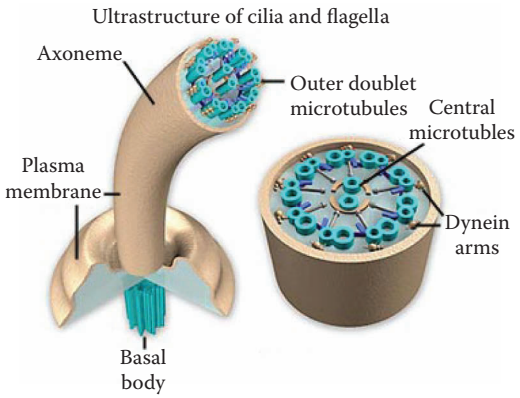

FIGURE 2.38 Dynein, found in cilia and flagella, causes a beating motion.

gave rise to the kingdom Animalia. Most eukaryotic cells, both animal and plant, range in size between 1 and 100 μm. The lack of a rigid cell wall allowed animals to develop a greater diversity of cell types, tissues, and organs. Specialized cells that formed nerves and muscles—tissues impossible for plants to evolve—gave these organisms mobility. The ability to move about by the use of specialized muscle tissues is a hallmark of the animal world, though a few animals, primarily sponges, do not possess differentiated tissues. Notably, protozoans locomote, but only via nonmuscular means, in effect, using cilia, flagella, and pseudopodia.

Different types of cells, such as neuronal cells and brain cells will be reviewed in more detail in the context of equipping micro- or nanomachines with a muscle and brains in Chapters 8 and 9, this volume, respectively.

Hydrophobic and Hydrophilic Forces Drive Self-Assembly in Nature

Introduction

Hydrophobic forces are most important with regard to self-assembly such as in protein folding, cell wall formation and formation of macromolecular assemblies (e.g., DNA hybridization). The concept of hydrophobic forces only was introduced in the 1950s and is hard to define, as the underlying physical principles are not easily understood.* Jencks's definition is one of the better ones: "hydrophobicity is an interaction between molecules that is stronger than the interaction of the separate molecules with water, and can not be accounted for by covalent, electrostatic, H-bonding or charge transfer processes."

As we saw in Volume I, Chapter 7, a hydrophobic molecule, also termed a nonpolar or lipophilic molecule, is a water-fearing or -repelling molecule. Since hydrophobic molecules are not electrically polarized, and because they are unable to form hydrogen bonds, water repels them in favor of bonding with other water molecules. Examples of hydrophobic molecules include the alkanes, oils, fats, and greasy substances in general. Hydrophilic or polar molecules is the term used for water-loving molecules. Examples include polar organic groups such as amino, carboxyl, and hydroxyl groups, such as those in amines, carboxylic acids, and alcohols. Amphiphilic or amphipathic molecules are molecules that have both a hydrophobic and a hydrophilic component, which makes them at the same time water-loving and water-repelling. They are compounds that exhibit both hydrophilic and hydrophobic properties simultaneously, for example, fatty acids and detergents. One type of an amphiphilic molecule has a water-soluble carboxylic group head and a water-insoluble hydrocarbon tail. Amphiphilic molecules of this sort are called surfactants. A surfactant is a soluble chemical amphiphilic compound that reduces the surface tension between two liquids. It is used in many detergents and soapy cleaning compounds because of its ability to surround grease particles and solubilize them. Another type of amphiphilic molecules, introduced below, is the phospholipids.

Hydrocarbon groups have greater polarizability (not to be confused with polarity) than water, so they prefer to interact with each other rather than with water. But this effect is rather small, so there must be a more dominant effect at work, especially since even if the force between nonpolar molecules is repulsive they are aggregating when put together in a polar medium. The complex that forms between nonpolar molecules has less unfavorable interaction with the solvent than the sum of the uncomplexed molecules (the lesser of two evils so to speak) (Figure 2.39). It is this latter effect that

* "The magnitude, range and origin of the hydrophobic interaction have been a mystery ever since the pioneering work by Kauzman and Tanford" (J. Israelachvili, 2005).[53]

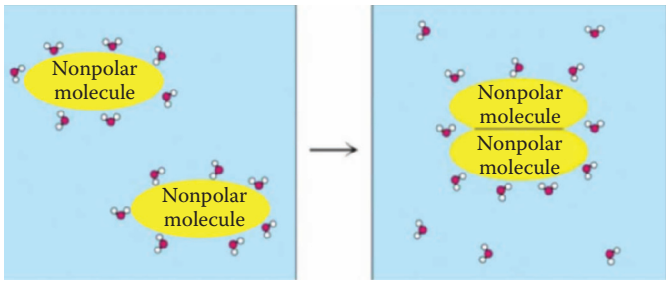

FIGURE 2.39 Aggregation reduces the hydrophobic surface area that requires ordering of water molecules for optimized solvation.

causes the hydrophobic interaction—which in itself is thus incorrectly named since the energetic driving force comes from the hydrophilic molecules.

The hydrophobic effect is illustrated in more detail in Figure 2.40 and in the sequence of events in Figure 2.41. Both figures clarify what happens when we dissolve lipid molecules in water. In Figure 2.40, we illustrate how hydrophobic compounds upset the structure of water and lead to the formation of a clathrate. A clathrate, clathrate compound, or cage compound is a chemical substance consisting of a lattice of one type of molecule trapping and containing a second type of molecule. The ordering of the shell of water molecules around the hydrocarbon solute in a clathrate compound (so as to minimize "dangling" H-bonds) causes a significant decrease in the entropy of the water ($\Delta S < 0$). Typically, the total change in entropy, ΔS, in dissolving small hydrocarbon molecules in water (at 298 K) is about –100 J K^{-1} mol^{-1}. This decrease in entropy (associated with the ordering of molecules) makes it unfavorable to mix "hydrophobic molecules" in water, or solvent entropy favors the removal of nonpolar solutes from solution. The overall enthalpy change of interaction of a nonpolar solute with water, on the other hand,

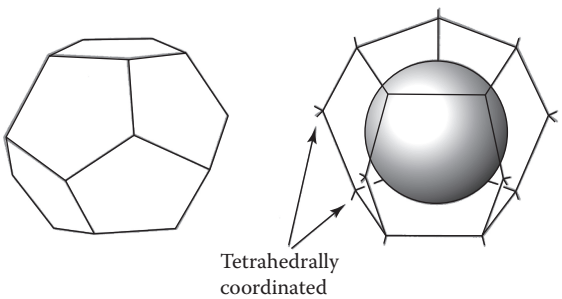

FIGURE 2.40 A water "cage" around another molecule or a clathrate.

is not particularly unfavorable ($\Delta H < 0$) because the nonpolar molecules induce cage-like ordering of the first shell of water molecules (clathrate), strengthening their H-bonding. Comparing the numbers, it is clear that the origin of the hydrophobic effect is mostly entropic.

The latter is also clear from the following example. When a hydrophobic molecule such as n-butane is added to water at 25°C, the Gibbs free energy changes as follows.

$$\Delta G = \Delta H - T\Delta S = -4.3 + 28.7 = +24.5 \text{ kJ/mol} \quad (2.7)$$

Generalizing, ΔH is related to bond formation/breaking, and ΔS is related to configurational freedom and water ordering. For a favorable reaction, we want the equilibrium constant to be $K > 1$, $\Delta G < 0$, $\Delta H < 0$, and $\Delta S > 0$, where $K = \exp(-\Delta G^{\circ}/RT)$ with $R = 8.3145$ $JK^{-1}mol^{-1}$. In the case of ΔH – negative, we have bond-making gain, and with ΔS – negative we lose entropy because of increased ordering. It is thus enthalpically favorable to place n-butane in water, but it is unfavorable from an entropic perspective (increasing order).

The sequence of events depicted in Figure 2.41 illustrates what happens when amphiphilic or amphipathic molecules are placed in water to form a micelle. A micelle is an aggregate of amphipathic molecules in water, with the nonpolar portions in the interior and the polar portions at the exterior surface, exposed to water. In Figure 2.41a, the water molecules around one amphiphilic molecule reduce the entropy of the water through ordering (forming of a clathrate). In Figure 2.41b, we show a dispersion of lipid molecules, where each molecule forces surrounding water molecules to become highly ordered. In Figure 2.41c, only lipids at the edge of the cluster force the ordering of water. Fewer water molecules are ordered, and the entropy is thus increased. Finally, in Figure 2.41d, all hydrophobic groups are sequestered from water; the ordered shell of water is minimized, the entropy is further increased, and a micelle is formed.

The two immiscible phases (hydrophilic and hydrophobic) change so that their corresponding interfacial area is minimized in the micelle construct. This effect constitutes a phase separation. Depending on their concentration and ionic strength in solution,

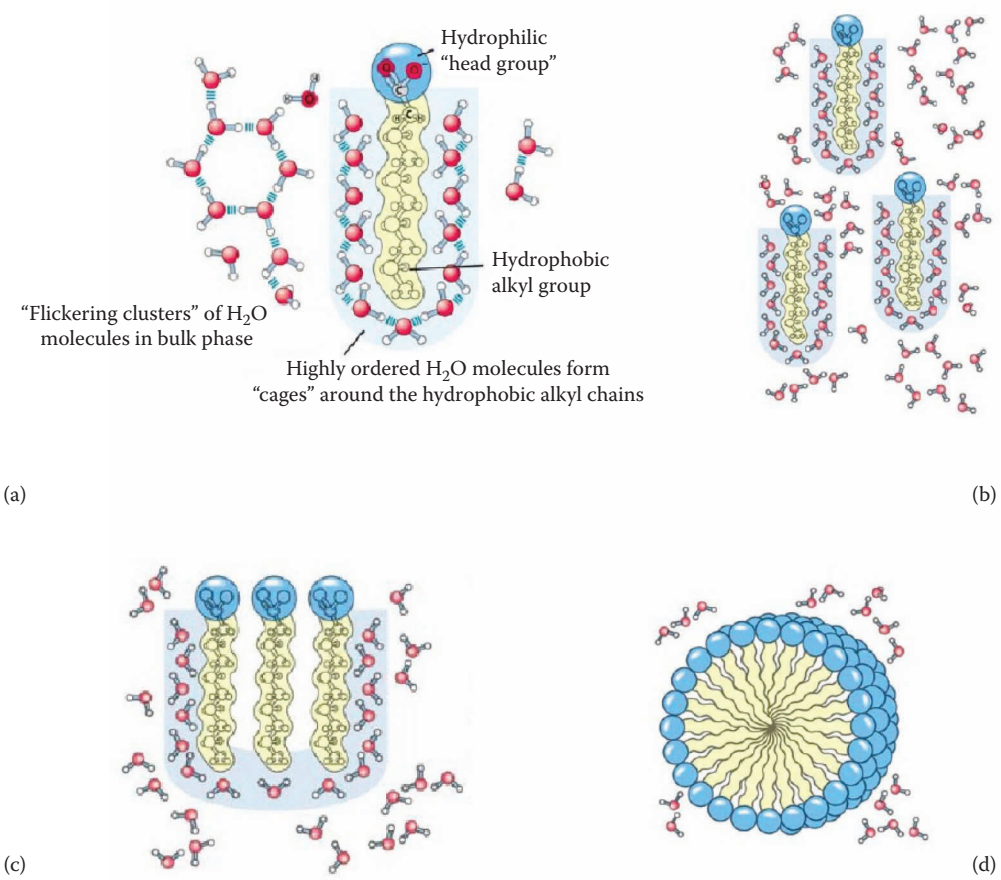

FIGURE 2.41 Steps involved in making a micelle. See text for explanation. (a) The water molecules around one amphiphilic molecule reduce the entropy of the water through ordering (forming of a clathrate). (b) Dispersion of lipid molecules, where each molecule forces surrounding water molecules to become highly ordered. (c) Only lipids at the edge of the cluster force the ordering of water. Fewer water molecules are ordered, and the entropy is thus increased. (d) All hydrophobic groups are sequestered from water; the ordered shell of water is minimized, the entropy is further increased, and a micelle is formed.

the temperature, and other factors, surfactants can assemble into spherical micelles, cylindrical micelles, or bilayers (membranes) or even saddle surfaces in bicontinuous structures (Figure 2.42). A bicontinuous surface, as shown in Figure 2.43, separates the oil phase and water phase. The oil and water are completely separated, but both are continuous across the system. Bilayer sheets are bent into "cubic phases," in which sheets are bent into a complex, ordered network of channels (see also http://www.nationalacademies.org/bpa/reports/bmm/bmm.html).

In a low-dielectric-constant solvent, micelles turn inside out, shielding their hydrophilic heads and forming a reverse micelle. Micelles form spontaneously—i.e., $\Delta G < 0$. When water is added to dried phospholipids, multilamellar vesicles (MLVs) form,

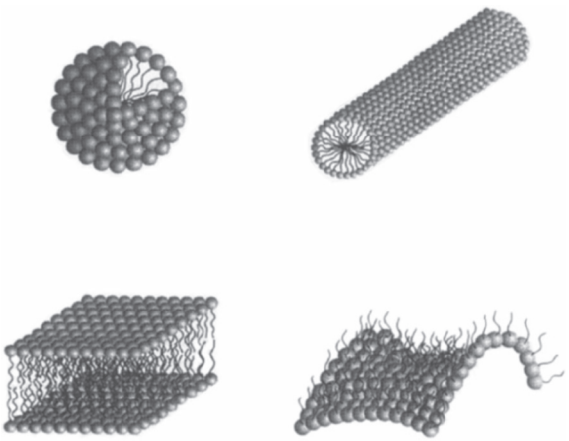

FIGURE 2.42 Surfactants can assemble into spherical micelles, cylindrical micelles, bilayers (membranes), or saddle surfaces in bicontinuous structures. (From I. W. Hamley. 2000. *Introduction to soft matter.* (2nd edition), J. Wiley, Chichester. With permission.)

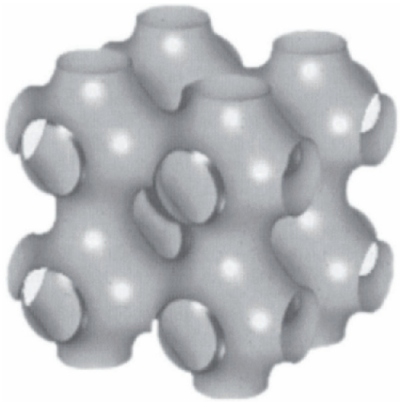

FIGURE 2.43 Surfactants can create a bicontinuous surface to separate an oil phase and a water phase. (From R. A. L. Jones. 2002. *Soft condensed matter.* Oxford University Press, Oxford. With permission.)

with water trapped between the successive polar head groups of the multiple bilayers. Sonicating these produces small unilamellar vesicles (SUVs).

From Micelles to Liposomes and Biological Cells

Introduction

It appears that the chemistry of life cannot take place in anything much simpler than a cell. A virus, a prototype life form, needs to invade a cell and assume control of the cell's chemical machinery by reprogramming it to produce more viruses. For life to have started, it seems essential that the important chemicals were somehow concentrated in order to increase their chance of meeting and reacting. This could have occurred when water evaporated in a small pond, or it could have involved reactions on a clay surface (meeting on a two-dimensional plane is more probable than meeting in three-dimensional space). Another possibility is that the chemicals became grouped in some kind of a vesicle. Thus, they could not diffuse away into the primordial broth. One of the many unanswered questions is, when did this cell-wall precursor take hold, before, during, or after the prebiotic chemical steps?

Micelles, Liposomes, and Biological Cells

Another type of an amphiphilic molecule (besides the detergents encountered above) consists of a phospholipid with an ionic phosphate head group and two hydrocarbon chains attached to it. A glycerol molecule links the two hydrocarbon chains together, and the phosphate group often has other hydrophilic molecules, such as choline and serine, attached to it. When a choline attaches, the molecule is called *phosphatidylcholine,* one of the most abundant phospholipids in all the cell membranes (Figure 2.44A). To form a micelle, water-soluble heads of amphiphilic molecules maintain contact with water, while the water insoluble ends are tucked inside.

A spherical micelle is the most stable configuration of amphipathic lipids that have a conical shape, such as fatty acids (Figure 2.44Ba). A bilayer is the most stable configuration of amphipathic lipids with a cylindrical shape, such as phospholipids (Figure 2.44Bb). Lipid bilayers are back-to-back arrangements of monolayers, and they typically form when there is more than one fatty acid chain connected to the polar head group. Double-chain fatty acids do not pack as well as single-chain fatty acids in a micelle configuration. Unilamellar vesicles, as shown in Figure 2.44Bc, are known as liposomes; multilamellar vesicles containing one or more bilayers arranged around the initial unilamellar vesicle. These types of vesicles are currently used as vehicles to deliver drugs in treatment of various diseases. For example, technologies have been developed to enclose chemotherapy and other drugs in unilamellar liposome bubbles.

The hydrophobic effect is essential for life. It forces the spontaneous clustering of lipids, forming biological membranes. Early in the development of life on Earth, chemicals organized themselves into cells, just like micelles. In humans, they are principally composed of phospholipids, formed from fatty acids, with some specialized proteins embedded in them, as shown in Figure 2.45. A wide variety of amphiphilic molecules can be accepted into a cell membrane. About half of a membrane surface is covered with proteins and sugars performing a wide variety of roles.

The bilayer that constitutes the cell surface—the plasma membrane—is permeable to some molecules, either passive or mediated by transmembrane proteins (pumps), impermeable to others (most water soluble molecules), and very flexible; call it a

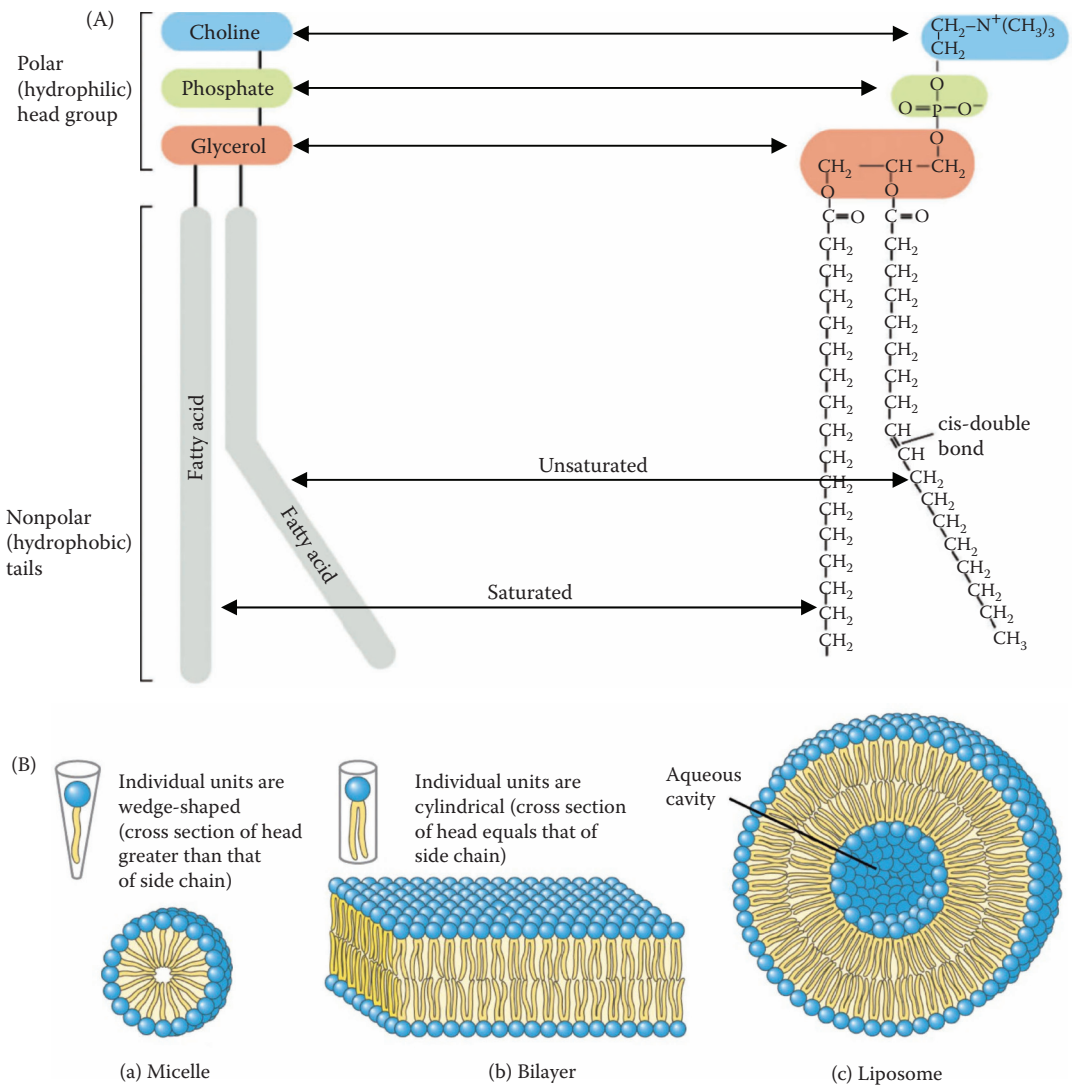

FIGURE 2.44 (A) Example of an amphiphilic molecule (phosphatidylcholine). (B) Amphiphilic molecules forming micelle (a), lipid membranes (b), and unilamellar liposome (c).

dynamic two-dimensional fluid in which lipids and proteins can move laterally. The membrane is also a very good electrical insulator, typically holding 70 mV over 45 Å (i.e., a field strength of 1.6 10^7 V/m), has no corners, and self-assembles.

As widely accepted as the idea of a plasma membrane with embedded proteins as ion channels and ion pumps has become, there are still valid objections to this model, as Gerald Pollack lucidly explains in *Cells, Gels and the Engines of Life.*[54] Pollack presents plenty of evidence that a cell is not enveloped by an ion-impermeant barrier. In this elegantly written book, he explains most cell functions by invoking the gel nature of the cytoplasm.

Natural Biopolymers

Even the most complex self-assembled structures of natural biopolymers, such as nucleic acids and proteins, are all driven by very simple balances of coil entropy and bond enthalpy; the coil entropy wants to expand, but the folded structure is held in place by enthalpic bonds such as hydrogen bonds, ionic bonds, and hydrophobic bonds. Being individually weak, these noncovalent interactions nevertheless can sum to an impressive total, often several hundreds of kilojoules, when many are present within a given macromolecule or between macromolecules. This explains the stability of the macromolecular structures. But being individually

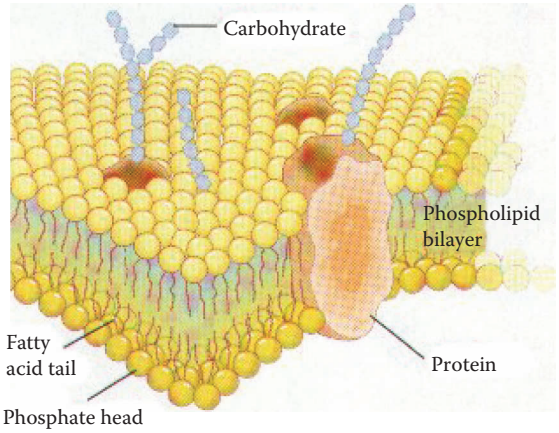

FIGURE 2.45 The cell wall of an animal cell is a phospholipid bilayer with embedded proteins regulating a series of functions, e.g., transport, recognition.

weak, individual noncovalent bonds in macromolecular structures can be broken and reformed rather easily. The latter in turn explains the flexibility in macromolecular structures. All biochemical processes have thus enthalpic and entropic contributions that combine to dictate spontaneity. DNA is a straightforward example of this, with a balance of mostly H-bonds and coil entropy (Figure 2.46). DNA structure arises from a favorable enthalpic term (enthalpy-dominated state) compensating for an unfavorable entropic term ($\Delta H < 0$ and $\Delta S < 0$). At a critical temperature $T_{critical}$, this reverses and entropy wins out. This *melting temperature* can be derived by solving $\Delta G = \Delta H - T\Delta S$, with ΔH from H-bonds balanced by ΔS from the amount of disorder, as follows.

$$T_{critical} = \frac{\Delta H}{\Delta S} \tag{2.8}$$

Because there are three hydrogen bonds between cytosine and guanine and only two between adenine and thymine, a higher C, G content makes for a higher melting temperature. The latter is illustrated in Figure 2.47.

In the 1980s, Nadrian Seeman (http://seemanlab4.chem.nyu.edu) from New York University took advantage of the intrinsic self-assembling properties of DNA molecules, as described here, to construct DNA molecular complexes. By synthesizing branched DNA and exploiting this behavior, Seeman and coworkers managed to assemble increasingly complex structures that do not occur in the natural environment (DNA-mediated assembly is described in Chapter 4, Figure 4.49). The use of stable branched DNA molecules permits one to make stick figures as depicted in Figure 4.49a, where we show a stable branched DNA molecule, and in Figure 4.49b, where we show such a molecule with sticky ends; four of these sticky-ended molecules are shown assembled into a quadrilateral. More exploits from the world of DNA nanotechnology, such as DNA origami, can be found in Chapter 3, this volume, on bottom-up manufacturing.

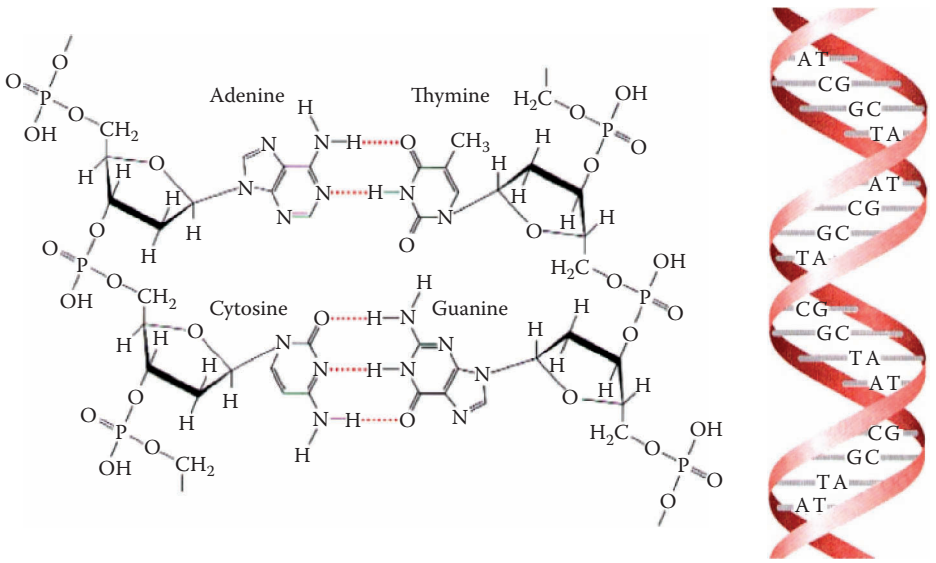

FIGURE 2.46 DNA: a question of entropy of coiling versus enthalpy of the hydrogen bonds (two between adenine and thymine and three between cytosine and guanine).

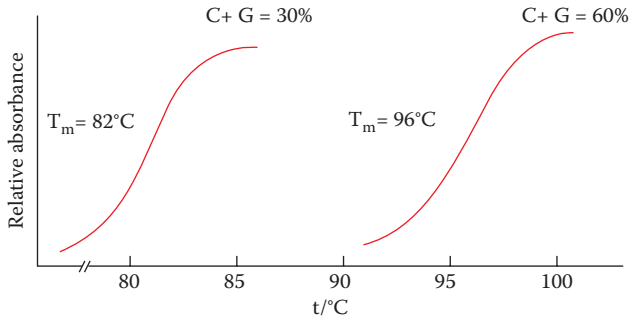

FIGURE 2.47 Melting temperature or critical temperature of DNA is reached at the moment that the entropy wins out. The higher the CG content, the higher the melting temperature.

Proteins are polypeptides prepared from 20 different amino acids, with a few different $\Delta H < 0$ bonds holding them together, to form a vast number of folded structures that govern biological function and biomaterials. As in micelle and DNA assembly, entropy and enthalpy balances are the basis of protein self-assembling behavior, such as the formation of a β-sheet, illustrated in the beautifully intricate "β-barrel" structure in green fluorescent protein (GFP) (see Volume I, Figure 7.108). In self-assembled, native proteins, the enthalpy wins over entropy (*H* dominated) and an increase in the temperature helps the entropy term till we observe denaturing or unfolding, as illustrated in Figure 2.48. Denaturing of a protein is the conversion of a biologically functional molecule into a nonfunctional form. There are many denatured states but only one native state, so entropically, the denatured protein state is by far the most favored condition for the protein to be in. Proteins can regenerate to their native state but only slowly. Denatured proteins have a greater tendency to aggregate. The transition from native to denatured happens at a critical temperature given by Equation 2.8. A typical coiling/ordering ΔS

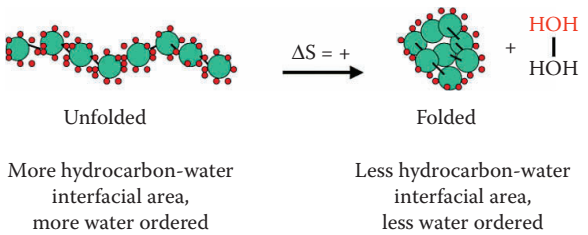

FIGURE 2.48 Protein folding and unfolding (denaturing).

penalty for a complex protein such as GFP may be of the order of 40,000 kJ, the number of H-bonds needed to balance this, at ~50 kJ each, is about 800 (ignoring any hydrophobic bond help). Most of the associative effects are enthalpic in origin, except for the hydrophobic effect, which is essentially entropic in origin.

In the exceptional case of a protein with an entropy dominated balance, such as with pyruvate carboxylase, a decrease in the temperature lowers the entropy term, and we observe denaturation at lower temperatures.

Biotechnology and Biomimetics

Introduction

Today, biotechnology is a major application target for miniaturization science, as engineered structures and nature's building tools have become similar in size, and financial rewards promise to be much larger for these life science ventures than they ever were for mechanical MEMS applications (see Chapter 10). After putting forward a definition for biotechnology and presenting examples of the use of miniaturization science in biotechnology, i.e., bio-MEMS, we make some concluding remarks on biomimetic approaches and finish this chapter by comparing some human and natural engineered structures. As examples of micromachining and nanomachining in biotechnology (bio-MEMS) we survey three examples here: genetically engineered proteins, miniaturized PCR and DNA chips. Other bio-MEMS and bio-NEMS examples, including electrochemical and optical immunosensors, microphysiometers, responsive drug delivery pills, glucose sensors, blood gas and blood electrolyte sensors, lab on a chips (LOCs), etc., can be found throughout the book. This section constitutes an attempt at sketching possible avenues for merging of biotechnology with nanochemistry and nanofabrication.

Biotechnology: Definition

Fermentation processes known from ancient times (the oldest known written recipe for beer brewing is written on a clay cuneiform tablet, part of an epic poem devoted to Ninkasi, the Sumerian goddess

of beer) evolved eventually into a larger endeavor called biotechnology, employing either cells or cell extracts (e.g., enzymes) to produce foods, drugs, insecticides, etc. Generally, modern biotechnology is an umbrella term that covers various techniques, applied mainly to cells or molecules, which take advantage of biological processes in very precise ways. The discoveries of three different enzymes in the late 1960s, especially, heralded its advent. The first of these discoveries was reverse transcriptase enzyme, which converts RNA into the corresponding DNA; the second, an enzyme that cuts DNA at predefined places; and the third, an enzyme that joins separate pieces of DNA. Using these gene technology tools, the pooled content of a cell can thus be used to manufacture proteins that can be used for human consumption (e.g., as medicine). Because the genetic code is universal, almost any cell in any organism can "read" a gene and translate it into a desired protein. Bacteria that have been genetically engineered to carry the human insulin gene, for example, can produce human insulin. Cells might also be reengineered and substituted in living things to correct for inherited deficiency or performance. "Gene therapy" has made great progress, especially in plant engineering.

Genetically Engineered Proteins

Binding chemistry of a target to a specific protein at the nanoscale translates into a mechanical movement/motion of the protein, known as a change in conformation. This conformational change of proteins upon binding with a target molecule has been exploited in the design of very selective and sensitive biosensors. This is accomplished by labeling the protein, say with a fluorescent probe, in such a way that the probe does not hinder the binding of the protein with its target, while the change in signal reported by the probe upon binding is maximized.

Two important examples of genetically engineered proteins: green fluorescent protein (GFP) and calmodulin. GFP, from the molecular system of the bioluminescent jellyfish *Aequorea victoria*, we saw in Volume I, Chapter 7, are making quite an impact on biotechnology today as fluorescent markers. Here we will explore genetic manipulation of the calmodulin protein and its uses.

Through judicious genetic manipulation of a protein such as calmodulin [a 148-amino acid (17-kD) molecule, shown in Figure 2.49], a rationally designed molecular biosensor can thus be developed. The key is to always select the right location for attachment of the probe in the protein structure. Calmodulin is a "regulatory" protein, involved in protein-protein interactions and in signaling pathways that involve stimulating or inhibiting the activities of many enzymes and proteins. Calmodulin is a notably tough molecule: it withstands a very low pHs and even survives boiling water. One of its binding partners is Ca^{2+} ion, which matches the versatility of the protein. Calcium ions are abundant in all biological systems, and its importance derives from its role as a universal messenger ion. The ion conveys signals received at the cell surface to the inside of the cell (the concentration of calcium inside the cell is 1,000- to 10,000-fold less than in the extracellular fluid). Calcium ions are involved in such processes as the regulation of muscle contraction; the secretion of hormones, digestive enzymes, and neurotransmitters; the transport of salt and water across the intestinal lining; and the control of glycogen metabolism in the liver. The binding of Ca^{2+} to multiple sites of a calmodulin molecule induces a major conformational change—a hinge-type motion—that converts it from an inactive to an active form, allowing for interactions with other proteins and peptides and thus regulating the function of

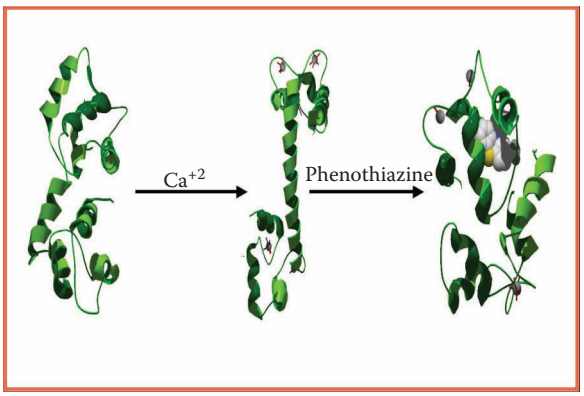

FIGURE 2.49 Model showing the exposure of drug binding site in calmodulin following binding of Ca^{2+}. Upon binding to calcium, calmodulin undergoes a change in conformation, which exposes two hydrophobic pockets located in the N- and C-domains. Certain hydrophobic peptides and the antipsychotic phenothiazine class of drugs interact with these exposed hydrophobic pockets.

the various enzymes and proteins. The calmodulin crystal structure has been well studied using x-ray crystallography and nuclear magnetic resonance (NMR) techniques, and it has been found to consist of two domains, the N- and C-domains.* Two high-affinity calcium-binding sites are located in the C-domain, and the other two calcium-binding sites (the low-affinity sites) are located in the N domain. Upon binding to calcium, calmodulin undergoes a change in conformation to an active form, which exposes two hydrophobic pockets located in the N- and C-domains. Certain hydrophobic peptides and the antipsychotic phenothiazine class of drugs interact with these exposed hydrophobic pockets, and in the presence of calcium ions, calmodulin also becomes a sensor for those peptides and drugs (Figure 2.49). Schauer-Vukasinovic et al.,[55] through site-directed mutagenesis of calmodulin, produced several mutants that varied from one another by a single cysteine residue at various positions in the protein skeleton. N-[2-(1-maleimidyl) ethyl]- 7-(diethylamino)coumarin-3-carboxamide (MDCC) (Invitrogen, CA, USA-prod #D-10253), a commercially available, environmentally sensitive, thiol-reactive fluorophore label was attached to the cysteine residue in each of the mutants, and the change in fluorescence signal upon binding the calcium ions was measured. Mutation sites were chosen on the basis of both the crystal and NMR structures of free calmodulin and calmodulin complexed with calcium. The MDCC-labeled calmodulin mutant showed a change in the fluorescence signal in the presence of calcium ions, the magnitude of which was dependent on the concentration of calcium.[55] By comparing the enhancement of the fluorescent response of the different mutants, a Ca^{2+} sensor with a detection limit as low as 2×10^{-9} M was built. The biggest change was noted for the mutant with a single cysteine at amino acid residue 109.[55] This sensing system is highly selective over other metals, including magnesium, europium, and barium. A calibration plot for calcium obtained with the MDCC-labeled calmodulin (CaM) mutant is shown in Figure 2.50.

* The N terminus of the protein denotes the first amino acid of its sequence, while the C terminus corresponds to the last one.

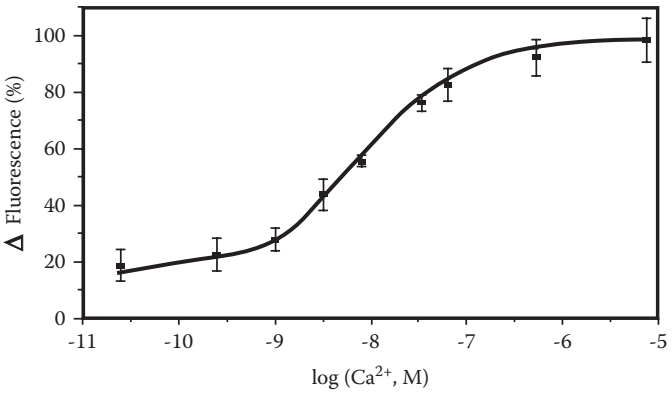

FIGURE 2.50 Calibration plot for calcium obtained with the MDCC [N-[2-(1-maleimidyl)ethyl]- 7-(diethylamino)coumarin-3-carboxamide]-labeled calmodulin (CaM) mutant. The *x*-axis denotes the concentrations of free calcium.[56]

In another study by the same team, when phenothiazine was added to calcium-bound fluorophore-labeled CaM109, a maximum of 100% quenching in the fluorescence was observed. This team then developed an compact disc based fluidic platform (see also Volume I, Chapter 6 on CD fluidics) for the sensing of phenothiazine-class of drugs based on this drug-dependent change in fluorescence signal.[56] This biosensing system also has been proposed as a model for the high-throughput screening of drugs that selectively interact with binding proteins.[57]

Polymerase Chain Reaction

The polymerase chain reaction (PCR) is to genes what Gutenberg's printing press was to the written word, but it took the 1995 O. J. Simpson trial to make PCR a household word. PCR perhaps is the most important tool of biotechnology today; it was conceived by Kary Mullis in 1983 (Figure 2.51). Mullis was granted a patent in 1989, and he received the 1993 Nobel Prize in Chemistry for his invention.[58] The invention of PCR, amplifying the amount of DNA in a sample, is as important for the biotechnology field as the transistor, amplifying electrons, is for electronics.

Mullis, a maverick, unbending to authority, never got the financial rewards or academic credit for his invention, a victim, to some degree, of commercial greed and academic jealousy. Mullis' technique enables the replication of any stretch of DNA as long as the arrangement of nucleotides at the two ends is known. Through PCR, a desired DNA sequence

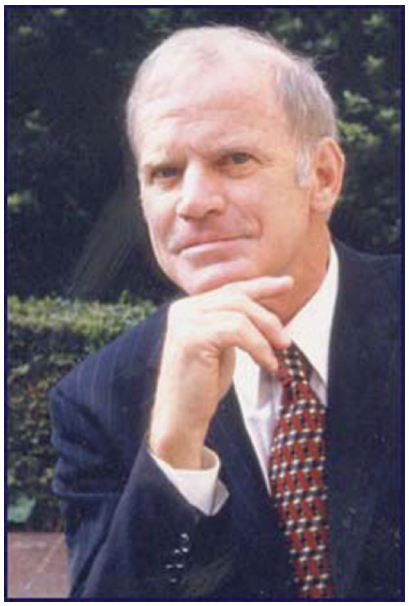

FIGURE 2.51 Kary Mullis, inventor of polymerase chain reaction.

of viral, bacterial, plant, or human origin can be amplified hundreds of millions of times in a matter of hours. By amplifying minute amounts of DNA to analyzable quantities and thus circumventing the need for lengthy cell-culture methods, the technique has had major impact on clinical medicine, genetic disease diagnostics, forensic science, and evolutionary biology. In addition, the ability to isolate genes from organisms by essentially copying them directly from their genome has allowed for the rapid cloning of a myriad of genes whose function was unknown. This has also benefited the fields of genomics and proteomics and thus had an impact on not only science but medicine and biotechnology as well.

Through miniaturization, PCR is becoming faster and applicable to ever smaller samples. The original PCR process is based on the heat-stable DNA polymerase enzyme from *Thermus aquaticus* (*Taq*) (see Figure 2.52), a thermophilic bacterium that can withstand high temperatures and that can synthesize a complementary strand to a given DNA strand in a mixture containing the four DNA bases and two primer DNA fragments (each about 20 bases long) flanking the target sequence.

The mixture is heated to separate (denature or melt) strands of double-helix DNA containing the target sequence and then cooled to allow 1) the primers to find and bind (anneal) to their complementary sequences on the separate strands, and 2) the *Taq* polymerase to extend the primers into new complementary strands. The *Taq* polymerase needs about 1 min to synthesize 1 kb pair, so the synthesis time depends on the length of the product. Repeated heating and cooling cycles multiply the target DNA exponentially, since each new double strand separates to become two templates for further synthesis. In Figure 2.53a, we illustrate how each PCR cycle doubles the amount of DNA.

A typical temperature profile (Figure 2.53b) for PCR is as follows:

1. Denature at 93°C for 15–30 s
2. Anneal primer at 55°C for 15–30 s
3. Extend primers at 72°C for 30–60 s

The primer extension step has to be increased by roughly 60 s/kb to generate products longer than a few hundred bases. The above are typical instrument times; in fact, the denaturing and annealing steps occur almost instantly, but temperature rates in commercial instruments (Figure 2.53c) usually are less than 1°C/s when metal blocks or water are used for thermal equilibration and samples are contained in plastic microcentrifuge tubes. Instantaneous temperature changes are not possible because of sample,

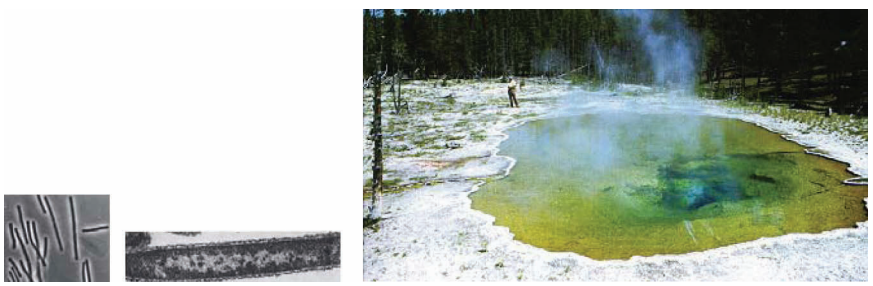

FIGURE 2.52 The bacterium *Thermus aquaticus* was first discovered in several springs in the Great Fountain area of the Lower Geyser Basin at Yellowstone National Park.

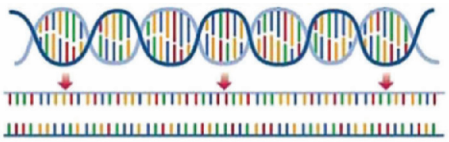
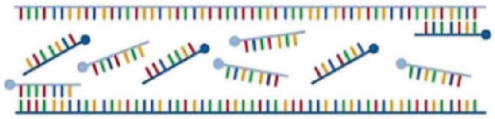
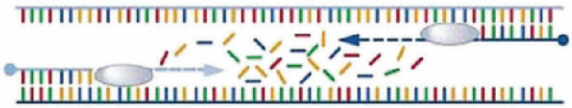
(a)



Step 1 – Denaturation (optimal temperature is 94°C). By heating the DNA, the double strand melts and opens to single-stranded DNA.

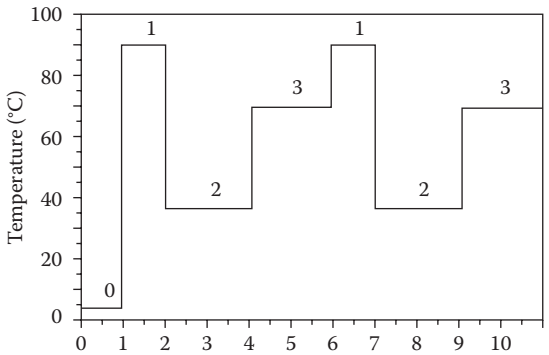


Step 2 – Annealing (optimal temperature is 60°C). The single-stranded primers bind to their complementary single-stranded bases on the denaturated DNA.



Step 3 – Extension: 72°C is the ideal temperature for the *Taq* polymerase to attach and start copying the template. The result is two new helixes in place of the first.

Step 4 – By applying this cycle several times, the quantity of DNA obtained is quickly enough to perform any analysis. Starting with one DNA molecule, after just 20 cycles there will be a million copies, and after 30 cycles there will be a billion copies.



(b)

(c)

FIGURE 2.53 Polymerase chain reaction (PCR). (a) How PCR cycle doubles DNA. (b) A typical PCR temperature profile (1, denature; 2, anneal primers; 3, extend primers; see text). (c) Commercial PCR instrument from Cepheid: the SmartCycler II System.

container, and cycler heat capacities, and extended amplification times of 2–6 h result. During the periods where sample temperature is making a transition from one temperature to another, extraneous, undesirable reactions occur that consume important reagents and create unwanted and interfering compounds.[59] Micromachining has improved PCR in several respects.

By micromachining thermally isolated, low-thermal-mass PCR chambers, one is able to mass-produce a faster, less expensive, more energy efficient, and more specific PCR instrument. To appreciate better the fast thermal cycling of a smaller heater, see Chapter 8 on miniaturization of thermal elements. Given the PCR chambers' small size, smaller amounts of sample and expensive reagents are required. Moreover, rapid transitions from one temperature to another ensure that the sample spends a minimum of time at undesirable intermediate temperatures, so that the amplified DNA has optimum fidelity and purity.[59] Northrup et al.[60] fashioned Si microchambers with integrated

thermally isolated heater elements and found that thermal cycling resulted in amplification without the need for active cooling. This is a direct result of the more effective cooling of these miniaturized Si structures (see Chapter 8). Northrup et al.[60] found that they could heat the PCR reactants as quickly as 35°C/s. Further work showed that integrated heaters on both sides of the reactant volume are required for optimal temperature uniformity. Later, it became evident that to make an economic miniaturized PCR instrument for diagnostic applications, the heater/cooler should be made part of a fixed reader instrument to enable a less expensive disposable unit. Along this line, Wilding et al.[61] performed a less integrated experiment with Si/glass microchambers of 4.4 to 8.9 μL inserted in a commercially available heater/cooler structure. The PCR total cycling time was reduced, but specificity was found to be inferior to that of commercial cyclers. This inferior performance may be linked to the fact that Si is poisonous to the *Taq* polymerase enzyme. The specificity problem can be avoided by derivatizing the Si surface or by machining PCR chambers from a more enzyme-compatible material. Another glaring problem with the two described Si-micromachined PCR approaches is that they do not provide an easy way to apply and remove the DNA sample. This is a major problem with miniaturized PCR and fluidic microsystems in general: the fabrication of connectors, receptacles, and packages that link the microstructure to the macroworld is still in its infancy (see Chapter 4). In principle, to avoid a hybrid connecting/packaging approach, this requires a manufacturing method with a very wide dynamic range, i.e., from microns to several millimeters or even centimeters. Also, for this reason using Si is not necessarily the best approach. The next three PCR examples illustrate nonsilicon alternatives.

Wittwer and Garling[62] and Wittwer et al.[63] optimized PCR temperature and cycle times, using a thermal cycler based on recirculating hot air and 10-μL samples in thin glass capillary tubes, with the sample temperature monitored by a miniature thermocouple. They found that product specificity could be improved significantly while decreasing the required amplification time by an order of magnitude. For a 536-base pair β-globin fragment from human DNA, optimal denaturation at 92–94°C took place in less than 1 s. Annealing for 1 s or less at 54–56°C gave the best product specificity and yield. Only elongation, at 75–79°C, required longer times. Denaturation yield actually decreased with times greater than 30 s, and nonspecific amplification was minimized with a rapid denaturation to annealing temperature transition. Wittwer's device has been commercialized by Idaho Technology; the RapidCycler from this company can perform 30 PCR cycles in less than 10 min.

The Si PCR work of Northrup et al.[60] eventually led to a commercial portable PCR instrument, i.e., the SmartCycler system (http://www.smartcycler.com) from Cepheid (see Figure 2.53c). This instrument incorporates a nonsilicon, rather large but thin PCR chamber with high thermal conductivity ceramic heater plates and integrated temperature sensors. At Cepheid it was understood early on that a major negative consequence of miniaturizing analysis equipment, in extremely small sample sizes, presents numerous chemicals and organisms that are present at levels below the typical detection limits. The topic of scaling of sample size was reviewed in Volume I, Chapter 6, on fluidics. There we saw that biological chemicals associated with clinical chemistry assays (between 10^{14} and 10^{20} copies/mL) and immunoassays (between 10^{7} and 10^{18} copies/mL) are readily assayed with very small sample volumes, in the range of picoliters and nanoliters. However, as evident from Figure 10.49, the minimum sample volume required for accurate DNA assays (from 10^{7} copies/mL to fewer than 100 copies/mL) is 100 μL, but a volume several milliliters of sample is more typical. As a consequence, an important Cepheid focus is the design of microfluidic diagnostic systems with sample preparation of larger input volumes. Along this line, the company fabricated a DNA capture device in which a continuous flow of biological sample results in a gradual accumulation of nucleic acid on the large silicon dioxide surface area of the chip.[59] It is not clear to this author why the latter device should be in Si, as there are many very large surface, porous materials available that are much less expensive.

DNA Chips

Introduction

With the rough draft of the Human Genome Project completed, the next most important question to solve is how genes relate to human health. Why do some people get certain diseases while others remain disease-free? A vast amount of expanding data supports the fact that it is rare for a single defect in one location on one gene to be responsible for a specific disease. The trend is toward the study of the biochemical and molecular functioning of a set of genes and how this complicated interaction leads to a diseased state. One way to tackle this study, we saw in Volume II, Chapter 8, is by using DNA microarrays. A DNA microarray, or DNA chip, consists of DNA molecules ranging from 20 to 1000 or more base pairs concentrated into specific areas on a solid support such as a glass chip.[64] The arrays are used as a capturing device of specific complementary gene products. Thousands of the same oligonucleotides can be attached in a specific location so that gene expression may be observed by counting the amount of oligos that bind. In this way, specific gene expression can be observed in particular cells, during specific stages of development, in diseased versus normal individuals, after administration of a drug, or in malignant cells, for example (see Volume II, Figure 8.23). Alternatively, one can incorporate many different oligonucleotides representing different genes on the same chip so that screening for the expression of many genes simultaneously is possible. The uses of this technology are broad and include disease diagnosis, individual response to drug therapy, and understanding the difference of gene expression between healthy and normal individuals.

Almost all current genetic testing either uses sequencing or hybridization. Sequencing involves hydrolyzing (digesting) a piece of DNA under controlled conditions, derivatizing the pieces as they come off the DNA strands, and analyzing them by chromatography or electrophoresis. In hybridization, pieces of genes bind to other pieces containing complementary sequences. Of the two techniques, sequencing is the more comprehensive and versatile, but hybridization is faster and, for small pieces of genes, more efficient. Rapid identification of genes or gene sequencing has become one of the main aims of medical diagnostics.

The field of DNA arrays involves microfluidics, MEMS machining, and self-assembly of DNA probes, which puts it at the forefront of mixing top-down and bottom-up manufacturing techniques. For the various microfabrication methodologies of DNA chips see Volume II, Chapter 8. In what follows we briefly review the major applications of microfabricated DNA chips.

Applications of DNA Arrays

In a typical cDNA array experiment, the genes of interest are first amplified using PCR (see above). After purification, the PCR products are printed on microscope glass slides by using a robot (see Volume II, Figure 8.22). For example, a DNA microarray, containing all of the genes in yeast (6400 of them) can be used to look at specific changes of gene expression in metabolism. Using in vitro reverse transcription, both the test and reference total RNA are labeled using two different fluorescent dyes. Laser excitation causes a specific emission that generates fingerprint-like spectra, which are measured using a scanning confocal laser microscope. The data are basically viewed as a change in the color of the two fluorescent readings at a specific point on the slide (a gene) when compared with a reference sample.

In an alternative DNA array approach, Fodor et al.[65] at Affymax (http://www.affymax.com) developed an elegant method combining on-chip combinatorial chemistry with established hybridization techniques and advanced fluorescence detection to make arrays of oligonucleotides (see Volume II, Figure 8.16). After synthesizing oligonucleotide arrays onto a glass slide, the glass slide is incubated with fluorescent-labeled DNA probes. After the DNA probes are hybridized to the oligonucleotide array, the complementary sequences are determined by fluorescent scanning. The oligonucleotide array format is used to detect mutations, locate target regions within genes, investigate gene expression, and identify gene function.[65] In this approach, the chemical synthesis and analysis of large numbers

of potentially useful compounds can be carried out on a single small chip (say, a centimeter square); therefore, it becomes orders of magnitude quicker and cheaper to identify potential ligands to build new drugs or analyze DNA sequences.[66] A key advantage of this approach is that it enables chips to be manufactured directly from sequence databases, thereby removing the uncertain and burdensome aspects of sample handling and tracking. Another advantage of this technology is that the use of synthetic reagents minimizes chip to chip variation by ensuring a high degree of precision in each coupling cycle. One disadvantage of this approach, however, is the need for photomasks, which are expensive and time-consuming to design and build. In Volume II, Chapter 8, we described how the more recent maskless array synthesizer might get around the latter obstacle (Figure 8.19). Also, the hybridization can occur only through DNA fragments finding each other through diffusion, which is slow.[67] The Nanogen DNA chip described in Example 8.2 (Volume II, Chapter 8) is much faster, as DNA fragments reach the chip hybridization sites through electrophoresis (Nanogen, a San Diego–based company, went out of business in early 2010). A more detailed list of pros and cons of the various DNA array approaches is presented in Volume II, Chapter 8. The integration of DNA arrays within a sample preparation platform (e.g., a microfluidic CD) was discussed in Volume I, Chapter 6, on fluidics.

Biomimetics: Some Concluding Remarks

Early examples of successful biomimetics include artificial materials for implants, tissue engineering, an artificial retina based on the architecture of the human eye, and neural network software based on the human brain. The devices mentioned are relatively large, however, and are fabricated using top-down methodologies. The neural network software example is only a very crude approximation of a human brain. Human-made devices crafted with bottom-up methods will open up a much more rewarding paradigm in human manufacturing; nanochemistry holds the promise of the versatility of design offered by nature itself, and molecular self-assembly and replication add to the tremendous appeal of this type of nanotechnology. Obviously, there is something very attractive about the small size of nature's preferred building blocks such as proteins. In biological systems, the energy efficiency is approximately proportional to the 2/3 power of the linear dimension. This is because metabolism is proportional to the second power of the linear dimension (surface of the organism, 1^2), and energy uptake (feeding) is proportional to the body volume (1^3), so the smaller organism is, the higher its efficiency (see the discussions of *scaling laws* in Chapter 7). Nature provides excellent examples in the design of efficient micro- and nanosystems as it optimizes scaling laws in the microdomain and even exploits the quantum-size effects of its components. These biosystems have been tested and selected by eons of evolution, and at a time when we find that micromachining tools are limiting the fabrication of ever smaller devices, exploration of some of nature's tools and building blocks promises to be very rewarding. As one of the many motivating examples of the promise of biomimetics, consider enzymes. There is a plethora of enzymes that outperform synthetic catalysts by several orders of magnitude. For instance, there is no artificial catalyst for producing ammonia from its elements at ambient temperature and pressure, as the nitrogenase of nodule-forming bacteria does (the industrial Haber-Bosch synthesis of ammonia from nitrogen and hydrogen at high temperatures and pressures pales in comparison).

Most miniaturization, especially in integrated circuits (ICs), over the next ten years will be based on top-down nanofabrication, and Moore's law will continue to run its course. In parallel, we will continue to adapt bottom-up nanochemistry principles and combine them with nanofabrication. There is a significant gap between the scale of individual molecular structures of nanochemistry and the sub-micrometer structures of nanofabrication. It is exactly in that gap, from about one nanometer to several hundred nanometers, where fundamental materials properties are defined. It is also on the nanometer scale that quantum effects become significant.

There is little doubt that biotechnology analysis tools will keep on improving at an increasingly

faster rate. Desktop DNA sequencers and 3D protein readers will be a reality in the not-so-distant future. Genetic engineering will have the most profound impact, though, on how humankind looks at manufacturing. Since it is already possible to synthesize a virus bottom-up, given the sequence of the bases in its genes, it seems quite likely that we will be able to manufacture synthetic viruses designed to enter a cell and carry out diagnostic and therapeutic tasks. Venter, we saw earlier, is using bottom-up synthesis methods to create a minimal gene setup required to sustain life in a test tube. Photovoltaic solar cells today have a high conversion efficiency of about 10–15% but are expensive to deploy and maintain. Crops grown for energy are also expensive, involve harvesting, and are only 1% efficient. It is conceivable that genetic engineering will enable the production of energy crops that convert sunlight into fuel at a 10% efficiency.[68] Through nanochemistry, the current digital information technology revolution might well be followed by a new analog manufacturing revolution. Today, computers let us shape our digital environment, but by giving computers the means to manipulate the analog world of atoms as easily as they manipulate bits, the same kind of personalization may be brought to our physical three-dimensional environment. In this context Gershenfeld from the Massachusetts Institute of Technology Media Laboratory envisions a personal fabricator akin to the personal computer.[69]

A human society based on nanomachining could perhaps be a much more balanced one, with a manufacturing approach based on how the species itself is made. Products will be based on a fundamental understanding of the assembly of their ultimate components, atoms, molecules, and proteins, and on how to induce self-assembly into useful objects. Materials will be degradable, flexible, and fully reusable. The smaller building blocks used in manufacture will enable products of more variety and intelligence. There will be less emphasis on the traditional engineering materials, such as steel, wood, stone, composites, and carbon, and proteins will become much more important.

The transition toward a nanosociety will require a major shift in workforce skill level as manipulation of data and applying knowledge of bioengineering will be part of a manufacturing worker's daily duties. In academia, less hyperspecialization and better grounding in all the sciences and engineering will be a must as the traditional "dry" engineering and sciences, such as electrical engineering and mechanical engineering, will merge with the "wet" sciences and engineering, such as biology and bioengineering.

Appendix 2A: Uses of Extremophiles

Source	Uses
Hyperthermophiles	
DNA polymerases	DNA amplification by PCR
Alkaline phosphatase	Diagnostics
Proteases and lipases	Dairy products
Lipases, pullulanases, and proteases	Detergents
Proteases	Baking, brewing, and amino acid production from keratin
Amylases, α-glucosidase, pullulanase, and xylose/glucose isomerases	Baking, brewing, and amino acid production from keratin
Alcohol dehydrogenase	Chemical synthesis
Xylanases	Paper bleaching
Lenthionin	Pharmaceutical
S-layer proteins and lipids	Molecular sieves
Oil degrading microorganisms	Surfactants for oil recovery
Sulfur oxidizing microorganisms	Bioleaching, coal and waste gas desulfurization
Hyperthermophilic consortia	Waste treatment and methane production

(*Continued*)

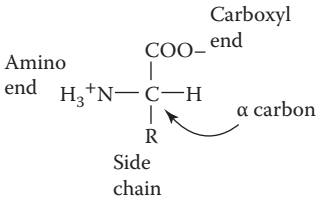
Appendix 2A: (*Continued*)

Source	Uses
Psychrophiles	
Alkaline phosphatase	Molecular biology
Proteases, lipases, cellulases, and amylases	Detergents
Lipases and proteases	Cheese manufacture and dairy production
Proteases	Contact-lens cleaning solutions, meat tenderizing
Polyunsaturated fatty acids	Food additives, dietary supplements
Various enzymes	Modifying flavors
ß-Galactosidase	Lactose hydrolysis in milk products
Ice nucleating proteins	Artificial snow, ice cream, other freezing applications in the food industry
Ice minus microorganisms	Frost protectants for sensitive plants
Various enzymes (e.g., dehydrogenases)	Biotransformations
Various enzymes (e.g., oxidases)	Bioremediation, environmental biosensors
Methanogens	Methane production
Halophiles	
Bacteriorhodopsin	Optical switches and photocurrent generators in bioelectronics
Polyhydroxyalkanoates	Medical plastics
Rheological polymers	Oil recovery
Eukaryotic homologs (e.g., *myc* oncogene product)	Cancer detection, screening antitumor drugs
Lipids	Liposomes for drug delivery and cosmetic packaging
Lipids	Heating oil
Compatible solutes	Protein and cell protectants in variety of industrial uses, e.g., freezing, heating
Various enzymes, e.g., nucleases, amylases, proteases	Various industrial uses, e.g., flavoring agents
γ-Linoleic acid, ß-carotene, and cell extracts (e.g., *Spirulina* and *Dunaliella*)	Health foods, dietary supplements, food coloring, and feedstock
Microorganisms	Fermenting fish sauces and modifying food textures and flavors
Microorganisms	Waste transformation and degradation, e.g., hypersaline waste brines contaminated with a wide range of organics
Membranes	Surfactants for pharmaceuticals
Alkaliphiles	
Proteases, cellulases, xylanases, lipases, and pullulanases	Detergents
Proteases	Gelatin removal on x-ray film
Elastases, keratinases	Hide dehairing
Cyclodextrins	Foodstuffs, chemicals, and pharmaceuticals
Xylanases and proteases	Pulp bleaching
Pectinases	Fine papers, waste treatment, and degumming
Alkaliphilic halophiles	Oil recovery
Various microorganisms	Antibiotics
Acidophiles	
Sulfur-oxidizing microorganisms	Recovery of metals and desulfurication of coal
Microorganisms	Organic acids and solvents

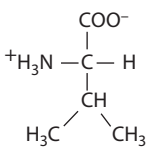
Appendix 2B: The Twenty Amino Acids Found in Biological Systems

Alanine, arginine, asparagine, aspartic acid, cysteine, glutamic acid, glutamine, glycine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, proline, serine, threonine, tryptophan, tyrosine, and valine.

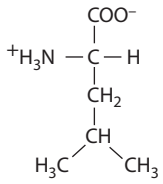
All amino acids have the same general formula:



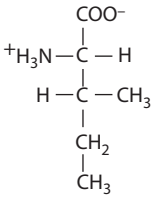
Amino acids with hydrophobic side groups



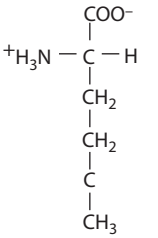
Valine (val)



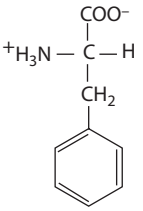
Leucine (leu)



Isoleucine (Ile)

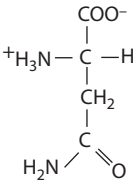


Methionine (met)

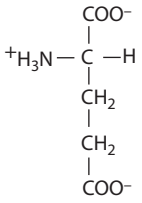


Phenylanine (phe)

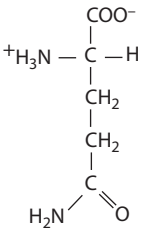
Amino acids with hydrophilic side groups



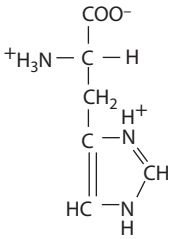
Asparagine (asn)



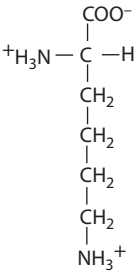
Glutamic acid (glu)



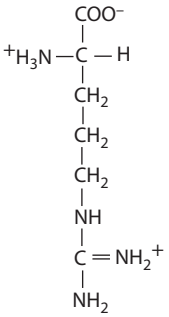
Glutamine (gln)



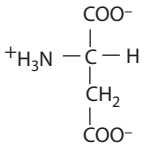
Histidine (his)



Lysine (lys)

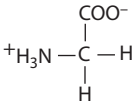


Arginine (arg)

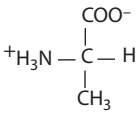


Aspartic acid (asp)

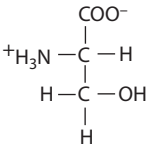
Amino acids that are in between



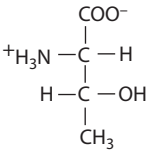
Glycine (gly)



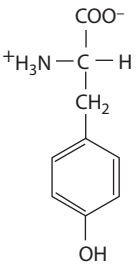
Alanine (ala)



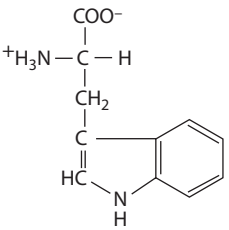
Serine (ser)



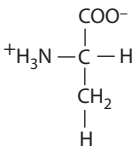
Threonine (thr)



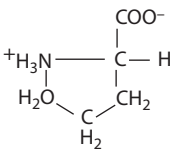
Tyrosine (tyr)



Tryptophan (trp)

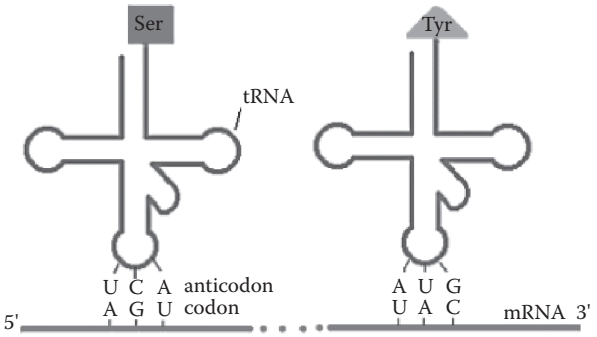


Cysteine (cys)



Proline (pro)

Appendix 2C: The Universal Code



2nd base in codon

1st base in codon	U		A	G	3rd base in codon
U	Phe	Ser	Tyr	Cys	U
	Phe	Ser	Tyr	Cys	C
	Leu	Ser	STOP	STOP	A
	Leu	Ser	STOP	Trp	G
C	Leu	Pro	His	Arg	U
	Leu	Pro	His	Arg	C
	Leu	Pro	Gln	Arg	A
	Leu	Pro	Gln	Arg	G
A	Ile	Thr	Asn	Ser	U
	Ile	Thr	Asn	Ser	C
	Ile	Thr	Lys	Arg	A
	Met	Thr	Lys	Arg	G
G	Val	Ala	Asp	Gly	U
	Val	Ala	Asp	Gly	C
	Val	Ala	Glu	Gly	A
	Val	Ala	Glu	Gly	G

FIGURE A2C.1 The genetic code.

Questions

2.1: Immunoassays are based on the specific binding of antibodies with antigens.
- (a) Describe an ELISA.
- (b) Explain how nonspecific binding can produce unwanted signals in both immunoassays and in DNA assays. (*Nonspecific binding* refers to the binding of adsorption of molecules onto the surface without any preference or selectivity.)

2.2: With the aid of diagrams, describe:
- (a) A competitive immunoassay
- (b) A sandwich immunoassay

2.3: Why are living systems, at first glance, violating the second law of thermodynamics?

2.4: Briefly discuss the "who was on first" dilemma: DNA, RNA, or proteins?

2.5: What models are complexity and communication sciences contributing to the biogenesis question?

2.6: Draw a diagram to illustrate how proteins are manufactured.

2.7: List examples of emergent properties of complex systems.

2.8: Find some examples of man-made materials that feature self-repair.

2.9: Which of the following statements regarding GFP is True/False?
- _____ The excitation maxima of GFP are at 395 and 470 nm.
- _____ GFP is extracted from *A. victoria* jellyfish.
- _____ GFP has a highly unstable molecular structure.
- _____ GFP emits light at high intensity but with a very low quantum efficiency.
- _____ GFP gets activated by red or infrared light.

2.10: What are DNA microarrays? What are their applications?

2.11: Define what an antigen and an antibody are. What class of proteins are antibodies? Sketch an antibody, and illustrate where the antigen binds to the antibody. Explain what forces contribute to the antigen-antibody interaction.

2.12: Explain the error catastrophe in gene copying.

2.13: Explain the difference between DNA cloning, reproductive cloning, and biomedical or therapeutic cloning.

2.14: PCR is a very important analytical methodology to amplify genetic material. Briefly describe how it works and the merits/problems miniaturization of PCR entails.

2.15: Contrast human manufacturing techniques with nature's methods.

2.16: What does the term "binding constant" refer to in antibody chemistry? What is the value of a typical binding constant between an antigen and an antibody? What does the term "cross-reactivity" mean?

2.17: What is the difference between polyclonal and monoclonal antibodies? Briefly discuss the advantages and/or disadvantages of monoclonal vs. polyclonal antibodies.

2.18: The antigen-antibody interaction is used in a good number of bioanalytical techniques. One such example is affinity chromatography.

Describe the principle of affinity chromatography and give one example where you would need to use affinity chromatography.

2.19: Match the following terms with the appropriate definitions:

(1) Fluorophore	(a) Crystals composed of materials from periodic groups II-VI, III-V, or IV-VI and can be conjugated to biomolecules
(2) Stokes shift	(b) Method used to measure the ability of a molecule to move around in a cell over time
(3) FRAP	(c) Intense fluorescent probe used in many biological studies
(4) Quantum dots	(d) Difference in wavelength between fluorescence excitation maximum and the fluorescence emission maximum
(5) Green fluorescent protein	(e) Molecule that can be excited by light to emit fluorescence

Thanks to Mr. Youssef Farhat, UC Irvine.

2.20: What is a biosensor? Draw a schematic of a typical biosensor with its components and explain its operation with an example.

Carbon nanotubes are usually made with bottom-up techniques.

Our ability to arrange atoms lies at the foundation of technology.

K. Eric Drexel
1986

Introduction

Nario Taniguchi coined the word *nanotechnology* in 1974 to describe machining with tolerances of less than 1 μm (see Volume II, Figure 6.3). Humans are still best at building structures we can grasp with our hands and see with our eyes, and we have only relatively recently started to intentionally craft objects at the nanoscale with nanotechnology. Over the last two decades, nanotechnology has come to mean two quite different things. In the broadest sense it is any technology dealing with building structures between 1 and 100 nm in size, in a narrower sense, as promoted by K. Eric Drexel, it involves designing and building machines in which every atom and chemical bond is precisely specified.[1]

About the first definition, one commentator quipped that some companies are willing to say their product is based on nanotechnology if it is made of atoms![1] Clearly, some further refinement is in order for a working definition. Our criteria for nanotechnology are that the miniaturized structures have at least one dimension smaller than 100 nm, are crafted with a novel technique, and have been intentionally designed with a specific nanofeature in mind. Medieval church stained glass, with embedded gold nanoparticles, does not qualify, since the reason for the color dependence on the size of the particles was not yet appreciated in the Middle Ages (Figure 3.1). Finally, nanotechnology attempts to control or manipulate matter at the atomic scale. Our definition dovetails nicely with the criteria adopted by the National Nanotechnology Institute (http://www.nano.gov/):

1. Nanotechnology involves structures in the 1–100-nm range
2. Nanotechnology creates and uses structures that have novel size-based properties
3. Nanotechnology takes advantage of the ability to control or manipulate at the atomic scale.

The manufacture of devices with dimensions between 1 and 100 nm is based on either top-down manufacturing methods (starting from bigger building blocks, say a whole Si wafer, and chiseling them down into smaller and smaller pieces by cutting, etching, and slicing) or bottom-up manufacturing methods (in which small particles such as atoms, molecules, and atom clusters are added for the construction of bigger functional units). The top-down approach to nanotechnology we call *nanofabrication* or *nanomachining*—an extension of the micromachining approaches [microelectromechanical system (MEMS)] introduced in previous chapters. The bottom-up approach we call *nanochemistry*. Nanochemistry is also called *molecular nanotechnology*; it is the arranging and building of more complex organic and inorganic structures at molecular level by chemistry, molecular biology, or mechanical positional assembly. An example of this second approach is the self-assembly of a monolayer from individual molecules on a gold surface (see Volume II, Figure 8.14). Bottom-up methods are nature's way of growing things. In biomimetics, one studies how nature, through eons of time, developed manufacturing methods, materials, structures, and intelligence. These biomimetic studies, expanded upon in Chapter 2, this volume, are now inspiring design, materials, and engineering of human-made miniature objects.

Both nanomachining and nanochemistry are considered nanotechnology. We start this chapter off by contrasting these two opposite methods to obtain nanostructures. Along the way we highlight the Drexel-Smalley debate about the "correct path" toward nanotechnology. We then list all the

FIGURE 3.1 Stained glass: *Labors of the Months* (Norwich, England, ca. 1480). The ruby color is due to embedded gold nanoparticles.

properties that make nanodevices special, i.e., physical and chemical behavior that depend on particle size and allow one to engineer their properties. In one extreme, we have atoms and molecules, generally less than a nanometer in size, studied in quantum chemistry, and in the other extreme we have bulk condensed matter physics that deals with solids with an infinite array of bound atoms. Nanoscience deals with the in-between mesoworld where neither quantum chemistry nor the classic laws of physics apply. The listing of nanoparticle properties is followed by a section on preparation of nanostructures in general: from high-energy ball milling to photolithography to gas phase and liquid phase processes. Finally, as more specific examples, we detail properties and highlight bottom-up manufacturing approaches of carbon nanotubes, graphene sheets, and nanowires.

Top-Down versus Bottom-Up Manufacturing

General Characteristics of Top-Down and Bottom-Up Manufacturing

Top-down nanofabrication is principally based on lithography and traditional mechanical machining, etching, and grinding, whereas bottom-up nanochemistry is based on chemical synthesis, self-assembly, and positional assembly. The distinction is clarified in Figure 3.2. These complementary developments constitute different aspects of nanotechnology; both aim to create and use structures, devices, and systems in the size range of about 0.1–100 nm (covering the atomic, molecular, and macromolecular length scales).

There are some important distinctions to be made between these two approaches to making very small things. Whereas top-down methods essentially impose a structure or pattern on a substrate, in self-assembly and self-organization-based bottom-up methods the assembly or organization of atomic and molecular constituents into larger structures is inherent through processes in the manipulated system. Self-assembly and self-organization are driven by thermodynamics and hold the intriguing potential of delegating more and more mechanical or logical operations to materials instead of to manufacturing machines. Assembly of atoms or molecules into larger aggregates in chemical synthesis is driven by chemical reactions with the Gibbs free energy changes dominated by the enthalpy changes associated with breaking and creating bonds ($\Delta G = \Delta H - T\Delta S$). In self-assembly the driving forces are

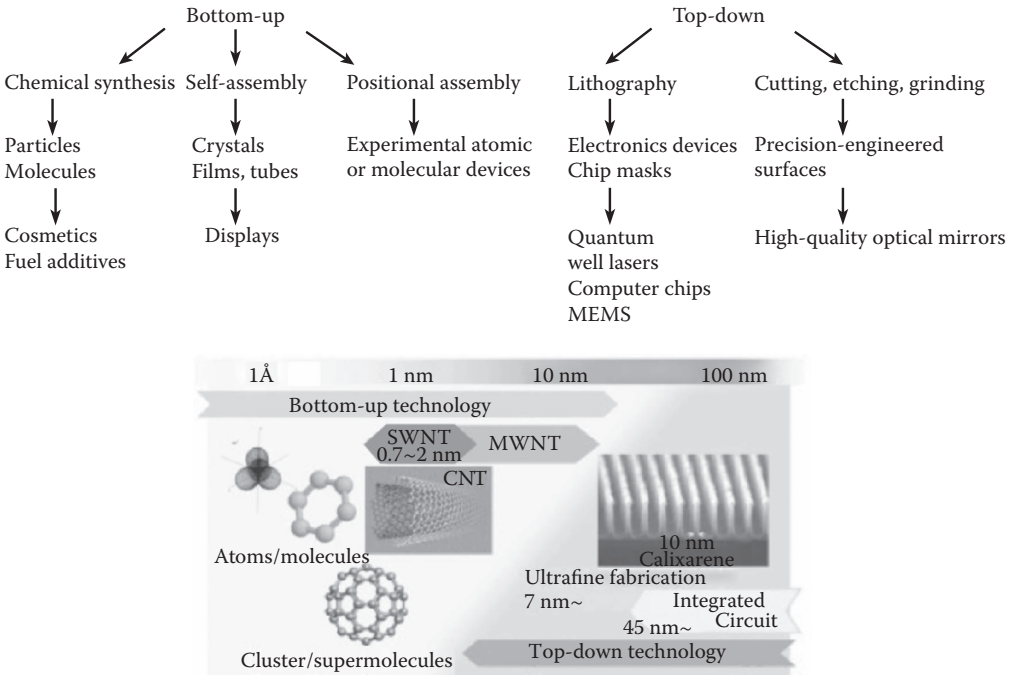

FIGURE 3.2 Contrasting bottom-up nanofabrication with top-down nanochemistry.[2] (SWNT: single wall nanotube; MWNT: multiwall nanotube; CNT: carbon nanotube.)

weak interactions (hydrogen bonds, van der Waals forces, hydrophobic/hydrophilic interactions, etc.; see Volume I, Chapter 7) and are usually driven by entropy changes only. Both chemical synthesis and self-assembly-based bottom-up processes are based on growth phenomena, and any growth scenario is governed by the competition between kinetics and thermodynamics. Positional assembly is the least mature bottom-up technique and uses mechanical means, e.g., an atomic force microscope (AFM), to assemble nanostructures by forcing atoms or molecules in close enough proximity and with the right orientation to form or break bonds (see Volume II, Figures 2.43 to 2.45).

A top-down manufacturing process (for example, the writing of an e-beam pattern) is deterministic, but a bottom-up process (for example, the chemical synthesis of a quantum dot from a colloidal solution) is stochastic. In the latter case, instead of dealing with only one possible "reality" of how the process might evolve under time, in a stochastic or random process there is some indeterminacy in its future evolution, described by probability distributions. This means that even if the initial condition is known, there are many possibilities to which the process might go, but some paths are more probable and others less (statistics take over). Current top-down manufacturing techniques are in a sense crude and wasteful compared with the bottom-up manufacturing techniques we survey in this chapter. Top-down, making a smooth edge requires grinding away and discarding trillions of atoms (i.e., removing excess material). The hope for bottom-up manufacturing is to build with atomic precision without wasting material.

Applying modified integrated circuit (IC) methods, MEMS led to major advances in manufacturing strategies, but the method still presents a limited choice of materials and works with building blocks that are large and crude compared with the nanochemistry arsenal. As humankind learns to build with the same construction set nature uses, we are bound to challenge nature in nanoengineering. Because it uses relatively large building blocks, human manufacturing is rapid. The expectation is that nature, because it uses much smaller building blocks, for example, atoms with a diameter of 0.3 nm, must be very slow. To offset the time it takes to work with small, basic building blocks, nature, in growing an organism, relies on additive processes featuring massive parallelism and self-assembly. Massive parallelism and self-assembly are two areas where human technology still is very backward compared with nature's methods. In Table 3.1 we compare some of the key characteristics of bottom-up manufacturing (nanochemistry) with MEMS technology.

In Figure 3.3 we illustrate the convergence over time of top-down and bottom-up methodologies. The lines representing top-down manufacturing in Figure 3.3 are a simplified representation of a 1974 diagram by Norio Taniguchi (see Volume II, Figure 6.3). The higher of the two lines, marking

Table 3.1 MEMS and Nanochemistry Compared

MEMS Technology	Nanochemistry
Top-down	Bottom-up
Miniaturization with micrometer and submicrometer tolerance	Miniaturization with atomic accuracy
Builds mostly on solid-state physics and the band model from quantum mechanics	Builds almost exclusively on quantum mechanics
Evolved from the integrated circuit fabrication technology	Evolved from molecular engineering, colloid chemistry, supramolecular chemistry, and scanning proximal tool assembly
Many MEMS products are commercially successful	Only a few nanomaterials are on the market
Deterministic processes	Stochastic processes
Limited set of building materials	Huge number of possible building materials
Relatively large building blocks make for a fast process	Very small building blocks necessitate massive parallelism and self-assembly

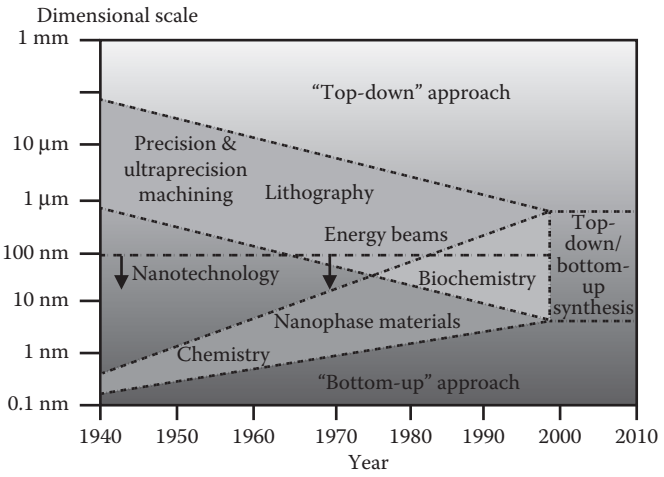

FIGURE 3.3 Convergence of bottom-up nanochemistry and top-down nanofabrication. The nanotechnology line is placed at 100 nm[2].

progress of absolute tolerance in top-down machining, corresponds to precision machining. The lower line represents absolute tolerance in ultraprecision machining, lithography, and energy beam techniques. Some caution is in order about the use of the term *absolute tolerance* in nanotechnology: a more rigorous definition of nanotechnology should differentiate between absolute tolerances in lateral and vertical nanostructures. Deposition of nanometer-thick films is relatively easy with all types of "traditional" chemical vapor deposition (CVD) and physical vapor deposition (PVD) techniques, but patterning of a thin film laterally, with critical dimensions (CDs) that extend from about 100 nm down to atomic orders of magnitude, is still quite a challenge when employing top-down methods. Bottom-up methods hold the potential for nanometric control in all three dimensions. This explains why we tend to make quantum wells with lithography-based top-down methods, since only the thickness direction requires tight control, but quantum wires and quantum dots are mostly made with bottom-up methods, since for those quantum structures we also need control in the lateral directions. Vertically layered structures, i.e., nanoscaled thin films, are obviously much easier to achieve than laterally patterned features. When people discuss breakthroughs in top-down nanotechnology, they mostly refer to better lateral patterning techniques. In the same context, in Volume II, Chapter 6, we explain how the excellent absolute tolerances for precision and ultraprecision mechanical machining only hold true for surface finishes, i.e., in the thickness direction, while in the lateral directions absolute tolerances are again worse. Mechanical machining lateral tolerances are worse than the lateral tolerances achievable with lithography, and those in turn are worse than what we can achieve with nanochemistry techniques: using electron beam machines we can cut shapes with a precision of 2.5 nm, about 1,000 times better than what is achievable in a standard machine shop (2.5 μm is standard, and 1 μm may be achieved in specialty shops), and precision in nanochemistry is about 1 Å, 25 times better than what e-beam offers today. The two lines in Figure 3.3 representing the bottom-up manufacturing progress in achievable absolute tolerances show how bottom-up processes evolved to enable, ever-larger structures through progress in nanochemistry. It is seen from this figure that from the mid-1970s on, feature sizes that could be achieved by nanofabrication (top-down) and nanochemistry (bottom-up) started to overlap. Over the next ten years, the size overlap of objects fabricated with either approach will continue, and molecular engineers and supramolecular chemists, jointly with IC, MEMS, and nanoelectromechanical system (NEMS) specialists, now making devices with 45-nm feature sizes and below, will find new ways to combine top-down and bottom-up manufacturing methods.

In Volume II, Chapter 6, we commented that the reason for the slowdown in electronic device miniaturization hinges on securing more mechanical stability in the positioning stages, but even more so on manufacturing cost and the fact that transistors are becoming too leaky below the 32-nm node, where quantum effects start playing a role. To further extend manufacturing accuracy in electronics one has to look beyond current manufacturing methodologies and consider methods such as molecular engineering and nanofabrication of quantum devices. Micromachining of special lithography tools will play a pivotal role in those new machining approaches. For example, the scanning tunneling microscope (STM), based on micromachining ultrasharp tips on Si cantilevers, creates machining opportunities with accuracies on the atomic level, well beyond the predictions of the

Taniguchi and Moore curves in Volume II, Figure 6.3. For mechanical NEMS structures, operation in the micro- and nanodomains imposes barriers other than those described for electronic devices. New design philosophies, producing results that are more error-insensitive with simpler mechanisms, smaller numbers of parts, and, wherever possible, flexible members rather than rigid ones must be adopted. Most of this book deals with top-down machining; in this chapter we deal in some more detail with bottom-up manufacturing.

Important Concepts in Bottom-Up Manufacturing

Introduction

Before reviewing nanostructure properties and listing methods for bottom-up nanotechnology manufacturing, some important contributing concepts and their definitions are in order. What follows are clarifications and definitions for concepts that are often utilized in bottom-up manufacturing but are not always well understood, such as self-assembly, self-organization, biomimetics, supramolecular chemistry, self-replication, and molecular assemblers.

Self-Assembly and Self-Organization

Self-Assembly

Self-assembly and self-organization are important concepts in both nanotechnology and biology. According to Maasden and Kaiser, about 10% of papers dealing with nanotechnology published between 1990 and 2005 address the concept of self-assembly, and among those, 3% deal with self-organization.[3] The distinction between self-assembly and self-organization is not always readily apparent, and this causes considerable confusion, especially when self-replication (see below) is thrown into the discussion.

Thermodynamics represents the simplest way to differentiate between self-assembly and self-organization. Self-assembly concerns equilibrium situations and is purely driven by the tendency of systems to minimize their free energy in accordance with the second law of thermodynamics. Self-organization, on the other hand, occurs in systems that are open and are driven by a constant input of energy and that are far from thermodynamic equilibrium. As we pointed out earlier, in self-assembly free energy minimization is often driven by entropy changes, ΔS (Equation 2.7). For natural examples of self-assembly, consider phospholipids with hydrophobic and hydrophilic ends placed in aqueous solution spontaneously forming stable structures (Figures 2.41–2.43, this volume) or the intricate three-dimensional (3D) patterns in protein folding (Figure 2.11, this volume). In technology, self-assembly is taken advantage of, for example, in sensors such as DNA probes and immunosensors, but is not used much in human manufacturing yet. We use self-assembly in manufacturing, for example, when growing crystals, in building self-assembled monolayers (see Volume II, Figure 8.14), and in colloid chemistry. In colloidal chemistry one can assemble inorganic solids, such as CdSe crystals, with astonishing regularity in size and properties, comparable to what can be accomplished with nanolithography, and this method has become an important route for building quantum dots (see Figure 3.23).

There is an upswing in self-assembly work that is bringing a renewed excitement to the nanotechnology field. In Chapter 4, this volume, on packaging, for example, we detail the differences between deterministic and stochastic parallel microassembly and clarify the need and tremendous opportunities for self-assembly in packaging of nanocomponents. Recent examples of work in self-assembly based packaging, clarified in Chapter 4, include DNA-mediated self-assembly of metallic and semiconductor components and micro-origami assembly of optical components and of small polymer sheets (see also the example that follows).

Example of Self-Assembly: Scaffolded DNA Origami

Weight

The reproducible generation of atomically precise patterns and shapes is at the heart of nanotechnology. Although research has shown improvement at creating nanosized shapes, it is still a tremendous challenge to create desired nanostructures that always do have the same size and shape with

FIGURE 3.4 Origami art. (From Origami.com, http://www.origami.com.)

atomic accuracy. Here we review a recently developed method that holds that potential. It involves a technique for folding long single strands of DNA (ssDNA) into arbitrary two-dimensional shapes using synthesized DNA staple strands in so-called "scaffolded DNA origami." Scaffolded DNA origami builds on Seeman's DNA nanotechnology, discussed in Chapters 2 and 4, this volume (e.g., Figure 4.49) and pushes it quite a few steps further.

Origami is the art of folding paper; it originated in China as "Zhe Zhi" and was adapted by Japanese monks in the sixth century AD (see an example of origami in Figure 3.4). Ancient origami is not self-assembly, but the scaffolded DNA origami reviewed here is. DNA by its nature does exhibit self-assembly (see base pairing in Chapter 2, Figure 2.6). The same characteristics that make DNA so effective genetically also make it a good choice for programmed self-assembly in nanotechnology:

- DNA can be manipulated to create exact copies that are extremely accurate (atomic accuracy).
- DNA is predictable and programmable.
- DNA also has the ability to store enormous amounts of information.

The most important part of controlling the way a DNA strand folds is knowing its genetic nucleotide structure. The scaffold strand that has been used most often is circular genomic DNA from the virus M13mp18 (natural M13mp18 is 7249 bases long). Synthesized DNA staple strands then bind to complementary base pairs on the scaffold M13mp18 viral genome as illustrated in Figure 3.5. Both the DNA strand and the staple strand must be known to avoid unwanted pairing and to ensure that the stapling takes place in desired locations only, as illustrated in Figure 3.6.

The design for a desired shape is made by raster filling the shape with the ~7-kilobase single-stranded scaffold molecule and by choosing more than 200 short oligonucleotide staple strands to hold the scaffold in place. Once synthesized, a large excess of staples (100×) is mixed with scaffold and annealed in a polymerase chain reaction (PCR) machine (<2 h) (for details on how PCR works, see Chapter 2, this volume, Figure 2.53). Synthesized DNA staples self-assemble, with the viral strands resulting in folded area shapes (squares, disks, five-pointed-star, etc.) approximately 100 nm in diameter, with a spatial resolution of 6 nm. A nucleotide may serve as a 6-nm pixel in these designs, so any type of word or image can be programmed. Individual DNA structures can also be made to form larger assemblies of two-dimensional (2D) periodic lattices. Sample DNA origami are deposited on mica and imaged with an AFM in tapping mode. Experimentally verified by the creation of a dozen shapes and patterns, the method is easy, has a high yield, and lends itself well to automated design and manufacture. So far, computer-aided design (CAD) tools for scaffolded DNA origami are simple, require hand-design of the folding path only, and are restricted to two-dimensional designs. If the method gains wide acceptance, better CAD tools will be required.[4]

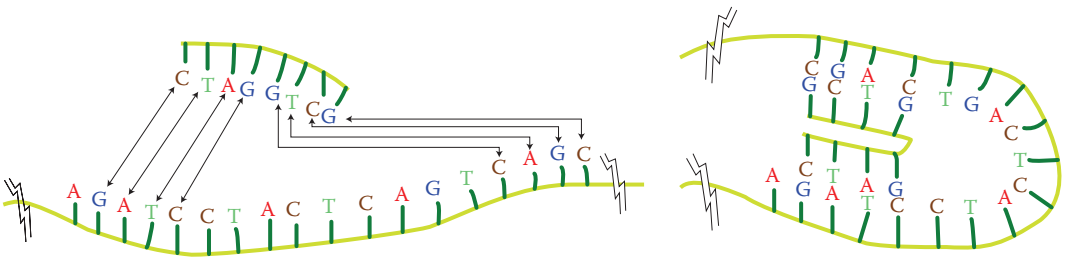

FIGURE 3.5 DNA staple concept. The sequence of DNA provides a unique address for each location. Staple strands bind locations together according to the design.

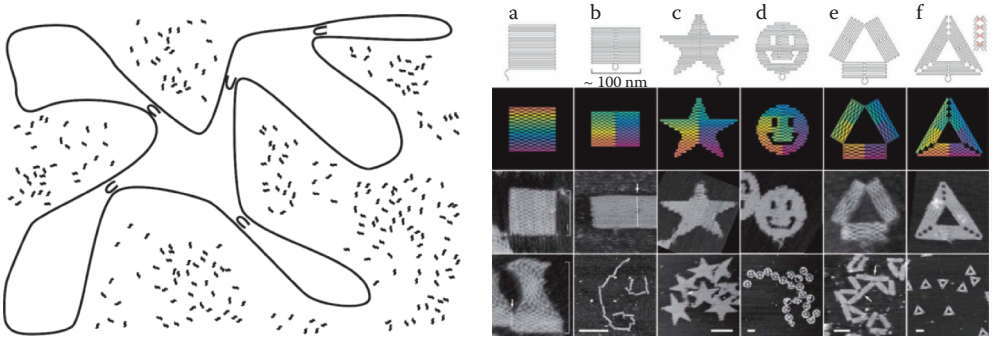

FIGURE 3.6 The design for a desired shape is made by raster filling the shape with the 7-kilobase single-stranded scaffold molecule and by choosing more than two hundred short oligonucleotide staple strands to hold the scaffold in place.[4]

Self-Organization

Self-organization is a term for those types of pattern forming systems that are open and thus driven by a constant input of energy and that are far from thermodynamic equilibrium. The Rayleigh-Bénard instability, or, more simply, Bénard heat convection, is regarded as a classic case of self-organization. This type of heat convection is named after French chemist Henri Bénard, who first recorded the effect in 1900. Because the British physicist Lord Rayleigh further investigated Bénard's observation, the conditions that produce it came to be called the *Rayleigh-Bénard instability*. Anyone can observe the formation of Bénard cells by heating a thin layer of oil in a pan, as illustrated in Figure 3.7. With the oil uniformly heated from below, a constant heat flux is established, moving from the bottom to the top of the oil layer in the pan. The oil itself remains at arest, and when the temperature difference between top and bottom of the oil layer reaches a certain critical value, thermal conduction is replaced by heat convection, in which the coherent motion of large number of molecules transfers the heat. At this point a very strikingly ordered pattern of hexagonal cells (a "honeycomb") appears, in which hot oil rises through the center of the cells, while cooler liquid descends to the bottom along the cell walls. The same physics underlies a weather phenomenon that leaves hexagonal patterns behind in sand or snow. The sun heats up the desert sand or a snowfield, and warm air from the surface rises, while cold air descends from the upper layers of the atmosphere. The conflict is resolved again by the emergence of orderly patterns of fluid flow under the action of an imposed temperature gradient, resulting in hexagonal circulation vortices that leave their imprints on sand dunes in the desert and on arctic snowfields.

During the 1960s, Ilya Prigogine (1917–2003), winner of the Nobel Prize in Chemistry, 1977, developed a new, nonlinear, irreversible thermodynamics, that mathematically describes the self-organization phenomenon described here.[5] It is

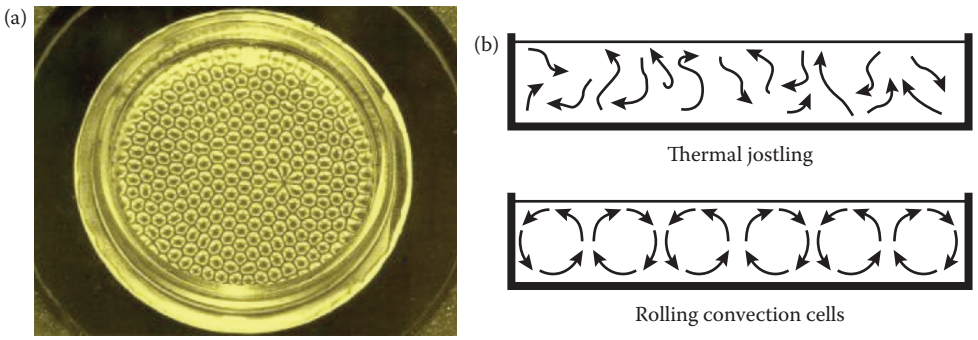

FIGURE 3.7 (a) Patterns of hexagonal Bénard cells viewed from above. The most interesting stable patterns appear right at the edge of chaos. This is happening far from equilibrium, thanks to the energy flowing through an open system and being dissipated. (b) The hexagonal cells—the simple global order—is more efficient at dissipating heat than the simple local motions.

quite unlikely that anyone would have deduced these phenomena from the Navier-Stokes equations (see Volume I, Chapter 6). On the basis of Prigogine's work, Bénard cells are now understood to arise from the properties of the liquid state at a bifurcation point in which a self-organizing structure emerges. The huge number of degrees of freedom of individual molecules in the fluid at this critical point suddenly organize into a coherent and simple flow pattern that dissipates heat more effectively than simple thermal conduction. In this new emergent behavior, convection (transport of heat by mass movement) in self-organized spatial structures becomes the dominant process. This change is initiated by an instability (noise) in the system, and the result obeys the second law of thermodynamics, since this mechanism is a more efficient way of disposing of the system's heat. More disorder must generally prevail (increase in ΔS), but one can still have a local increase in order, such as in the hexagonal Bénard cells, as long as overall they contribute to the wider disordering of the surroundings, i.e., the dissipation of energy as entropy or waste heat.

What is happening at a molecular level in the frying pan is that when the pan is only gently warmed, each heated molecule moves by itself, and the molecules all chaotically barge about and only eventually emerge at the surface, where they shed their excess heat. But at a certain critical temperature, a phase transition occurs. The jostling molecules are becoming entrained into a coherent flow, the rolling convection current that moves them smoothly from the heated bottom to the cooler surface. The hexagonal cells—the simple global order—is more efficient at dissipating heat than the simple local motions (see Figure 3.7b). But when one heats a Bénard cell just a little more, its orderly hexagonal cells soon break up and instead turbulence results and disorder appears again. The order turns out to exist only for a very finely controlled balance between heat input and heat dissipation.

In self-organization what differs from what happens in self-assembly is that internal variations, called *fluctuations* or *noise*, trigger self-organization. The increase in organization corresponds to a decrease of entropy equivalent to an increase in redundancy, information, or constraint. In other words, after the self-organization process, less ambiguity about which state the system is in results. Prigogine called systems that continuously export entropy in order to maintain their organization *dissipative structures*, i.e., systems that exist far from thermodynamic equilibrium, dissipate the heat generated to sustain them, and have the capacity to change to higher levels of orderliness or self-organization. In classic thermodynamics the dissipation of energy in heat transfer, friction, and the like was always regarded as waste. Dissipative structures introduced a radical change in this view by showing that in open systems, dissipation becomes a source of order. According to Prigogine, dissipative systems contain subsystems that continuously fluctuate. At times, a single such fluctuation or a combination of them may become so magnified by possible feedback that it shatters the preexisting organization in what is called an emergent new property. At such moments, called *bifurcation points*, it is impossible to determine in advance whether the system will disintegrate into "chaos" or leap to a new, more differentiated, higher level of "order." While dissipative structures receive their energy from outside, the instabilities and jumps to new forms of organization are the result of internal fluctuations amplified by positive feedback loops. Thus, amplifying "runaway" feedback, which was traditionally seen as destructive, now appears as a source of new order and complexity in this model.

Self-assembly and self-organization are fundamentally different from a thermodynamics point of view: while self-assembly stems from minimization of the free energy, self-organization requires an open system and a constant energy input.* Whereas self-assembly is quite well understood and is clearly important at small length scales in biology (protein folding, for example), self-organization is not as well understood, and the length scale at which it comes into play in biology is still under debate. For the specific case of cell membrane assembly, it is believed that both processes eventually lead to quite similar patterns, but that their evolution occurs on very different length and time scales. Self-assembly produces periodic protein patterns on a spatial scale below 0.1 μm in a few seconds followed by extremely slow coarsening,

* Unfortunately, important players in this field, such as Whitesides, seem to maintain their own definitions of self-assembly, and J.M. Lehn uses both terms more or less interchangeably to characterize the synthesis of supramolecular structures.

whereas self-organization results in a pattern wavelength comparable to the typical cell size of 100 μm within a few minutes, suggesting different biological functions for the two processes.[6] One thing that everyone agrees on is that living organisms cannot arise wholly from self-assembly, because in the absence of a continuous supply of energy they die. In summary, crudely said: viruses self-assemble, but elephants (perhaps) self-organize (http://www.softmachines.org/wordpress/?p=178). Another parallel to living systems here is that such dynamical structures are not devised to exhibit this behavior: they develop spontaneously from random initial conditions (we emphasize: not from special initial conditions).

The behavior of interest, such as that of the Bénard cells, is often found in the transition between order and chaos—at the edge of chaos—and is classified as a kind of organized complexity. The same type of behavior is involved in adaptive path minimization by ants, wasp and termite nest building, army ant raiding, fish schooling and bird flocking, coordinated cooperation in slime molds, synchronized firefly flashing, evolution by natural selection, game theory, the evolution of cooperation, etc. When a flock of birds is taking off from a lake (see Figure 3.8), birds compete for position, try to get free of the maelstrom of their fellow birds and go up into the air. They want to be part of the flock, yet at the same time try to avoid collisions with each other. Computer models show that each bird's attempt to keep a minimum and maximum distance from others causes flight paths to couple into feedback loops of attraction and repulsion. Positive and negative feedback balance so that the individual birds appear transformed into a single organism. The late Prigogine wrote about the reception his irreversible thermodynamics received at first:

> It is difficult today to give an account of the hostility that such an approach was to meet. For example, I remember that towards the end of 1946, at the Brussels IUPAP meeting, after a presentation of the thermodynamics of irreversible processes, a specialist of great repute said to me, in substance: "I am surprised that you give more attention to irreversible phenomena, which are essentially transitory, than to the final result of their evolution, equilibrium."
>

Biomimetic Nanomanufacturing

Introduction

Biomimetics is the application of designs, materials, and systems found in nature to engineering and technology. As we saw in Chapter 2, this volume, where we cover biomimetics in much more detail, engineers and scientists tend to increasingly turn toward nature for inspiration on designs, materials, and systems, spawning a number of technology innovations. There is an obvious reason behind this trend: the rigorous competition of natural selection means that waste and inefficiency are not tolerated in natural systems, unlike many of the technologies developed by humans. For this same reason, many researchers now give natural, biomimetic manufacturing methods another look. Within this context, the guiding principles involved in the construction of living organisms are as follows.[7,8]

- The use of composites (rather than monolithic materials in human engineering)
- Several successive levels of organization (hierarchy), often in the form of two prevalent natural design motives: fractals (trees, lungs, the brain, the cardiovascular system, etc.) or layered structures (tree rings, onions, etc.) and combinations thereof
- Very wide range of manufacturing sizes: from atoms to several meters, i.e., 10^{12} orders of magnitude

- The use of carbon instead of Si
- Ambient temperature versus the high temperatures used in human engineering
- Low energy (ATP) versus high energy
- Mobility of components (Brownian motion) versus rigidity with no or few fluctuations
- Operation in aqueous solution rather air (wet vs. dry engineering)
- Compartmentalization in cells
- Plasticity: soft, flexible materials that change conformation in response to the environment versus rigid components
- Self-assembly (see above), self-organization (see above), and self-replication all through weak bonds
- Order out of noise versus noise as a nuisance (see above)
- The use of templates (e.g., the reading of genes by messenger RNA to build proteins in the cells' ribosomes, as shown in Figure 2.12)
- Variable number of components versus fixed number of components
- Adhesive surfaces (van der Waals) versus separated surfaces
- Robustness through stochastics versus through redundancy

These principles provide inspiration for the implementation of human nanotechnology. As noted in Chapter 2, this volume, biomimetics should not be taken too far beyond inspiration from nature, because the ultimate goal in nature is spreading genetic information to the next generation, not to generate the most efficient manufacturing technique. We add a few comments now for several of the attributes of a natural growing process listed above.

Nanocomposites

Nanocomposite materials are widespread in biological systems, such as bone, cell walls, and soft body tissue. The nacre (mother-of-pearl) of abalone shell, an oriented coating composed of alternating layers of aragonite ($CaCO_3$) and a biopolymer, is an oft-studied example (Figure 3.9). The laminated structure provides strength, hardness, and toughness. Nacre is twice as hard and 1000 times as tough as its constituent phases. Humankind has

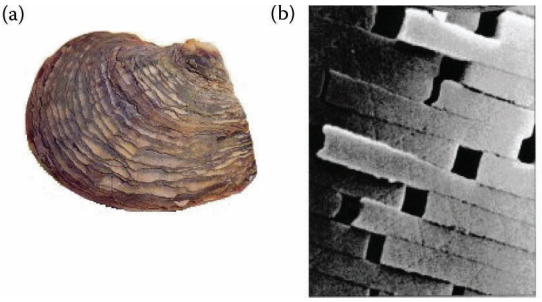

FIGURE 3.9 Abalone shell nanocomposite structure: (a) abalone shell and (b) scanning electron microscope image of the aragonite composite structure.

accumulated plenty of experience with composite materials, but attempts to make "biomimetic" nanocomposite assemblies are quite recent. Along this line, Sellinger et al. reported on an efficient self-assembly process for preparing nanolaminated organic-inorganic coatings that mimic nacre.[9] New biomimetic materials such as scaffolds for regrowth of tendons tend to be composites too, although not on the nanoscale; in the case of tendon scaffolds, composites are made from carbon fibers and polylactic acid.[7]

Hierarchical Organization and Range of Manufacturing Sizes

Proteins, bone, and tissue fibers have a hierarchical organization (see Figure 2.11 for the various protein structural levels) much more complex than that of materials of the nonliving world (e.g., crystals). This organization bestows many benefits on living organisms, such as a high strength-to-density ratio and the ability to serve several functions simultaneously. The ability of humans to mimic this feat is still limited and will improve only if we become more adept at manipulating a wider variety of materials at the nanoscale, use smaller building blocks, and build in three dimensions with more dexterity. Traditional lithography is mostly limited to 2D structures and is impractical for printing feature sizes below 0.1 μm. While 3D lithography techniques, as described in Volume II, Chapter 9, are limited in feature size, they do offer a possible route to 3D microstructures.

Two ubiquitous design patterns of hierarchical structures in nature are fractals (trees, brains, river

(a) (b)

FIGURE 3.10 Examples of fractals. (a) Romanesco cauliflower. (b) The fractal coastline of eastern Greenland, with its many fjords.

deltas, fjords, snowflakes, blood circulation system, etc.; see Figure 3.10) and layers (onions, tree rings, etc.) and combinations thereof. Consider a tree where the trunk forks into branches and the branches into smaller twigs. Twigs have leaves, which themselves repeat the dendrite pattern in their veins. The tree also has a layered build-up radially in its stem, branches, and twigs. An object is called a *fractal* if it has structures at a large number of levels. If they are identical, the fractal is said to be *self-similar* (see Chapter 7, this volume, on scaling, for more details on the similarity concept). Self-similarity can also be called *scale invariance* because we always find the same pattern upon zooming into at different length-scales.

In Chapter 9, this volume, we show that the underlying reason for fractal hierarchical structures is simply that such a shape maximizes surface area while minimizing the energy involved in reaching each point on that surface. A fractal network can both absorb and excrete at a maximal rate, whether it is water and electricity, oxygen, carbon dioxide, bloodstream nutrients, or even neural control information. We calculate in Chapter 9 that for a fractal the resistance is minimized and the surface-to-volume (S/V) scale is invariant. We also demonstrate that in a zero-order approximation, a layered structure attains the same goals as a fractal, with both resistance and S/V scaling, in the same way a fractal does when miniaturized.

Using these ubiquitous hierarchical design patterns (fractals and layers) and combinations thereof, nature covers sizes of biological life forms from the atom to several meters (e.g., a 10-m-tall tree), i.e., it covers at least twelve orders of magnitude in size. Human manufacturing techniques, on the other hand, typically are limited to much smaller ranges of size capability (e.g., lithography from 90 nm to 1 cm, i.e., hardly three orders of magnitude). In Figure 3.11, we sketch the challenge involved in making an artificial fractal, say a carbon tree. As indicated in this drawing, as the size ranges we work with approach the atomic and molecular size, stochastic manufacturing techniques (1 Å–100 nm), perhaps from a solution in a beaker, must take over from the larger scale deterministic manufacturing means, such as lithography (100 nm–1 cm) and computer numerical controlled (CNC) machining (1 cm–10 m). In other words, we are forced to switch to different manufacturing options as we move across different length-scales.

The Use of Carbon Instead of Si

Although silicon, human's foremost technological material, is abundant in silicate minerals, carbon is the key to life. In Chapter 5, this volume we explore how in nature, carbon occupies a very special place as the essential building block of life, and we notice how also in human enterprise carbon in its various forms has acquired an enviable position. To name a few, diamonds are made of carbon, and graphite, coke, diamond-like carbon, and glassy carbon are all forms of carbon. So are the more recently discovered buckyballs, carbon fibers, and carbon

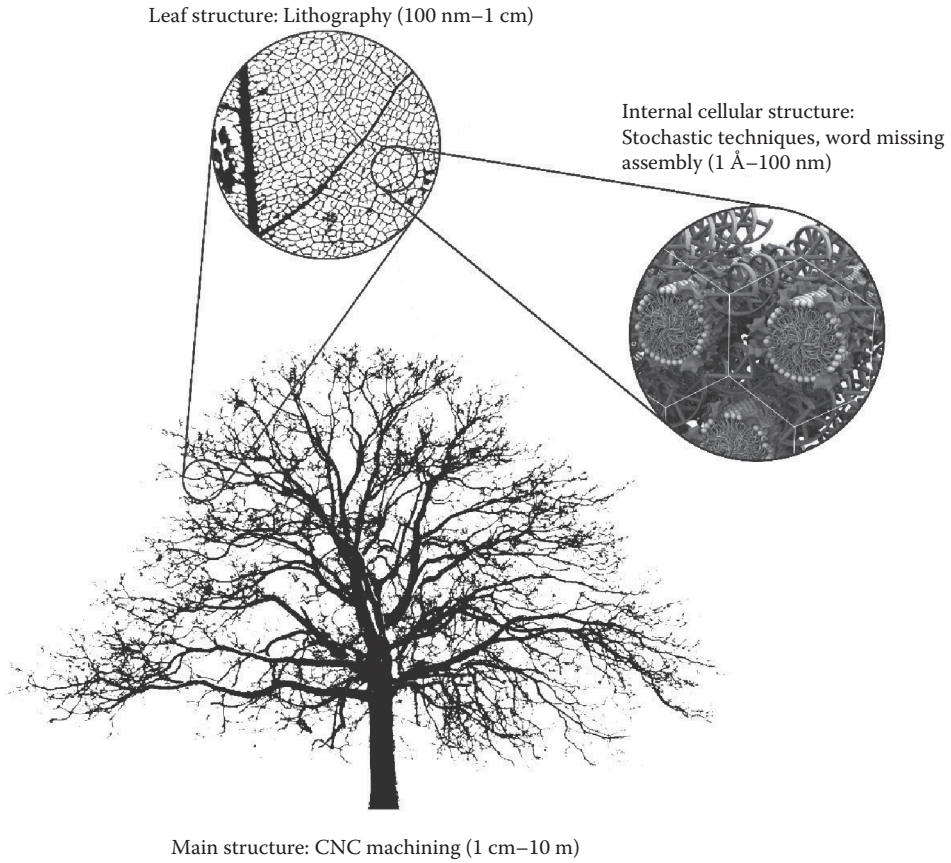

FIGURE 3.11 Making an artificial carbon tree would require switching to various manufacturing strategies, depending on the size. (Drawing by George O'Quinn, UC Berkeley.)

nanotubes (CNTs). It can rightfully be argued that carbon is now also becoming a more and more important material in human technology. Some key advantages of carbon compared with Si are summarized in Table 5.9. As we see from this table, carbon polymerizes better than Si (making organic chemistry a field all on its own); it comes in all types of forms (amorphous, graphite, nanotubes, etc.); it has a wide electrochemical stability window; and it is biocompatible, low cost, chemically inert, and easy to functionalize.

In Chapter 5, this volume, we further introduce the reader to a vision of a carbon-based MEMS and carbon-based NEMS world.

Ambient Temperature, ATP, Soft Materials, Compartimentalization (Cells), and Water Management

Of the many motivating examples of the promise of biomimetics we encountered in Chapter 2, this volume, consider enzymes. There are a plethora of enzymes that outperform synthetic catalysts by several orders of magnitude. For instance, there is no human-made catalyst for producing ammonia from its elements at ambient temperature and pressure, as the nitrogenase of nodule-forming bacteria does (the industrial Haber-Bosch synthesis of ammonia from nitrogen and hydrogen at high temperatures and pressures pales in comparison).

Molecular motors, also covered in Chapter 2, this volume, are in a sense nanomachines that do mechanical work through the hydrolysis of ATP, the energy source of the cell (Figure 2.24). During hydrolysis of ATP, a shape change occurs within the motor protein (a mechanochemical process), and mechanical work is performed. The force generated by a motor protein is as large as 100 pN, a very large torque, comparable to a person rotating a 150-m rod. Such a rotary motor, with a diameter of only 30–40 nm, drives the rotation of the flagellum at around 300 Hz at a power level of 10–16 W, with energy conversion efficiency close to 100%. These

protein motors appear to be fuelled by a flow of protons across a pH gradient and can push an average-sized cell at 30,000 nm/s, or 15 body-lengths per second—and can also run in reverse! The structural designs and functional mechanisms revealed in the complex machinery of the bacterial flagellum could provide many novel technologies that may become the basis for future nanotechnology, from which we should be able to find many useful applications.

In comparison, the surface micromachined motors of Volume II, Chapter 7 (see Figure 7.64) are hopelessly impractical. The biological motors are more error-insensitive, with simpler mechanisms and smaller numbers of parts, and wherever possible, flexible members rather than rigid ones are adopted.

In biology, it is important to note that the compartmentalization in cells constitutes an efficient water management system. Since neither proteins nor DNA functions in a dry environment, water needs to be actively controlled by the cell wall. It is no coincidence that more and more of the nanotechnology is focusing on nanochemistry (wet) instead of nanofabrication (dry). In human technology, when working with small droplets the evaporation rate is very high because of the high surface-to-volume ratio, requiring a water management system. Similarly, when working with natural polymers, results can only be obtained when working in an aqueous environment.

Self-Replication and the Use of Templates

We defined self-assembly and self-organization earlier in this chapter: self-replication is yet different. Self-replication is a process in which an object makes a copy of itself. Biological cells, we saw in Chapter 2, this volume, will, given a suitable environment, reproduce by cell division. During cell division, DNA is replicated and is transmitted to offspring during reproduction. Biological viruses can reproduce, but only by hijacking the reproductive machinery of cells. Computer viruses reproduce using the hardware and software already present on computers. Memes reproduce using the human mind and culture as their reproductive machinery. In self-replication, we saw in Chapter 2, this volume, molecules such as DNA encode the genetic information for cells and the resulting organisms, thus allowing the information to be passed on from cell to cell and from generation to generation.[10] PCR and research results with RNA and certain peptides, described in Chapter 2, this volume, are manifestations of this self-replication capability of biological molecules.

Example of Self-Replication in Human Engineering: Self-Replicating Robots

Self-replicating machines have been the subject of theoretical discussion since the early days of computing and robotics. Only three human made mechanical devices that can replicate themselves have been reported so far. One uses Lego parts assembled in a two-dimensional pattern by moving them along tracks, and another uses an arrangement of wooden tiles that tumble into a new arrangement when given a push. The third and most recent self-replicating machine is the most fascinating one. Hod Lipson, from Cornell Laboratory, made the first robots that self-replicate.[11] His robots are made up of a set of modular cubes called *molecubes;* each cube contains identical machinery and a computer program for replication. These machines are simple compared with biological replication, but they demonstrate that mechanical replication is possible and is not limited to biology. Electromagnets on the face of the cubes allow them to selectively attach to and detach from one another, and a complete robot consists of several cubes linked together. Each cube is divided in half along a long diagonal, which allows a robot composed of many cubes to bend, reconfigure, and manipulate other cubes (Figure 3.12).

A tower of cubes can thus bend itself over at a right angle to pick up another cube (Figure 3.13). To start

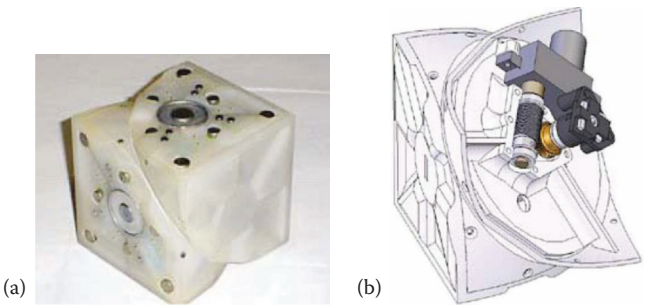

FIGURE 3.12 (a) Each module of the self-replicating robot is a cube about 4 in. on a side, able to swivel along a diagonal. (b) A cutaway drawing shows the motor mechanism.[11]

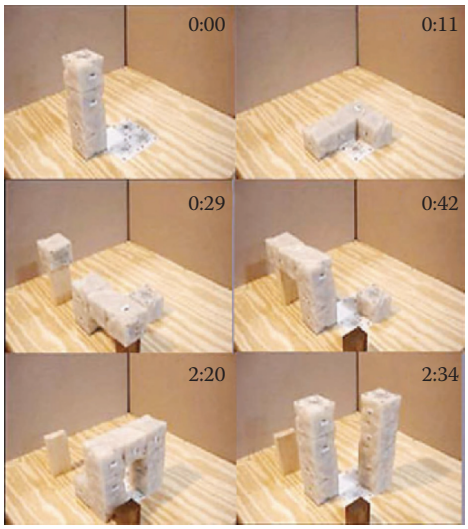

FIGURE 3.13 Frames from a video show the replication process. A robot consisting of a stack of four cubes begins by bending over and depositing one of its cubes on the table. The remaining three cubes pick up additional cubes from "feeding stations" and transfer them to the new robot, which assists in the process by standing itself up. Video is available online at http://www.news.cornell.edu/stories/may05/selfrep.ws.html.

the replication process, a stack of cubes bends over and sets its top cube on the table. Then it bends to one side or another to pick up a new cube and deposit it on top of the first cube on the table. Repeating this process, one robot made up of a stack of cubes creates another just like itself. One robot cannot reach across another robot of the same height. The robot being built assists in completing its own construction. These replicating robots are very dependent on their environment; they draw power through contacts on the surface of the table and cannot replicate unless the experimenters "feed" them by supplying additional modules.

Supramolecular Chemistry

Chemistry beyond the molecule gave rise to supramolecular chemistry—a new field of chemistry pioneered by researchers such as Nobel laureate Jean-Marie Lehn from the University of Strasbourg.[12,13] Self-assembly leads to large supramolecular architectures: no chemist needs to specify the individual atom or molecule positions in these systems.[14] For example, after disintegration of ribosomes (see Figure 2.12 for a ribosome in action) into their protein and RNA building blocks, the molecules will reorganize into functional units in a test tube given the right conditions.

An early suggestion of supramolecular chemistry came from Nobel laureate Hermann Emil Fischer who, in 1890, suggested that enzyme-substrate interactions take the form of a "lock-and-key,"* implying the concepts of molecular recognition and host-guest chemistry. The same lock-and-key assembly is involved in neurotransmitters assembling with molecular recognition sites on proteins that elicit chemical responses, for example, acetylcholine recognition at nerve-muscle junctions, resulting in muscle contractions.[15] The fundamental concepts underpinning supramolecular science are processes in which atoms, molecules, aggregates of molecules, and components arrange themselves into ordered, functioning entities without human intervention.[16] In the early twentieth century noncovalent bonds were understood in gradually more detail. The weak interactions typically involved are as follows (see Volume I, Chapter 7, for more details):

- Hydrogen bonds (described by Latimer and Rodebush in 1920)
- Electrostatic attractions
- Van der Waals forces (the existence of intermolecular forces was first postulated by Johannes Diderik van der Waals in 1873)
- Hydrophobic interactions
- Weak covalent bonds

Through supramolecular chemistry with weak ionic and hydrogen bonds and van der Waals interactions (0.1–5 kcal/mol), structures with dimensions of 1–100 nm are possible. For chemical synthesis, the largest of these dimensions often is too large, and for microfabrication, it often is too small. The types of interactions listed above allowed scientists to finally interpret protein and DNA behavior. Chemists started to study synthetic structures based on no covalent interactions, such as micelles and microemulsions. Eventually, these concepts, derived from

* The lock-and-key concept of biochemical interactions has, over the years, been modified in favor of a "hand-in-a-glove" concept, because some reorganization (conformational change) is required to make two biomolecules complementary to each other.

biological systems, were applied to synthetic chemical systems. The first big breakthrough along this line came in the 1960s with the synthesis of the crown ethers by Charles J. Pedersen.[17] Donald J. Cram, Jean-Marie Lehn, and Fritz Vögtle became active in the synthesis of shape- and ion-selective receptors, and throughout the 1980s research in the area gathered a rapid pace, with concepts such as mechanically interlocked molecular architectures emerging. The emerging science of nanotechnology also had a strong influence on the subject, with building blocks such as fullerenes, nanoparticles, and dendrimers becoming involved in synthetic systems. By the 1990s, supramolecular chemistry had become an established avenue toward nanoelectronic and nanomechanical systems, with researchers such as Fraser Stoddart developing molecular machinery and highly complex self-assembled structures[18] and researchers such as Itamar Willner developing sensors and methods of electronic and biological interfacing.[19] Stoddart pioneered the development of the use of molecular recognition and self-assembly processes in template-directed protocols for the syntheses of two-state mechanically interlocked compounds (bistable catenanes and rotaxanes) that have been employed as molecular switches and as motor-molecules in the fabrication of nanoelectronic devices and NEMS (see Figure 3.14 for a rotaxane switch).[20] Rotaxanes can act as molecular switches because they can oscillate back and forth between two stable states.

Yet more recently, electrochemical and photochemical motifs have become integrated into supramolecular systems in order to increase functionality, research into synthetic self-replicating system began, and work on molecular information processing devices began. For example, the Stoddart and Zink groups have developed donor-chromophore-acceptor-based molecular triads that can transduce light into electrical energy by mimicking the photosynthesis pathway.[21] A nanoscale power supply in the form of a light-harvesting molecular triad has been developed (Figure 3.15). Donor-chromophore-acceptor-based molecular triads that can convert light to electrical energy are some of the most effective molecules that can serve the purpose of energy transduction. Yet more impressively, it has been demonstrated that the photocurrent generated by the triad can be utilized to drive a supramolecular machine in the form of a pseudorotaxane.[22] The molecular triad is based on tetrathiafulvalene-porphyrin-fullerene (TTF–P–C60), which generates electrical current by harnessing light energy when self-assembled onto gold electrodes. The triad is composed of three unique electroactive components: 1) an electron donating TTF unit, 2) a chromophoric porphyrin unit, and 3) an electron-accepting C60 unit. A disulfide-based anchoring group was tagged to the TTF end of the molecule in order to allow self-assembly onto gold surfaces. In a closed electrical circuit, the triad-functionalized working electrode generates a switchable photocurrent of ~1.5 μA/cm^2, when irradiated with a 413 nm krypton-ion laser. The electrical energy generated by the triad is then exploited to drive a supramolecular machine in the form of a [2]pseudorotaxane composed of a π-electron-deficient tetracationic cyclobis(paraquat-

p-phenylene) (CBPQT4+) cyclophane and a π-electron-rich 1,5-bis[(2-hydroxy-ethoxy)-ethoxy] naphthalene (BHEEN) thread (Figure 3.15). The dethreading of CBPQT4+ cyclophane from the BHEEN thread was monitored by measuring the increase in the fluorescence intensity of the BHEEN unit. A gradual increase in the fluorescence intensity of the BHEEN upon illumination confirmed that the dethreading process is driven by the photocurrent generated by the triad.

Dendrimers form a special set of molecules in supramolecular chemistry. They are globular polymer-based macromolecules of monodisperse size in which all bonds emerge treelike from a central core in a regular branching pattern and may be as small as 3 nm across (the size of a typical protein). These fractal-like macromolecules, introduced by Tomalia et al.[23] and Newkome et al.[24] in 1985 have attracted a lot of attention because of their novel structure and intriguing properties.[25,26] Dendrimer synthesis allows for nearly complete control over the critical molecular design parameters, including size, shape, reaction site distribution, surface/interior chemistry (e.g., number and size of internal voids), flexibility, and topology. The process involves a stepwise, repetitive sequence that guarantees completed reactions for each generation of reaction products, resulting in monodisperse final products. There are three major strategies involved in effective dendrimer synthesis: the starburst divergent strategy, the convergent growth strategy, and the self-assembly strategy. In the divergent approach, growth starts at the core and proceeds radially outward toward the periphery, and in the convergent approach, growth starts at what will become the periphery of the dendrimer and proceeds inward. Although the majority of dendrimers prepared to date have been constructed of covalent bonds[25,27] using convergent or divergent

strategies, several noncovalent dendrimers[25,28] have been prepared by a variety of self-assembly processes involving, for example, hydrogen bonding[29] or supramolecular coordination chemistry.[30]

Balzani and coworkers[31,32] described the use of metal branching coordination centers, such as ruthenium and osmium, and multidentate ligands for the construction of metallodendrimers centers more than a decade ago. Since this work, a large number of self-assembled dendritic structures have been prepared by using metal ligand complexes (Figure 3.16a), hydrogen bonding moieties (Figure 3.16b), or ionic interactions (Figure 3.16c) for the assembly.

Figure 3.16a shows a small bimetallic dendrimer obtained in a flexible synthesis strategy that is used to prepare many larger dendrimers with a variety of arrangements of the internal and peripheral metal centers.[32] These polynuclear complexes may be redox-active and/or luminescent, can be used as electrochemical and/or photochemical molecular devices, and may prove useful in areas such as energy harvesting and conversion, signaling, and diagnostics. Among the numerous self-assembling dendritic systems that have been reported, those involving assembly into columnar or spherical structures are particularly intriguing. Percec and coworkers[33,34] used van der Waals interactions and H-bonding to self-assemble functionalized polyether dendrons into cylindrical columnar or spherical assemblies that mimic the shape and architecture of certain types of viruses. Similarly, Aida and coworkers[35] have used weak metal-metal interactions to effect the hierarchical self-assembly of small dendrimers into luminescent superhelical fibers. Given their sizes, optical properties, and electronic properties, such assemblies could well find display, storage, or other applications in micro- and nanoelectronics.

As summarized in Figure 3.17, dendrimers can be designed to aggregate to form cylinders or spheres depending upon the nature of the fundamental building unit. Pie-shaped dendrimers assemble into cylinder segments (donuts) that then further aggregate into cylinders (Figure 3.17a). Cone-type dendrimers organize into spheres (two to twelve per sphere depending on generation), which then pack into the unusual Pm3-n (A-15)-type cubic crystal structure having spheres at the corners and body center of the cube plus two on each face (Figure 3.17b).

The layered architecture of dendrimers, their globular shape, highly controlled monodisperse size,

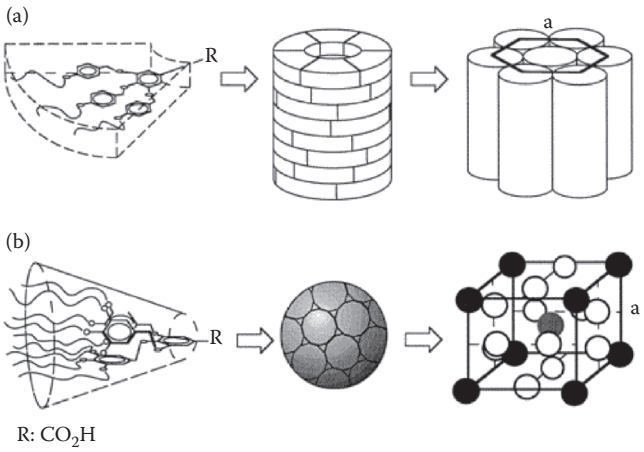

FIGURE 3.17 Assembling cylinders (a) and spheres (b) from dendritic molecules.[37]

radially controlled chemical makeup, multivalent periphery, variable inner volume, and controlled intramolecular dynamics endow dendrimers with unique features such as the ability to morph into a variety of supramolecular arrangements in response to external stimuli. On the basis of these properties, dendrimers may provide the key to reliable and economical fabrication of functional nanoscale materials with unique electronic, optical, optoelectronic, magnetic, chemical, or biological properties. Some of these applications are already being researched. Specially designed dendrimers with a hydrophobic interior and a hydrophilic[38] periphery, so-called "unimolecular micelles," are capable of molecular inclusion and solubilize hydrophobic molecules, such as pyrene in aqueous solution, and are at least as good at it than traditional micelles; moreover, they do not display a critical micelle concentration.[39,40] Classic micelles are thermodynamic aggregates of amphiphilic molecules and therefore dynamic assemblies of small molecules, while "unimolecular micelles" are static and retain their cohesion regardless of concentration. Also, dendrimer monolayers are finding a number of applications from surface-confined chemical sensor arrays[41,42] or affinity biosensors[43,44] to resists for nanolithography.[38,45]

Molecular Assembler

A molecular assembler was defined by K. Eric Drexler as a "device able to guide chemical reactions by positioning reactive molecules with atomic precision."[46] Some biological molecules, such as ribosomes, constructing a wide variety of proteins from their amino acid constituents, fit this definition (see Figure 2.12). However, the term *molecular assembler*, as defined by Drexel, refers to artificial mechanical machines, envisioned to work in air rather than in an aqueous solution. Molecular assemblers are broader than self-replicating machines (see above and Figures 3.12 and 3.13), as in theory they can both self-replicate and make other products. Drexel logically pointed out that if self-replication of molecular assemblers is not restrained, it might lead to competition with naturally occurring organisms. This is referred to as the "gray goo" scenario.[47] One method to construct molecular assemblers in solutions is to mimic natural evolutionary processes. As a result, production of complex molecular assemblers might evolve from simpler systems.

One of the most outspoken critics of the mechanical "molecular assemblers" was Richard Smalley (1943–2005). Smalley argued that such assemblers were not physically possible and introduced two major objections to them, termed the "fat fingers problem" and the "sticky fingers problem."[48] He believed that these two problems would exclude the possibility of molecular assemblers that worked by precision picking and placing of individual atoms.

In the fat fingers problem, Smalley argues that in an ordinary chemical reaction, five to fifteen atoms near the reaction site engage in an intricate three-dimensional waltz in a very cramped region of space measuring no more than a nanometer on each side, so there is not enough room in the nanometer-size reaction region to accommodate all the fingers of the mechanical manipulators necessary to exert complete control of the chemistry. Drexel's counterargument is that two reactants can be brought together with controlled trajectories if one reactant is bound to a substrate and the second reactant is positioned and moved by a single finger. He correctly points out that this has already been done experimentally by using the tip of an STM.[49] For example, Ho and Lee[50] physically bound a CO molecule to an iron atom on a silver substrate using an STM (see Volume II, Figures 2.44 and 2.45, for more complex STM molecular assembly). Drexel also points out that if steric constraints near the tool tip do make

it too difficult to manipulate particular individual atoms or small molecules with sufficient reliability, a simple alternative is to use conventional solution or gas phase chemistry for the bulk synthesis of somewhat larger nanoparts, consisting of 10–100 atoms. These larger nanoparts could then be bound to a positional mechanical device and assembled into larger structures without further significant steric constraints. This is the approach taken by the ribosome in the synthesis of proteins, where individual amino acids are sequentially assembled into an atomically precise polypeptide without the need to manipulate individual atoms. *Atomically precise* is a description of the precision of the final product, not a description of the manufacturing method. It must be argued though that once we are dealing with a cluster of atoms the original objective of atomic scale control has been abandoned and a ribosome still recognizes the individual base pairs to stitch the protein together from its amino acid components.

Smalley also advances the sticky fingers problem, which is the claim that "the atoms of the manipulator tool will adhere to the atom that is being moved. So it will often be impossible to release this minuscule building block in precisely the right spot."[48] Drexel's counterargument is that the sticky fingers problem is not a fundamental barrier to building mechanical assemblers since reactions exist that allow the synthesis of a useful range of precise molecular structures. As an example, he mentions that the application of a voltage between a manipulator tool and the workpiece that cause the target atom or moiety to move to the desired position. He points again to work by Ho and Lee[50] for experimental proof.

A final criticism by Smalley was that these mechanical assemblers would be far too slow to be ever practical.[48] Here, a counterargument could be the possible use of arrays of assemblers, as we saw in the IBM Millipede (see Volume II, Figure 2.4b).

All in all, the Smalley-Drexel debate is about how to make molecular assemblers, not whether they are possible or not. To push either extreme, i.e., to claim that only biology/chemistry can do it (Smalley) or to put too much emphasis on mechanical assembly (Drexel), is to ignore that the solution might well be one that incorporates a combination of both. Drexel is indeed pointing at chemical synthesis (up to a nanocluster) and then mechanical positioning for further assembling of these clusters as a possible solution.

Nanostructure Properties

Introduction

In this section we introduce all the different properties that nanostructures bring to the table that do differ from microstructure properties. On the broadest level the differences may be summarized as shown in Table 3.2. Nanostructures occupy very high surface area and have a vastly increased surface area per unit mass, e.g., upwards of 1000 m^2 per gram. In terms of suface-to-volume (S/V) ratio, a 3-nm iron particle has 50% of its atoms on the surface, a 10-nm particle has 20%, and a 30 nm particle only 5% (see Volume I, Figure 2.49). Nanoparticles are quantum mechanical, wave-like, with discrete energies and quantized currents. Quantum size effects result in unique mechanical, electronic, photonic, and magnetic properties. The chemical reactivity of nanoscale materials greatly differs from that of more macroscopic forms. Microfabricated microstructures, on the other hand, exhibit relatively small S/V, behave mostly classically (semiclassically) and

Table 3.2 Comparison of Microstructures and Nanostructures

	Microstructure	Nanostructure
Physics	Semiclassic	Quantum mechanical
Electron nature	Particle-like	Wave-like
E- or k-space	Continuous	Discrete
Current	Continuous	Quantized
Decision	Deterministic	Probabilistic
Fabrication method	Microfabrication	Nanofabrication
Surface area/volume	Small	Very large
Packing density	Low	Very high

are particle-like, with continuous energy and currents. All the properties of nanoparticles we mention below are ultimately a consequence of the more fundamental ones listed in Table 3.2.

Melting Temperature, Thermal Transport, and Heat Capacity

In Chapter 7, this volume, on scaling, we learn that the surface-to-volume (S/V) ratio of particles scales as $1/r$, where r is the characteristic dimension of the particles. The smaller a particle, the more of its atoms find themselves at it surface. A bulk solid material will typically have less than 1% of its atoms on its surface, whereas 10-nm particles have about 15% of surface atoms. The high S/V ratio of nanoparticles makes them more reactive as catalysts in chemical reactions and lowers their melting temperature (T_m). There is an inverse linear relationship between melting temperature and the surface-to-volume ratio. This makes sense since atoms on a surface are more easily accessed and rearranged than atoms in the bulk. As a consequence, the melting temperature of particles is always lower than the bulk. As observed from Figure 3.18 the melting point of gold particles decreases dramatically as the particle size gets below 5 nm. For nanoparticles embedded in a matrix, melting point may be lower or higher, depending on the strength of the interaction between the particles and the matrix.

Macroscopic thermal transport theory, with Fourier's law (Volume I, Equation 3.53) and the diffusion equation (Volume I, Equation 3.54), breaks down for applications involving thermal transport in NEMS. Whereas for bulk materials, interface effects (surface or grain boundaries) dominate only at low temperatures, in nanometer-scale thin films and particles, the room temperature thermal conductivity can be significantly modified. One can think about the reduction in thermal conductivity in these structures as corresponding to a lower mean free path for the energy flux. In the case of conductors, electrons dominate the thermal conductivity and the mean free path depends on electron scattering phenomena. At lower temperatures, the electron mean free path (λ_e) is constant and controlled by defect scattering, whereas at higher temperatures, phonon scattering takes over and the mean free electron path falls off, as shown in Volume I, Figure 3.161, where we plot mean free electron path (λ_e) versus temperature. From Volume I, Figure 3.162, plotting electronic thermal conductivity (κ_e) versus temperature for Cu and Al, we see that thermal conductivity increases with temperature in the defect scattering regime and then goes down with temperature increase when phonon conduction takes over at higher temperatures. Phonons dominate the thermal conductivity in insulators. Phonons, like electrons, scatter at boundaries, defects, and other phonons (phonon-phonon scattering). For nanodevices the device boundary might take over from defect control. Scattering of heat flow at any of these interfaces significantly reduces thermal conductivity. The size effect on the thermal conductivity can exceed two orders of magnitude for layers of thickness near 1 μm at $T < 10$ K. Figure 3.19 illustrates this for three different thin-film Si layers (thickness d_s) versus bulk Si.[52]

Heat capacity (C_v) of a material is related to its atomic structure or its vibrational and configurational

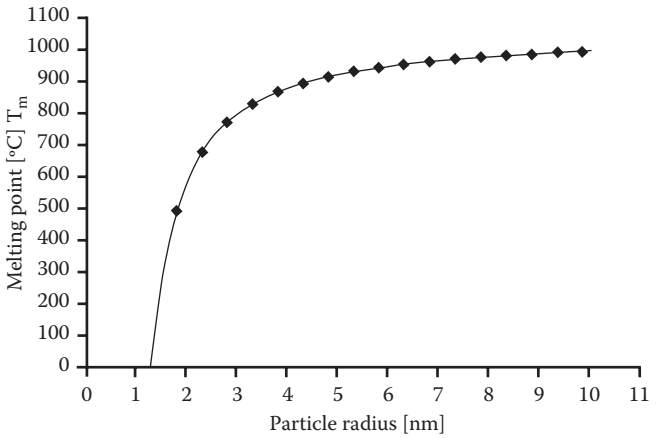

FIGURE 3.18 Melting temperature (T_m) of gold particles as a function of their radius.[51]

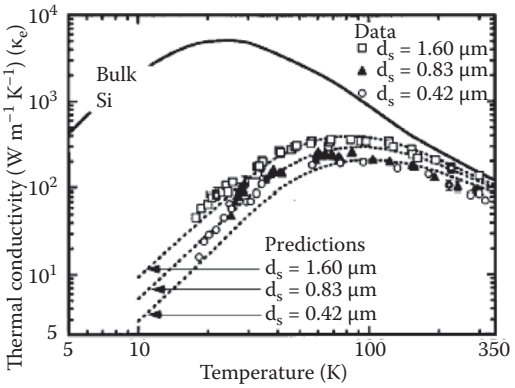

FIGURE 3.19 Thermal conductivity (κ_e) of thin Si films versus bulk Si. d_s is the Si layer thickness.[52]

entropy, which is controlled by all the possible nearest-neighbor configurations. Nanocrystalline materials feature ultrafine crystalline grains. A large fraction of atoms are located in the metastable grain boundaries in which the nearest-neighbor configurations are much different from those in the crystallites. The grain-boundary possesses an excess volume with respect to the perfect crystal lattice, therefore, heat capacities (C_v) of the nanocrystalline materials are expected to be higher than those of the corresponding coarse-grained polycrystalline counterparts.

For nanocrystalline materials, the C_v values, in practice, are indeed observed to be higher than their bulk counterparts. For example:

Pd: 48% up from 25 to 37 J/mol·K at 250 K for 6 nm crystalline
Cu: 8.3% up from 24 to 26 J/mol·K at 250 K for 8 nm
Ru: 22% up from 23 to 28 J/mol·K at 250 K for 6 nm

The phonon contribution to the molar specific heat capacity (C_v) of these polycrystalline materials, we saw in Volume I, Chapter 3, is given by the Dulong-Petit law (Volume I, Figure 3.15), with values for different materials approaching $C_v = 3R$ or 25 J/mol·K at high temperatures. As calculated by Debye, a constant value for C_v is reached at $T \gg \theta_D$ and for $T \ll \theta_D$ (where θ_D is the Debye temperature) he found:

$$C_v = \frac{12}{5}\pi^4 R\left(\frac{T}{\theta_D}\right)^3$$

(Volume I, Equation 3.331)

A T^3 temperature dependency for the specific heat stems from a T^4 dependency of the internal energy U ($C_v = \frac{dU}{dT}$). Since the density of phonon states, [$G(E)$], depends on the dimensionality of the structure, the specific heat of the lattice also depends on the dimensionality of the structure (3D, 2D, 1D, or 0D). Generalizing for different dimensions (D), one derives:

$$U \propto T^{D+1} \text{ and } C_{v,lat} \propto T^D$$

(Volume I, Equation 3.338)

Besides phonon contributions, if the material is an electronic conductor, the electronic contribution to the heat capacity must be counted as well. The electronic specific heat capacity for a 3D structure we introduced in Volume I, Chapter 3 as follows.

$$C_{v,el} = \frac{dU}{dT} = \frac{\pi^2}{3}k_B^2 TG(E = E_F)_{3D} = \frac{\pi^2}{2}\left(\frac{k_B T}{E_F}\right)n_{3D}k_B$$

(Volume I, Equation 3.307)

This expression must be modified again for different dimensionalities since the internal energy (U) depends on the density of electronic states $G(E)_{\#D}$ and $C_{v,el} = \frac{dU}{dT}$.

Thermoelectric Power

In the 1960s, semiconductor thermoelectrics were considered for replacement of mechanical refrigerators and diesel generators. The idea was that if transistors could replace vacuum tubes for electronics, then surely thermoelectrics could replace those outdated machines. The efficiency of cooling and heating is controlled by a dimensionless parameter Z given by the following equation:

$$ZT = \frac{S^2\sigma T}{\kappa} \tag{8.78}$$

where T is the absolute temperature; σ and κ are the electrical and total thermal conductivities (lattice and electrons) of the material, respectively; and S is the Seebeck coefficient. Consequently, requirements for a good thermoelectric material are a high figure of merit ZT; this in turn requires a high Seebeck coefficient (S), a high electrical conductivity (σ), and a low thermal conductivity (κ). For the best thermoelectric materials, one has a ZT of ~0.9, which remained the upper limit for many years. The biggest problem was that ZT had to be improved from ~0.9 to 3 or higher to become commercially attractive [ZT needs to improve to >1.3 at 300 K for a major impact in electronics cooling and to around 2.5 for a revolutionary impact in air-conditioning and power from waste heat (energy scavenging)]. Minimizing thermal conductivity and maximizing electrical conductivity has been the biggest dilemma for the last forty years. Dresselhaus et al. show that

lower dimensional structures such as nanowires based on Bi, BiSb, Bi_2Te_3, and SiGe nanotechnology give additional controls and can lead to a higher *ZT* (see Chapter 8, this volume).[53] Combining a superlattice with a nanowire structure enhances thermopower because of the sharper density of states than ordinary 1D nanowires (enhances *S*) and reduction of the lattice thermal conductivity by increasing the phonon scattering at the segment interfaces (decreases κ). The reason is that the higher density of electron states at the Fermi level increases σ, the increased phonon-boundary scattering lowers κ, and both factors contribute to making *ZT* higher. Figure 8.32 shows the thermoelectric figure of merit *ZT* of a Bi quantum well and Bi quantum wire as a function of size.

In 2008, two teams, one at Caltech and one at the University of California, Berkeley, separately reported that they could increase Si's ability to convert heat into electric current by as much as 100 times[54,55] (see also http://www.spectrum.ieee.org/jan08/5879). Bulk Si used to be a poor material for thermoelectric conversion, because its thermal conductivity is too high; heat travels across it too well so that it is difficult to create the necessary temperature gradient. Bulk Si at room temperature has a *ZT* of only 0.01, but the Berkeley team increased that to 0.4, and the Caltech team increased it to 0.6. This puts Si nanowires almost on par with bismuth telluride. Making thermoelectric devices out of Si, which is much more abundant, cheaper, and easier to handle than bismuth telluride, could help create a large market for these devices.

By fashioning Si into nanowires with diameters of 10–100 nm and introducing defects in the wires that slow the flow of phonons, both teams have found that they can decrease silicon's thermal conductivity without losing too much of its electronic conductivity, and in doing so increase *ZT*. Defects at three different length scales were engineered into the nanowires. First, with silicon in the shape of nanowires, the material is small enough compared with the phonons that the size of the wires themselves affects how the phonons move. Secondly, the surface of the nanowires is made rough, introducing a set of defects at a smaller scale. Finally, the silicon nanowires are doped with boron to introduce defects at the atomic level. Heath at Caltech induced a greater drop in thermal conductivity by making his nanowires even smaller than Yang's group at Berkeley—only 10–20 nm in diameter.[55] Normally, a wire can carry two types of phonons: one that causes the wire's diameter to expand or contract, and one that causes it to lengthen or shorten. But when the nanowires get small enough, these two vibration modes merge into a single type of phonon, which slows down the heat transport even more. Unfortunately, using wires only 10 nm wide may give the best results for thermal conductivity, but the electrical conductivity crucial to thermoelectric conversion also drops.

One of the applications for these silicon nanowires is for recycling waste heat from computer chips into electricity, i.e., energy scavenging (see Figure 3.20).

Mechanical Properties

Small grains, over a certain size range, lead to improved strength and hardness in lightweight nanocomposites and nanomaterials, altering bending and compression properties. This mechanical change is explained as follows. Dislocations are blocked by grain boundaries, so slip is blocked, and therefore, since the smaller the grain size the larger the surface of the grain boundaries, a larger elastic limit is obtained. The latter is expressed in the empirical Hall-Petch equation representing the maximum elastic yield strength (σ_Y = stress at which the material permanently deforms) of a polycrystalline material as a function of grain size. As we learned

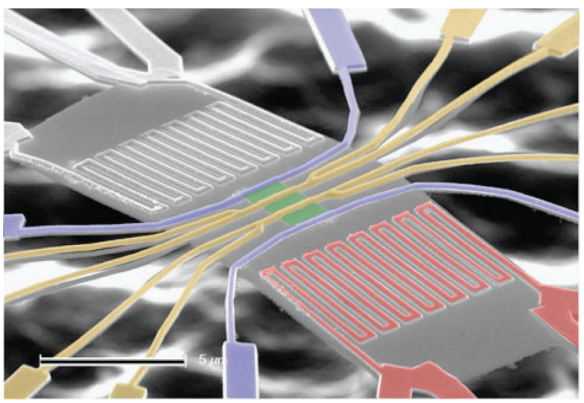

FIGURE 3.20 A nanofurnace: an array of nanowires (green) convert heat from the temperature difference between two slivers of a microchip. Current flowing in through a heater (red) causes the temperature difference. (From James Heath, http://www.spectrum.ieee.org/jan08/5879.)

in Volume I, Chapter 2, Hall and Petch, working independently, found that the yield strength of a polycrystalline material follows the following dependence:

$$\sigma_Y = \sigma_0 + \frac{K}{\sqrt{d}}$$

(Volume I, Equation 2.70)

where d is the average diameter of the grains in micrometers, with σ_0 the frictionless stress (N/m^2) and K a constant. The strength of a material thus depends on grain size (see Table 3.3). The strength of a material thus depends on grain size. In a small grain, a dislocation gets to the boundary and stops, i.e., slip stops. In a large grain, the dislocation can travel farther. So small grain size equates to more strength. For example, the elastic limit of copper doubles when the grain size falls from 100 µm to 25 µm. Instead of yield strength, one might also plot the hardness (H) of the material as a function of grain size, which creates a similar relationship.

The Hall-Petch relation holds for conventional grain sizes (from 0.1 to 100 µm) but for grains smaller than 20 nm, this relation breaks down (see Figure 3.21). For nanometer grains, a reverse Hall-Petch effect has actually been observed, i.e., the strength and hardness of materials from a small grain size on starts to decrease with decreasing grain size. In other words, an optimal grain size (d_c) exists, as suggested by the plot in Figure 3.21 (see also Volume II, Figure 7.54). The classic Hall-Petch relationship is based on the idea that grain boundaries act as obstacles to dislocation movement and since dislocations are carriers of plastic deformation, this manifests itself macroscopically as an increase in material strength. The Hall-Petch behavior breaks down when the smallest dislocation loop no longer fits inside a grain. The deformation mechanism for materials with very small grains (<20 nm)

TABLE 3.3 The Strength of a Material Depends on Grain Size

Material	Yield Strength
Cold worked copper	393 MPa
400-nm copper	443 MPa
100-nm nanograin copper	900 MPa
10-nm nanograin copper	2.9 GPa

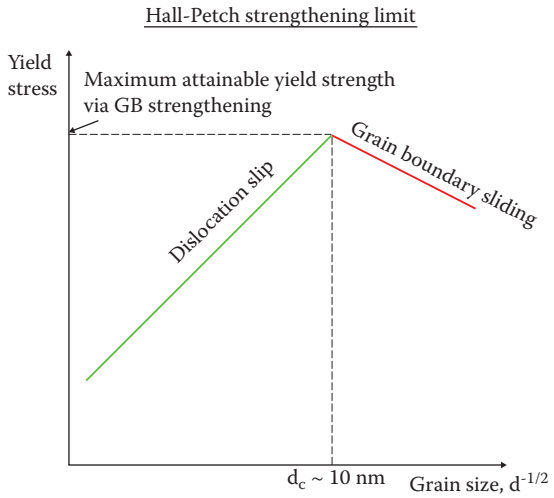

FIGURE 3.21 Hall-Petch reversal.

is different and it has been suggested that plastic deformation in this case is no longer dominated by dislocation motion and it is believed that individual atoms migrate, diffuse, and slide along grain boundaries and through triple junctions (Y-shaped grain boundary intersections).

The increase of the surface-to-volume (S/V) ratio in nanoparticles leads to an increasing dominance of the behavior of the surface atoms over those in the interior of the particle. This results in more interactions between the intermixed components in ceramic nanocomposites; those nanophase powders compact more easily in the sintering process, and successful sintering enhances their hardness.

Chemical Effects

Surface chemistry effects that are barely noticeable in large particle systems become overwhelming in nanoparticle systems that demonstrate enhanced reactivity due to their unusual adsorptive properties. In bulk solids, all molecules are surrounded by and bound to neighboring atoms, and forces are in balance. Surface atoms on the other hand are bound only on one side, leaving unbalanced atomic and molecular forces on the surface. These forces attract gases and molecules through the van der Waals force, and at low temperatures this leads to physical adsorption or physisorption. At high temperatures, electron sharing or valence bonding with gas atoms, resulting in chemical adsorption or chemisorptions, may satisfy those same unbalanced surface

forces. Chemisorption is a much stronger interaction than physisorption, with a heat of adsorption up to 800 KJ/mol. Adsorbing gas or vapor molecule splits into atoms, radicals, or ions, which form a chemical bond with the adsorption site. These processes are the basis for heterogeneous catalysis (key to production of fertilizers, pharmaceuticals, synthetic fibers, solvents, surfactants, gasolines, other fuels, and automobile catalytic converters). Nanostructured materials offer many advantages for this type of catalysis applications including the following:

- Huge surface area, high proportion of atoms on the surface
- Enhanced intrinsic chemical activity as size gets smaller, for example, likely due to changes in crystal shape
- When the shape changes from cubic to polyhedral, the number of edges and corner sites goes up significantly
- As crystal size gets smaller, anion/cation vacancies can increase, thus affecting surface energy; also, surface atoms can be distorted in their bonding patterns
- Enhanced solubility, sintering at lower *T*, more adsorptive capacity

All the properties discussed so far, unlike the quantum effects that we turn our attention to next, change gradually as the dimensions of the particles change.

Blue Shift in Semiconductor Nanoparticles

In Volume I, Chapter 3, we saw that whenever electrons are confined to a small space their behavior as tiny quantum wave packets takes precedence over their particle behavior. For a particle confined to a region of the *x*-axis of length Δx, the uncertainty in momentum is given by $\Delta p_x \sim \hbar/\Delta x$ (see Equation 3.106). If the particle has a mass *m*, the confinement gives it an additional kinetic energy of magnitude $E_c = (\Delta p_x)^2/2m \sim \hbar^2/2m(\Delta x)^2$ (Volume I, Equation 3.162). The confinement energy becomes significant if it is comparable to or greater than the kinetic energy of the particle due to its thermal motion, i.e., $E_c \sim \hbar^2/2m(\Delta x)^2 > \frac{1}{2}k_BT$, and the quantum size effect will be important if $\Delta x \sim \hbar/(mk_BT)^{1/2} \sim \hbar/p_x \sim \lambda_{DB}$ (Where λ_{DB} is the thermal de Broglie wavelength, i.e., roughly the average de Broglie wavelength of the particles in an ideal gas at the specified temperature, see Volume I, Equation 3.216). Thus, if the particle motion is confined in a region of the order of the particle de Broglie wavelength, one will observe effects of size quantization.

When the de Broglie wavelength of an electron is comparable to the size of the system in one or more directions, since only an integer number of half-waves of the electrons can be put in any finite system, one obtains a set of discrete electron states and energy levels, each of which is characterized by the corresponding number of half-wavelengths. This situation is summarized for 3D, 2D, 1D, and 0D degrees of freedom of electrons in Figure 3.22 (see also Volume I, Chapter 3).

A semiconductor quantum dot (QD) can be regarded as an artificial solid-state atom with delta-function-like density of states. Electrons in a quantum dot arrange themselves as if they were part of an atom, even though there is no nucleus for them to surround. The atom these assembled electrons emulate depends on the number of electrons and the exact geometry of the confining nanoprison. Here we calculate, as an example, the spacing between the lowest two energy levels, $\Delta E = E_{n+1} - E_n$, for a spherical

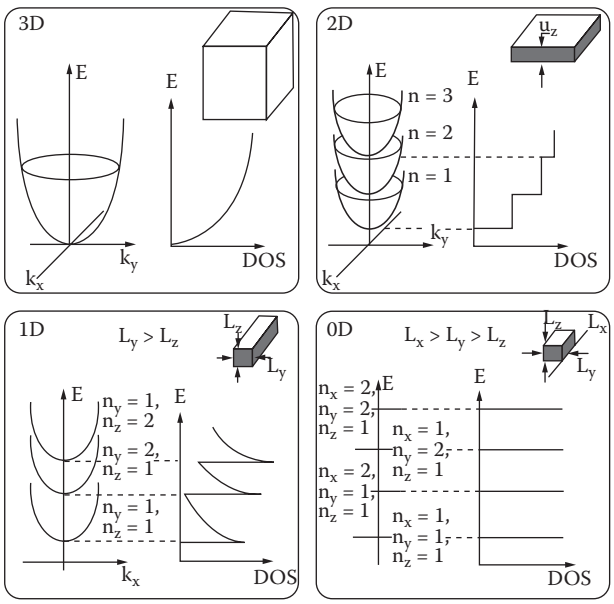

FIGURE 3.22 Quantization in zero (3D), one (2D), two (1D), and three (0D) directions.

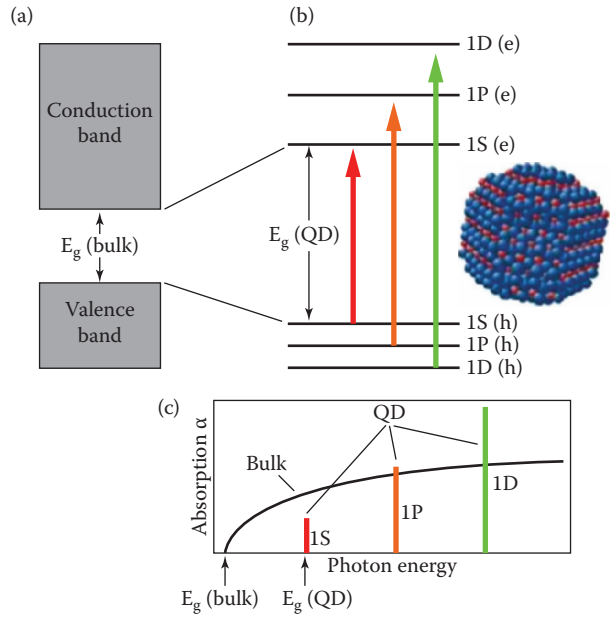

FIGURE 3.23 Blue shift in CdSe quantum dot. (a) CdSe bulk semiconductor. (b) CdSe quantum dot (QD). (c) Quantum dot photon energy absorption spectrum.

CdSe semiconductor quantum dot (see Figure 3.23). Such a spherical nanocrystal may be made from solution using colloid chemistry instead of the epitaxial methods used to make the cubic nanoparticle considered in Volume I, Figure 3.141. The dimensions of this nanocrystal are smaller than the electron de Broglie wavelength or the exciton Bohr radii (see also Volume I, Chapter 3). Semiconductor QDs possess high radiative efficiency, are compatible with semiconductor device technology, and are considered promising elements for implementing the coherent control of the quantum state, which is essential for quantum information processing.

In the case of an electron in a spherical quantum well, the Hamiltonian separates into angular and radial parts, and because of the spherical symmetry this results in the following eigen-energies and eigen-states:

$$E_{n,l,m} = E_{n,l} \quad \text{and} \quad \Psi(r,\theta,\phi) = Y_{l,m}(\theta,\phi)R_{n,l}(r) \qquad (3.1)$$

with $Y_{l,m}(\theta,\phi)$ the spherical harmonics and $R_{n,l}(r)$ the radial wave functions. The energy levels and wave functions do of course depend on the details of the confining potential. If that potential is an infinite spherical well, where $V = 0$ for $r < R$ and $V = \infty$ for $r > R$, then the solutions are the atom-like spherical Bessel functions from Volume I, Figure 3.81, described in the following expressions:

$$E_{n,1} = \frac{\hbar^2 \beta_{n,1}^2}{2m_e^* R^2} \text{ and} \qquad (3.2)$$

$$R_{n,1} = j_1\left(\frac{\beta_{n,1} r}{R}\right) \text{ for } r < R \qquad (3.3)$$

where $j_l(x)$ is the l^{th} spherical Bessel function and the coefficient $\beta_{n,l}$ is the n^{th} zero crossing of $j_l(x)$, with example values $\beta_{0,0} = \pi$ **(1S)**, $\beta_{0,1} = 4.5$ **(1P)**, $\beta_{0,2} = 5.8$ **(1D)**, $\beta_{1,0} = 2\pi$ **(2S)**, and $\beta_{1,1} = 7.7$ **(2P)**. In parentheses and boldface, we list the atomic notations for the orbitals involved. This outcome explains why these spherical nanocrystals are often called *artificial atoms*.

The spacing between the lowest two energy levels $\Delta E = E_{0,1} - E_{0,0}$, also called the *1S transition*, for a CdSe nanocrystal with a conduction band effective mass m_e^* of 0.13 m_e and a radius R of 2 nm is calculated, using Equation 3.2, as follows:

$$E_{n,1} = \frac{2.9 \text{ eV}}{R^2}\left(\frac{\beta_{n,1}}{\beta_{0,0}}\right)^2 \qquad (3.4)$$

or $\Delta E = E_{0,1} - E_{0,0} = 0.76$ eV, which is much larger than the thermal energy of the carriers (kT). This result is schematically represented in Figure 3.23, where in panel c we compare the absorption α of light by bulk CdSe with that by a nanocrystal of CdSe, clearly indicating that the bandgap is wider for the nanoparticle, which results in a blue shift. The probability of optical transitions between two quantum states is controlled by Fermi's Golden Rule (see Volume I, Chapter 3), which predicts that optical absorption must be proportional to the density of states, because a photon cannot be absorbed if there is no final state available for the electronic transition to go to. Bulk semiconductor and nanocrystal have the same overall absorption per unit volume when integrated over all frequencies. But in the case of a nanocrystal, the absorption spectrum consists of a series of discrete transitions with very high absorption transitions (sharp peaks), whereas a bulk semiconductor has a continuous absorption

spectrum. This spectral concentration of a quantum dot enhances all resonant effects and increases the energy selectivity. The sharpening of the density of states (DOS) at specific energies induced by quantum confinement is at the origin of many improvements in the properties of nanostructured materials compared with bulk materials.

The 1S (e) electron level shown in Figure 3.23b increases in energy with a decreasing R, while the 1S (h) energy level decreases for a decreasing R. As a consequence, the bandgap of CdSe grows over a wide range as one varies R, resulting in a dramatic shift in the optical spectra with changing particle size. This is called the *blue shift*, as the energies shift to higher values or shorter wavelengths for a decreasing particle size. The particle size sensitivity of optical spectra enables one to tune continuously those spectra from blue to infrared, for both absorption and emission. This can lead to applications ranging from new more intense light-emitting diodes to more stable fluorescent labels. As an important example, the very strong optical transitions at particular frequencies have motivated researchers to develop quantum dot lasers (the laser principle, which is explained in Volume I, Chapter 5). Arakawa and Sakaki, in 1982, predicted significant increases in the gain and decreases in the threshold current of semiconductor lasers utilizing quantum dots.[56] These predictions set off an intense effort worldwide to fabricate such structures.

In Volume I, Chapter 5, we compared the energy separation calculated above for a semiconductor particle to that of a metal nanoparticle of the same size (2 nm). We found that quantum effects are much more readily observed for semiconductor particles than for metal particles (see "Optical Properties of Metals").

Plasmonic Effects in Metal Nanoparticles

Surface plasmon (SP) waves are coherent electron oscillations at the interface between any two materials where the real part of the dielectric function changes sign across the interface (say a metal-dielectric interface). In the case of metal nanoparticles, we saw in Volume I, Chapter 5, that these surface plasmon waves are localized and are readily observed. These "localized plasmons" may be excited directly by light absorption. For metallic nanoparticles significantly smaller than the wavelength of light, light absorption then concentrates to a narrow wavelength range and results in brilliant colors (see Volume I, Figure 5.94). With changing particle size and shape, those colors change because of changes in the surface plasmon resonance frequency ω_p, the frequency at which conduction electrons oscillate in response to the alternating electric field of the incident electromagnetic radiation (see Equation 5.216). For a gold spherical particle, the frequency is about 0.58 of the bulk plasma frequency. Although the bulk plasma frequency for bulk gold is in the UV range, the SP frequency is in the visible range (close to 520 nm). The Au plasmon effects are illustrated by the historic stained glass which adorn medieval cathedrals (see Figure 3.1). Only materials with free electrons (essentially Au, Ag, and Cu and the alkali metals) possess plasmon resonances in the visible spectrum. Au and Ag often are used in nanophotonics because of their excellent chemical stability and very good conductivity. For nonspherical particles, such as rods, the resonance wavelength depends also on the orientation of the electric field. Confinement and quantization phenomena are visible in semiconductors already at dimensions of 200 nm, whereas in metals they typically are seen only at 1–2 nm. Metallic nanostructures exhibit major changes in their optical spectra due to light absorption by plasmonics waves at the surface of these structures. The plasmonic effects of metal nanoparticles often mask the metal nanoparticle quantum effects.

Transparent Ceramic Nanoparticles

Previously, we dealt with the fascinating quantum properties of semiconductor quantum dots and the plasmonic behavior of metal nanoparticles. Here we clarify the properties of insulating ceramic nanoparticles. Ceramics can be defined as inorganic, nonmetallic materials. They are typically crystalline in nature and are compounds formed between metallic and nonmetallic elements, such as aluminum and oxygen (alumina: Al_2O_3), calcium and oxygen (calcia: CaO), and silicon and nitrogen (silicon nitride: Si_3N_4). The two main categories of ceramic nanoparticles are metal oxide ceramics, such as titanium, zinc, aluminum, calcium, and iron oxides, to name just a few, and silicate nanoparticles (silicates, or silicon oxides), generally in the form of nanoscale

flakes of clays. It is the width of the forbidden bandgap (E_g) that determines whether these ceramics act as insulators ($E_g > 2$ eV) or as semiconductors ($E_g < 2$ eV). The fact that the dimensions of these ceramic nanoparticles are below the critical wavelength of light renders them transparent, which makes for a convenient property for their use in packaging, cosmetics, and coatings. Ceramic nanoparticles, like metal and semiconductor nanoparticles, also can be formed into coatings and bulk materials at lower temperatures than their non-nanocounterparts, reducing manufacturing costs.

Superhydrophobicity and the Lotus Effect

In Volume I, Chapter 6, we saw how nanofeatures on a surface improves the wettability for hydrophilic surfaces ($\theta < 90°$). A drop on such surface will seem to sink into the hydrophilic surface (see Volume I, Figure 6.45a). This phenomenon is called *superhydrophilicity*. For hydrophobic surfaces ($\theta > 90°$) the wettability decreases for a nanotextured surface compared with a polished surface of the same material. It is energetically unfavorable to wet a rough hydrophobic surface and this result in an increased water repellency or superhydrophobicity (Volume I, Figure 6.45b). Superhydrophic surfaces, like a lotus leaf, are also self-cleaning. As we saw in Volume I, Figure 6.46, a droplet on an inclined superhydrophobic surface does not slide off; it rolls off. When droplets roll over contaminant particles, the particles are removed from the surface if the force of absorption of the particles by the droplet is higher than the stiction force between the particles and the surface. Usually the force needed to remove particles is very low because of the minimized contact area between the contaminants and the surface. As a result, the droplet cleans the leaf by rolling off the surface. The combination of the chemistry, the nanostructures, and the adherence properties of dirt and water to the surface, is what Barthlott and Neinhuis named the lotus effect.[57] In the lotus plant, the effect arises because lotus leaves have a very fine surface structure and are coated with hydrophobic wax crystals of around 1 nm in diameter. In the lotus plant, the actual contact area is only 2–3% of the droplet-covered surface.

Several surface treatments have been developed for roof tiles, fabrics, wood, paper, etc., that can stay dry and clean themselves in the same way as the lotus leaf (see Figure 3.24). Water does not adhere to the wood surface shown in Figure 3.24 but rolls off the paint, picking up and washing away debris in the process. By remaining dry, the coating also resists better mold, mildew, and algae. The lotus effect can be achieved, for example, by using special fluorochemical or silicone treatments on structured surfaces or with compositions containing microscale and nanoscale particulates. In one method, by Guo et al.,[58] an aluminum surface is made superhydrophobic by immersing it in sodium hydroxide for several hours (which roughens the surface) followed by spin coating a layer of perfluorononane to a thickness of 2 nm. This procedure increases the water contact angle from 67° to 168°. Electron microscope images show that the aluminum surface resembles that of a lotus surface, with a porous microstructure containing trapped air. Any surface treatment that creates micro- or nanoscale roughness with features having a height to width ratio greater than 1 that is subsequently coated with a thin hydrophobic coating will exhibit the lotus effect. Clothing that repels water has already been developed and marketed by brands such as Gap and Dockers; it uses a fabric named Nano-Care http://www.usato day.com/tech/columnist/cckev060.htm.

The BASF's lotus-effect aerosol spray, demonstrated in Figure 3.24, combines nanoparticles with hydrophobic polymers such as polypropylene,

FIGURE 3.24 Water-repellant wood: BASF's lotus-effect aerosol spray combines nanoparticles with hydrophobic polymers such as polypropylene, polyethylene, and waxes. As it dries, the coating develops a nanostructure through self-assembly. BASF says that the spray particularly suits rough surfaces such as paper, leather, textiles, and masonry.

polyethylene, and waxes. It also includes a propellant gas. As it dries, the coating develops a nanostructure through self-assembly.

Magnetic Properties of Nanoparticles

Magnetic behavior of nanostructured materials was investigated from the early days of nanotechnology. One of the key findings so far is that the coercivity H_c, the intensity of the magnetic field needed to reduce the magnetization of a ferromagnetic material to zero after it has reached saturation, as a function of particle size goes through a maximum (see Figure 8.52).[59,60] The coercivity first increases linearly with decreasing grain size. The reason for the coercivity H_c increasing proportional to $1/d$ is that as particles decrease in size the magnetic domain size starts to coincide more and more with the grain size. As an example, for Fe the $1/d$ scaling is observed from 100 μm down to 40 nm. In the single-domain region a change of magnetization can only be produced by rotation of the magnetization of a single grain or crystallite as a whole, which requires strong magnetic fields, depending on the shape and anisotropy of the particle. As the size of the magnetic elements is further scaled down the coercivity goes over a peak and then decreases very fast (with a d^6 dependence). In this regime, a transformation from ferromagnetic to superparamagnetic behavior takes place. Typical particle sizes for the ferrro- to superparamagnetic phase transformation are between 10 and 20 nm for oxides and 1–3 nm for metals. In the superparamagnetic state of the material, the room temperature thermal energy, kT, overcomes the magnetostatic energy of the domain or particle. The resulting fluctuations in the direction of magnetization cause the magnetic field to average to zero. Thus, the material behaves in a manner similar to paramagnetism, except that instead of each individual atom being independently influenced by an external magnetic field, the magnetic moment of the entire crystallite tends to align with the magnetic field. Superparamagnetic particles are attracted to a magnetic field but retain no residual magnetism after the field is removed (no hysteresis). These superparamagnetic nanoparticles, feature a high saturation magnetization, high relative permeability, low coercivity, high resistivity, and low hysteresis loss, and all of this benefits a large number of applications,* including in ferrofluids (see Figure 8.53).

The quest for a high-throughput manufacturing method for nanoparticles—be they semiconductors, metals, or insulators—is driven by their many extraordinary properties, some of which are summarized in Table 3.4.

Nanoparticle Manufacture

Introduction

Generally, nanoparticle manufacturing techniques sort out in either "bottom-up" methods or "top down" methods. In bottom-up methods, as we saw above, the nanoparticles are synthesized directly to the desired shape and size. One such bottom-up method is chemical synthesis in a liquid. An example of a top-down technique is a mechanical method such as ball milling (also called *mechanical attrition*). A further way of categorizing nanoparticle production techniques is based on the phase in which the process takes place, i.e., gas phase, liquid phase, and solid phase methods. The solid phase method is limited in terms of producing nanometer scale particles. The liquid phase method and the gas phase method are more suitable. Yet another way of classifying nanoparticle manufacturing techniques, the method we adapt in this chapter, is as follows:

1. In situ fabrication: These techniques incorporate lithography, vacuum coating [e.g., molecular beam epitaxial growth (MBE) and metallorganic chemical vapor deposition (MOCVD) epitaxial growth] and spray coating on solid surfaces.
2. Mechanical manufacturing: This is a top-down method that reduces the size of particles by attrition, for example, ball milling or planetary grinding.
3. Liquid phase synthesis (wet chemistry): This is fundamentally a bottom-up technique; i.e., it starts with ions or molecules and builds up into larger structures. These nanoparticle

* On the other hand, it is also because of superparamagnetism that hard drives are expected to stop growing once they reach a density of 150 gigabits per square inch.

Table 3.4 Semiconductor, Metal, and Insulator Nanoparticle Properties

Semiconductor
Quantum confinement at dimensions ~10–100 nm. Blue shift when the nanoparticle is of the size of the exciton's Bohr radius.
Light absorption is determined by the band-edge transition, which is strongly size- and shape-dependent, making the absorption highly tunable.
Density of states: electronic energy levels around the Fermi level are strongly affected for sizes in the 10–100-nm range.
Luminescence is very intense and can be tuned.
The I-V behavior is characterized by the Coulomb blockade.
Quantum efficiency (~0.1–0.5), spectral range of emission (400–2000 nm), and cross-section ~10^{-19} m^2.
A very high S/V ratio leads to very high catalytic properties and lowers the melting temperature T_m.
Metal
Quantum confinement at smaller dimensions ~2–3 nm. Electron motion is limited by the size of nanoparticle.
Light absorption is determined by the surface plasmon resonance, which is size- and shape-dependent.
Density of states: electronic energy levels around the Fermi level are strongly affected for sizes in the 1–2-nm range.
Luminescence is very weak.
The I-V behavior is characterized by the Coulomb blockade.
Quantum efficiency (~10^{-4}), spectral range of emission (500–9000 nm), and cross-section ~10^{-13} m^2.
A very high S/V ratio promotes very high catalytic properties and lowers melting temperature T_m.
Superparamagnetic nanoparticles feature a high saturation magnetization, high relative permeability, low coercivity, high resistivity, and low hysteresis loss, and all of this benefits ferrofluids.
Insulator
Improved sintering and hardness. Nanophase powder compacts more easily in the sintering process. Successful sintering enhances hardness of materials. Nanophase powders compact more easily than their analogous submicrometer particles.
Strength and hardness. Better for materials with smaller crystal grains, as dictated by the Hall-Petch relation (Volume I, Equation 2.70).
The specific heat capacity (C_v) of nanocrystalline materials is higher than that of their bulk counterparts.
A very high S/V ratio promotes very high catalytic properties and lowers melting temperature T_m.

manufacturing techniques historically can be placed under the title of colloid chemistry and involve classic "sol-gel" processes or other aggregation processes.

4. Gas phase synthesis: These methods include plasma vaporization, chemical vapor synthesis, and laser ablation.

Terminology one encounters frequently when discussing manufacture of nanoparticles includes:

- Cluster: A collection of units (atoms or reactive molecules) of up to about fifty units
- Colloids: A stable liquid phase containing particles in the 1–1000 nm range
- Nanoparticle: A solid particle in the 1–100 nm range that could be noncrystalline, an aggregate of crystals, or a single crystal
- Nanocrystal: A solid particle that is a single crystal in the nanometer range

In Situ Fabrication

Lithography Techniques

In a lithographic top-down approach, electron beam or ion beam lithography may be used to etch in situ a pattern of columns in a quantum well heterostructure [e.g., a GaAs/AlGaAs quantum well (Figure 3.25)]. The quantum well heterostructure provides

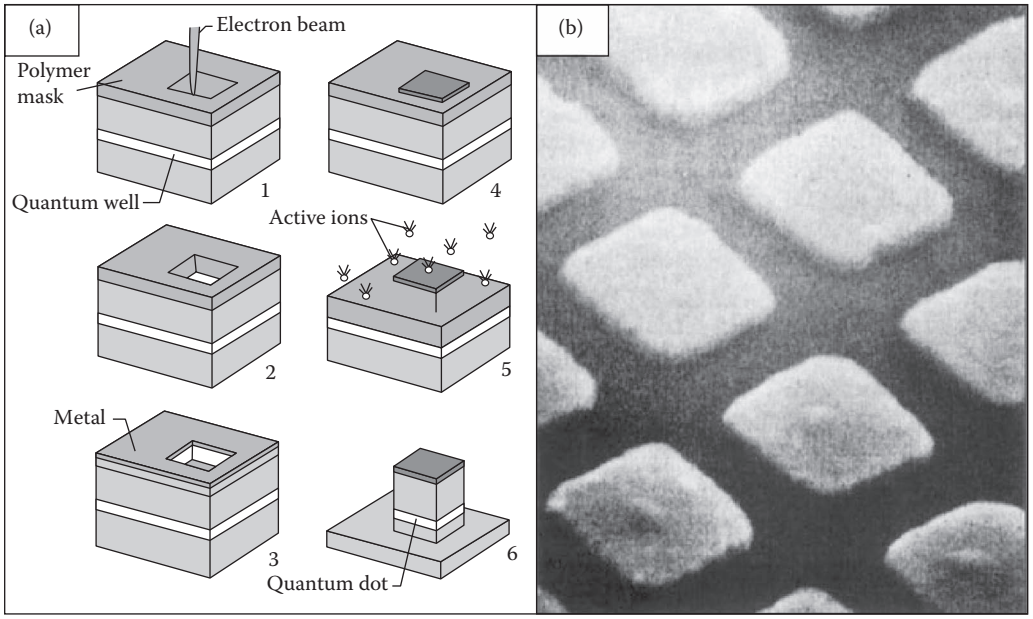

FIGURE 3.25 Fabrication of small, laterally patterned multiple quantum dot columns by e-beam lithography in a GaAs/AlGaAs. (a) Process of quantum dot etching. (b) Etched quantum dots in a Gas/AlGaAs well (scanning electron microscope picture).[61]

1D electron confinement in a plane because of the mismatch of the bandgaps of the two composing materials resulting in the formation of a potential energy well at their interfaces (see also Volume I, Figures 3.122 and 3.128). In the example in Figure 3.25, a positive resist is used as electron or ion beam mask and in the exposed areas the mask is removed. Next, the entire surface is covered with a thin metal layer. After a lift-off development, the polymer film and the protective metal layer are removed, and a clean surface of the sample is obtained, except for the previously exposed areas, where the metal layer remains (4). Next, by reactive ion etching, the areas not protected by the metal mask, slim pillars are created, containing the cut-out fragments of quantum wells (5–6). In this way, the motion of electrons, which initially is confined in the plane of the quantum well, is further restricted to a small pillar with a diameter of the order of 10–100 nm. Owing to the simplicity of the production of thin, homogeneous quantum wells, GaAs is the most commonly used material for creating dots by means of etching. Disadvantages of this technique are that it is slow, low density, and prone to defect formation.

As pointed out in Volume I, Chapter 3, confinement in lateral directions may also be implemented using electrostatic confinement with metal electrodes, lithographically patterned on the surface of a quantum well structure (see Volume I, Figure 3.138, for a quantum wire and Figure 3.144 for a quantum dot).

Self-Organized Epitaxial Growth

Self-organized epitaxial growth is another example of in situ nanoparticle manufacture. Oriented growth is referred to as epitaxy and, as we saw in Volume II, Chapter 7, it is subdivided into homoepitaxy and heteroepitaxy. Homoepitaxy is epitaxy performed with only one material: a crystalline film is grown on a substrate or film of the same material. Heteroepitaxy is epitaxy performed with materials that are different from each other: a crystalline film grows on a crystalline substrate or film of another material. This technology may be applied for growing crystalline films of materials of which single crystals cannot be obtained and for the integration of crystalline layers of different materials. Examples include gallium nitride (GaN) on sapphire or aluminum gallium indium phosphide (AlGaInP) on gallium arsenide (GaAs). Here, we will use the heteroepitaxy technique to form islands (quantum dots) of one material on the surface of another. To understand this method better, we first gather some

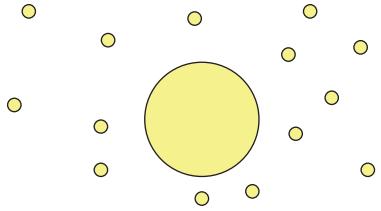

FIGURE 3.26 Nanoparticle growth in a vapor.

background on nucleation and growth of particles in air and on a solid surface.

Consider a droplet of radius r in contact with a vapor (Figure 3.26). The Gibbs free energy change ΔG for this system is given by the following expression:

$$\Delta G = \frac{4}{3}\pi r^3 \Delta G_V + 4\pi r^2 \gamma \tag{3.5}$$

where γ = surface tension, the first term on the right is the free energy change per unit volume, and the second term on the right is the free energy change per unit area of surface. The first term can be calculated as follows:

$$\Delta G_V = \frac{kT}{\Omega}\ln\left(\frac{P_V}{P_S}\right) = \frac{kT}{\Omega}\ln(1+S) \tag{3.6}$$

with S defined as supersatuation $S = \frac{P_v - P_s}{P_s}$, Ω = the atomic volume (volume per atom), P_v the actual pressure in the gas phase, and P_s the saturated vapor pressure at equilibrium. When $P > P_s$, one defines supersaturation, $P = P_s$ means equilibrium is attained, and at $P < P_s$ the gas phase is undersaturated. The presence of surface tension, as illustrated in Figure 3.27, always produces an activation barrier to the nucleation of condensed phases. This is true for solids and for liquids (see, for example, the case of etching a single crystal in a solution as illustrated in Volume II, Figure 4.60).

The critical nucleus size, marked r_c in Figure 3.27, can be calculated from the following:

$$\frac{\partial \Delta G}{\partial r} = 4\pi r^2 \Delta G_V + 8\pi r \gamma \tag{3.7}$$

The maximum of the curve is at $\frac{\partial \Delta G}{\partial r} = 0$, so that $r_{critical} = \frac{2-\gamma}{\Delta G_v}$ and, with $\Delta G_v = \frac{kT}{\Omega}\ln\left(\frac{P_v}{P_s}\right) = \frac{kT}{\Omega}(1+S)$ (Equation 3.6) we obtain:

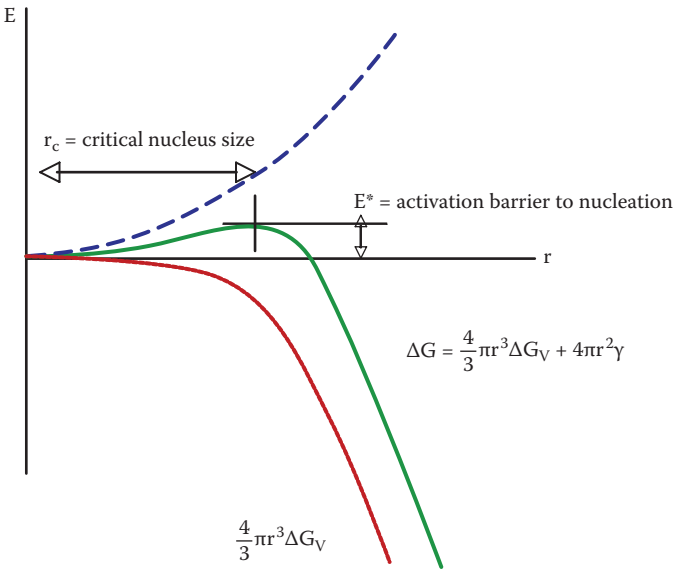

FIGURE 3.27 The Gibbs free energy as a function of particle radius.

$$r_{critical} = \frac{-2\gamma\Omega}{kT\ln(1+S)} \tag{3.8}$$

and also:

$$\Delta G^*_{critical} = \frac{16\pi\gamma^3}{3(\Delta G_v)^2} \tag{3.9}$$

From Equation 3.8, as supersaturation S increases, the critical nucleus size decreases, so that for very small particles one needs high super-saturation and rapid nucleation.

The deposition rate of atoms on the nanoparticle is then given as follows:

$$\frac{dN}{dt} = hn_s A^* \exp^{\frac{-\Delta G^*_{critical}}{kT}} \tag{3.10}$$

where h = the Arrhenius pre-exponential
n_s = the number density of atoms in the gas phase
A* = the area of the critical nucleus

The Schwöbel barrier ($\Delta G^*_{critical}$) determines the kinetics (dN/dt) of the system.

For condensation of atoms on a solid surface (Figure 3.28) instead of on a spherical particle, Equation 3.5 is modified to the following expression:

$$\Delta G = l_1 l_2 h \Delta G_V + l_1 l_2(\gamma) + l_1\beta_1 + l_2\beta_2 \tag{3.11}$$

Surface tension — Line tension

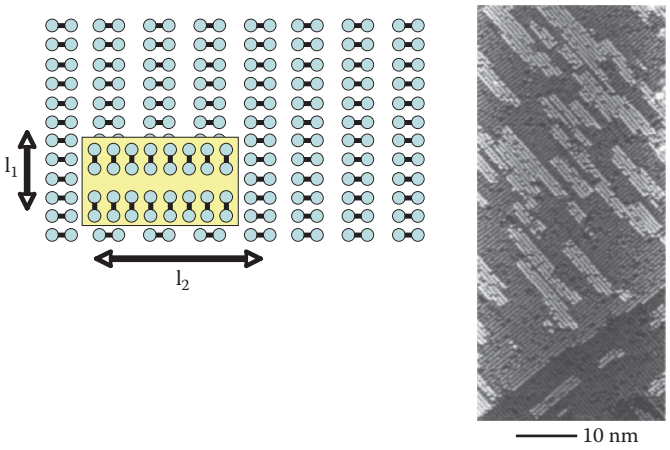

FIGURE 3.28 Island formation on flat solid surfaces.[62]

To identify l_1 and l_2 see Figure 3.28. The product $l_1 l_2$ corresponds to the area of the adsorbate coverage. Where γ is the surface tension and β_1 and β_2 are line tensions. A line tension represents an additional contribution to the surface tension due to the presence of steps. The step line tension may be calculated as the difference between the surface tension of stepped and flat surfaces per step and step length. When an adsorbate coverage as shown in Figure 3.28 exceeds one monolayer, one speaks of thin-film growth. Thin-film growth is controlled by the interplay of thermodynamics and kinetics, and the following elementary processes take part: adsorption, surface diffusion, re-evaporation, capturing by defects, and combination with other adatoms to form clusters (nucleation). Small clusters are metastable, but they become stable at a critical island size, determined by the energy gain for condensation and the energy cost to form new surfaces. Depending on the surface diffusion of atoms, different growth modes result, governed by the bond strength between the atoms in the layer and the atom-substrate bonds. The occurrence of these different growth modes can be understood qualitatively in terms of the surface tension, γ (surface energy) as depicted in Figure 3.29.

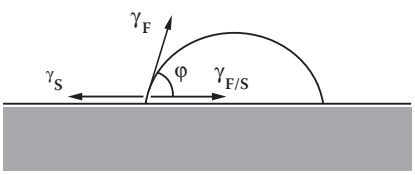

FIGURE 3.29 Surface tension of a film forming on a solid surface (see also Volume I, Figure 6.43).

The surface tension, represented by the symbol γ (see Volume I, Equation 6.88), is the force along a line of unit length, where the force is parallel to the surface but perpendicular to the line. Surface tension is therefore measured in force per unit length. Its SI unit is Newton per meter, but the cgs unit of dynes per centimeter is most commonly used. The wetting angle φ of a drop-like island, illustrated in Figure 3.29, is determined by the surface tensions of substrate (γ_S), film (γ_F), and film-substrate interface (γ_{FS}). Balance of these forces changes during growth. Flat surfaces exhibit three canonical growth modes, depending on the surface and interface energies. Beyond that, one finds more exotic growth modes at stepped surfaces.

In the case of $\gamma_S > \gamma_F + \gamma_{FS}$, typically, the first layer wets the surface but subsequent layers do not. The first atomic layer tries to coat the whole surface to provide optimal free energy reduction but with subsequent layers the situation changes: the first atomic layer reduces the surface energy of the substrate and new atoms do not experience the same interface energy as the first atomic layer. In addition, the added layers have to absorb the misfit strain energy, which grows with increasing film thickness (see below). Therefore, one can have either a continued layer-by-layer growth mode (Frank-van der Merwe mode), which is relatively rare, or the formation of islands on top of a flat first layer (Stranski-Krastanov growth mode). If the energy balance at the interface is tipped the opposite way, i.e., $\gamma_S < \gamma_F + \gamma_{FS}$, the overlayer has a tendency to nucleate three-dimensional islands right away and leave the low-energy substrate exposed (Volmer-Weber growth). This situation usually occurs when growing more reactive materials on top of an inert substrate, such as in the case of transition metals on a noble metal or an oxide.

The Stranski-Krastanov growth (SK growth; also spelled Stransky-Krastanov or Stranski-Krastanow) is one of the three primary modes by which thin films grow epitaxially at a crystal surface or interface. Also known as *layer-plus-island growth*, the SK growth mechanism was first noted by Ivan Stranski and L. Von Krastanov in 1939. It was not until 1958, however, in a seminal work by Ernst Bauer published in *Zeitschrift für Kristallographie*, that the

SK, Volmer-Weber, and Frank-van der Merwe mechanisms were systematically classified as the primary thin-film growth processes. Since then, SK growth has been the subject of intense investigation, not only to better understand the complex thermodynamics and kinetics at the core of thin-film formation, but also as a route to fabricating novel nanostructures for application in the microelectronics industry.

The range of possible growth modes becomes richer when going down in dimensionality. For example, when growing one-dimensional stripes on a two-dimensional, stepped surface. In addition to an extension of the three growth modes described above, one finds additional phenomena that are related to the interaction with the one-dimensional steps. As we saw in Equation 3.11 when stepped surfaces are involved line tensions due to the presence of steps contribute to the surface tension. Layer-by-layer growth turns into row-by-row growth, which is often called *step flow growth* because the step edge propagates downhill. There are other modes as well, such as the reverse step flow, where the material accumulates at the top of the step edge and propagates in the opposite direction. For manipulating these different growth modes, it is important to understand and control the surface and interface energies. Broadly speaking, one distinguishes three classes of solids where three different terms dominate the surface energy. Metals try to achieve the highest possible number of neighbors. Therefore, the surface with the lowest free energy is close-packed. Ionic solids, such as alkali halides, have the constraint that a stable surface needs to be charge neutral. Otherwise the Coulomb energy of a sheet of charge diverges. Covalent solids, such as semiconductors, have very directional bonds that rearrange themselves extensively in order to minimize the density of broken bonds at the surface. Bond counting is a first approximation, but the intricate rearrangement of atoms at semiconductor surfaces often defies our expectations. The absolute values of the surface energy are typically highest for transition metals and rare earths (2–3 Jm^{-2}); intermediate for covalent semiconductors, noble metals, and simple metals (1–2 Jm^{-2}); and lowest for ionic insulators (0.3–1 Jm^{-2}). The three growth modes are summarized in Figure 3.30.

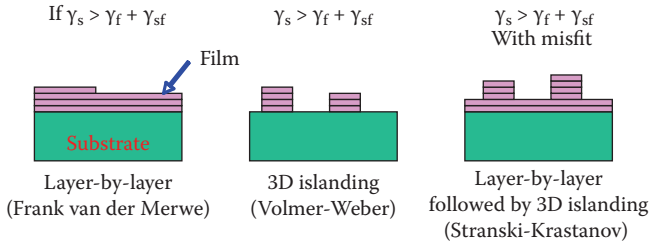

FIGURE 3.30 Summary of the three film growth mechanisms.

1. $\gamma_S > \gamma_F + \gamma_{FS}$. At the highest surface diffusion rates, layer-by-layer or Frank-van der Merwe growth mode is observed. The growing layer reduces the substrate surface very fast, i.e., it wets the surface.
2. $\gamma_S < \gamma_F + \gamma_{FS}$. High rate of incoming atoms and high Ehrlich-Schwöbel barrier, leads to island growth or Volmer-Weber growth. The growing layer wants to minimize interface energy and its own surface energy and the layer "balls up" on the surface.
3. $\gamma_S > \gamma_F + \gamma_{FS}$ with misfit. Layer plus island or SK growth. SK growth is possible in a heteroepitaxial system (misfit). This is the case of most interest for nanomanufacturing.

If the crystal structure (lattice constants) is different for substrate and film, strain appears at the interface because of this misfit. The strain depends on the size of this misfit: $\varepsilon = (b - a)/a$, with *a* and *b* the lattice constants for substrate and film (see also Vegard's law, Volume I, Equation 4.74). The elastic strain of a lattice mismatch can be accommodated either by a pseudomorphic growth or by misfit dislocations, as illustrated in Figure 3.31.

In Figure 3.32, this is illustrated for the case of Ge on Si, where we see how the island structure forms (see also Volume I, Figure 4.59). In this case, since the Ge lattice is 4% bigger than Si, bonding of Ge to Si compresses the Ge lattice by 4%. As the deposited film gets thicker, atoms continue to be forced to adapt to a different lattice constant, and the total strain energy increases linearly with the thickness of the growing film:

$$E_{strain} = \lambda \left(\frac{\Delta a}{a} \right)^2 At \qquad (3.12)$$

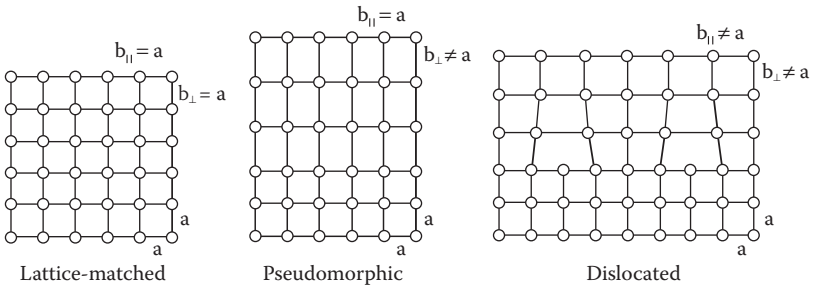

FIGURE 3.31 The deposited atoms try to adopt to the lattice constant. A lattice mismatch can be accommodated by pseudomorphic growth or by misfit dislocations.

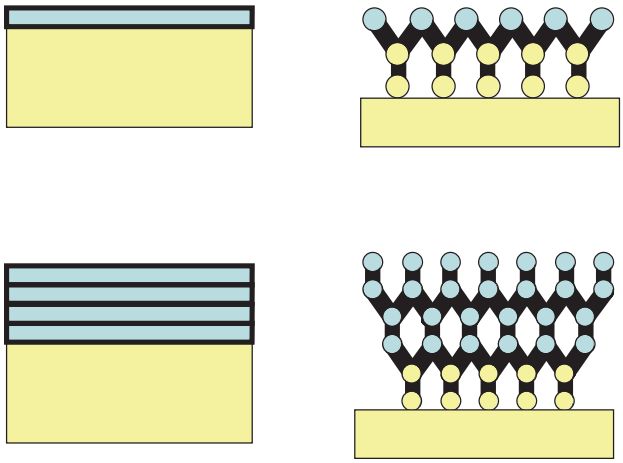

FIGURE 3.32 As the germanium lattice is 4% bigger than that of Si, bonding of Ge to Si compresses the Ge lattice by 4%. As the deposited film gets thicker, atoms continue to be forced to adapt to a different lattice constant, and the total strain energy increases linearly with the thickness of the growing film.

where

λ = elastic modulus
Δa = forced change in lattice constant
a = "free" lattice constant
A = area
t = thickness

In lattice-mismatched systems, self-organized quantum dots can be achieved by utilizing the Stranski-Krastanov growth mode (in an MBE or MOCVD reactor). In this mode, isolated islands form spontaneously above a certain critical thickness to relieve the mismatch strain energy. This is illustrated in Figure 3.33.

Depending on the growth conditions, one can get compact islands or ramified (fractal) islands. The compactness of the islands depends on the diffusion probability along its edges: this in turn depends on the surface temperature. In the extreme case of hit-and-stick, at low temperatures, where surface diffusion is limited, a diffusion limited aggregation model holds, which predicts fractal islands. This is demonstrated for the example of Pt growth on Pt(111) in Figure 3.34a (left-most image). The equilibrium shapes are hexagons (at 700 K) (Figure 3.34 panel c). The size distribution of the islands is affected by critical island size, coverage, and substrate temperature. According to scaling theory, one can derive a scaling relation for the size distribution, which depends only on the critical size.[63]

Certain surfactants may change the growth modes. Adding surfactants, a modification of the kinetics takes place rather than a change of the energetics. For example, the adatom diffusivity on the terraces might be influenced, the number of nucleation centers can be changed, the Schwöbel barrier may be changed, etc. The classic example is the growth of Ge on Si(111). On the bare surface there is a Stranski-Krastanov (SK) growth. With Sb as a surfactant, the film grows in a layer-by-layer fashion. Another example is the influence of H on Si(111) on the growth of Ag.

A successful method for quantum dot laser fabrication is based on the self-organized SK growth described here. SK growth occurs, we just saw, when a few monolayers of QD material (e.g., InGaAs) are deposited on a lattice mismatched material (e.g., GaAs). First, a quantum well-like wetting layer forms, from which quantum dots emerge. Strain, surface energy, and interaction with surrounding dots determine the dot shape, size, and distribution. Self-organized quantum dots are distributed on a semiconductor surface in a random way, and their size is subject to variations of a few percent (see

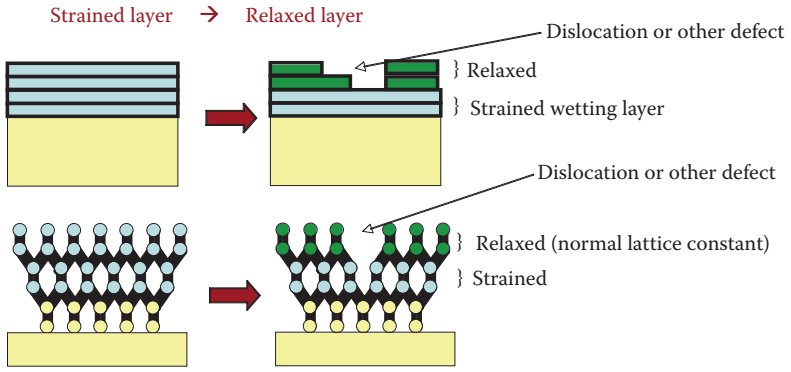

FIGURE 3.33 Stranski-Krastanov growth mode (in an MBE growth or MOCVD reactor): isolated islands form spontaneously above a certain critical thickness to relieve the mismatch strain energy.

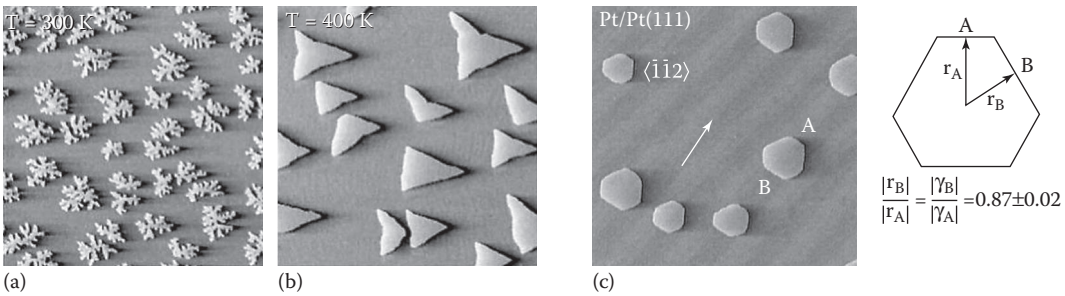

FIGURE 3.34 STM image of Pt growth on Pt(111). At 300 (a), 400 (b), and 700 K (c).

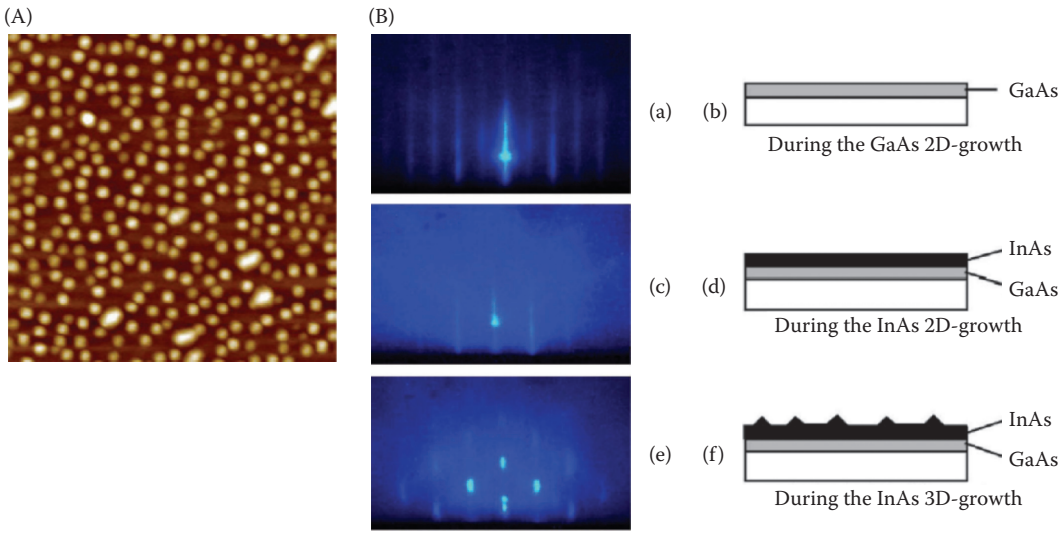

FIGURE 3.35 InAs quantum dots on a GaAs surface. (A) Atomic force microscope (AFM) picture of InAs/GaAs quantum dots. (B) Reflection high-energy electron diffraction (RHEED) patterns (a, c, e) during the two-dimensional (2D) deposition of GaAs (b) and the 2D deposition of InAs (d), and the 3D deposition of InAs (f) on a (100)GaAs buffer layer.[64]

Figure 3.35 with InAs quantum dots on a GaAs surface). While single quantum dots have sharp, atom-like emission lines, ensembles of quantum dots show an inhomogeneously broadened spectrum. Size, distribution, composition, and shape of the quantum dots can be chosen by different growth conditions such as temperature and precursor pressure. Larger quantum dots emit longer wavelengths, and smaller dots emit shorter wavelengths. The main advantages of self-organized growth are its integration into a single growth run, the low defect density, and the high dot density. The main limitations of this method are the cost of fabrication and the lack of control over positioning of individual dots. Some claim that Stranski-Krastanov methods for growing self-assembly quantum dots has rendered the

lithographic approach to semiconductor quantum dot fabrication virtually obsolete.

Reflection high-energy electron diffraction (RHEED) is very sensitive to surface changes, because of either structural changes or adsorption, and is a good method by which to monitor island growth. In RHEED, a high-energy electron beam (3–100 keV) is directed at the sample surface at a grazing angle. The distance between the streaks in a RHEED pattern (see Figure 3.35) gives us the surface lattice unit cell size. For an atomically flat surface, sharp RHEED patterns result and with rougher surfaces one gets diffused RHEED patterns. In layer-by-layer growth mode, RHEED oscillations are observed (Figure 3.35Ba). These are a direct measure of growth rates in MBE: the oscillation frequency corresponds to the monolayer growth rate. The incident angle dependence of the oscillations suggest that interference between electrons scattering from the underlying layer and the partially grown layer contribute to these oscillations. The magnitude of the RHEED oscillations damps out (see Figure 3.35Be) because as the growth progresses, islands nucleate before the previous layer is finished.

Epitaxial growth on patterned substrates can organize the quantum dots on a surface into a regular pattern, as illustrated in Figure 3.36 where the growth of AlGaAs in pyramid-shaped recesses is shown. The recesses are formed by selective ion etching. The main disadvantage of this technique is that the density of QDs is limited by the mask pattern.

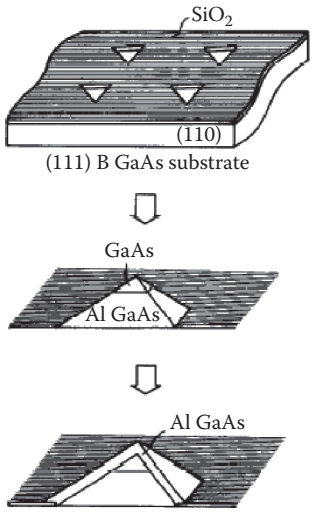

FIGURE 3.36 Growth of quantum dots in pyramid-shaped recesses on a GaAs substrate.[65]

Solid-State Processes

Solid-state processes, involving top-down grinding or milling to produce ceramic nanoparticles, are also referred to as mechanical attrition methods. In mechanical attrition, macro- or microscale particles are ground in a ball mill or in other size-reducing mechanisms. The resulting particles are air classified to recover the nanoparticles. Ball milling involves using fixed and moving elements to reduce larger particles into micron-sized and nanosized particles. The material to be ground is reduced in size because of the interaction of the fixed elements, the moving elements, and the material itself. The milling materials, the milling time, and the atmosphere all affect the nanoparticle properties. The kinetic energy transfer from balls to the powder in the milling bowl accomplishes the reduction in grain size. Since the kinetic energy of the balls is a function of their mass and velocity, dense materials such as steel or tungsten carbide are preferred. Other materials used as balls are agate, sintered corundum, zirconium dioxide, Teflon, chrome nickel, silicon nitride, etc. In order to prevent excessive abrasion, the hardness of the grinding bowl used and of the grinding balls must be higher than that of the materials that are being ground. Normally, grinding bowls and grinding balls should be made of the same material.

In the initial stage of milling, a fast decrease of grain size occurs that slows down after extended milling. Initially the kinetic energy transfer leads to the production of a myriad of dislocations in the powder grains resulting in atomic level strains. At a certain strain level, the dislocations annihilate and recombine to form small-angle grain boundaries, separating the individual grains. This way, subgrains with reduced grain size are formed. During further milling, this process extends throughout the entire sample. To maintain this reduction in size, the material must experience very high stresses. However, extended traditional ball milling cannot maintain the required high stresses, and hence reduction of grain size is limited. The other two parameters also causing a limit to grain size reduction in traditional ball milling are the local temperature developed due to ball collisions and the overall temperature in the bowl. A rise in temperature also results from

Table 3.5 Traditional Ball Milling Compared with High-Energy Ball Milling

	Ball Milling	High-Energy Ball Milling
Milling time	<1 h	20–200 h
Impact energy (W/g per ball)	0.001	0.2
Particle size	μm	μm clusters
Structural changes	No	Yes
Chemical changes	No	Yes
Atmosphere	No control	Vacuum, inert gas
Temperature	No control	Liquid nitrogen, –700°C

collisions between balls and balls, balls and powder, and balls and wall. Traditional ball milling thus produces only fine powders. In addition, traditional ball milling requires an increasing amount of energy and time to produce incrementally smaller particles. To produce nanomaterials, high-energy ball milling must be used (see Table 3.5).

High-energy ball milling uses steel balls to transfer mechanical energy into materials and creates structure changes and chemical reactions at ambient temperature (mechanochemistry). The impact energy is considerably higher, longer milling times are employed, and the process is carried out at liquid nitrogen temperatures in vacuum or in an inert atmosphere. High-energy ball milling can produce nanosized oxides and nitrides (<100 nm) via mechanical chemistry and has been recognized as one important synthesis method for nanomaterials, including nanoparticle, nanotube, nanocrystalline, nanoporous, and nanocomposite materials.

High-energy ball milling (see Figure 3.37 for a typical high-energy ball mill) is used for the commercial manufacture of magnetic, catalytic, and structural nanoparticles. Unfortunately, ball milling usually produces nanoparticles that are nonuniform in size and shape. The attrition approach is used to produce nanoparticles from materials that do not readily lend themselves to gas or liquid phase preparation.

FIGURE 3.37 High-energy ball milling in a rotating steel ball mill.

Liquid Phase Synthesis

Several liquid phase nanoparticle synthesis methods were reviewed in Volumes I and II. Here, we briefly review the most salient points about those different liquid phase synthesis methods.

An important example of liquid phase nanoparticle synthesis is colloidal processing as detailed in Volume I, Chapter 7, where the Derjaguin, Landau, Verwey, and Overbeek theory (the DLVO theory) was used to describe the stability of a colloid (see "Intermolecular Forces"). A colloidal system, we remember, consists of two separate phases: a dispersed phase (or internal phase) and a continuous phase (or dispersion medium) that can be a solid, a liquid, or a gas. The colloids of interest here are sols, in which solid particles are dispersed in a liquid. Chemical reactions can be fine-tuned into forming dispersed nanoparticles, and capping the dispersed solid particles, formed by these chemical reactions with appropriate ligands, stabilizes them. This method is widely used for preparation of quantum dots (semiconductor nanoparticles) and was pioneered by Columbia University's Louis Brus (Volume I, Figure 3.68) in the late 1970s when he was at Bell Labs and it was carried on by two of his post docs, Paul Alivisatos and Moungi Bawendi. As we learned in Volume I, Chapter 3, before 1993, quantum dots (QDs) were often prepared from colloidal aqueous solutions with added stabilizing agents to avoid colloid precipitation. In 1993, Bawendi and coworkers synthesized the best luminescent CdSe quantum dots made up to that time by using a high-temperature organometallic procedure instead.[66,67]

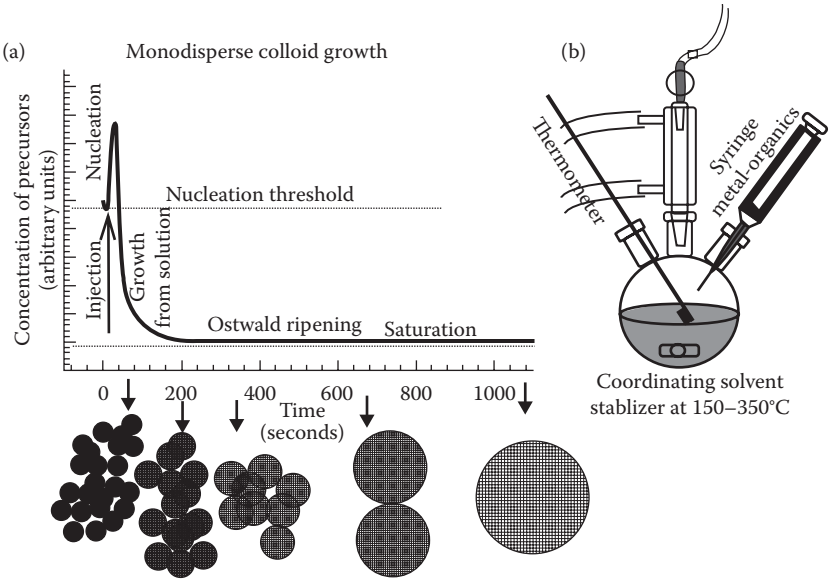

FIGURE 3.38 (a) Schematic depicting the stages of nucleation and growth for the preparation of monodisperse quantum dots (QDs) in the framework of the La Mer and Dinegar model. As nanocrystals grow over time, a size series of QDs may be isolated by periodically removing aliquots from the reaction vessel. (b) Representation of a typical apparatus used in monodisperse QD synthesis.[68]

Crystallites from –12 Å to –115 Å in diameter with consistent crystal structure, surface derivatization, and a high degree of monodispersity were prepared in a single reaction based on the pyrolysis of organometallic reagents by their injection into a hot coordinating nonaqueous solvent (see Figure 3.38b and Volume I, Figures 7.102 and 7.103).

A schematic to explain the formation of uniform nanoparticles in solution is shown in Figure 3.38a. In homogeneous precipitation, a short single burst of nucleation occurs when the concentration of constituent species reaches critical supersaturation. LaMer and Dinegar (1950) applied classic nucleation theory to qualitatively describe the kinetics of this type of burst nucleation. They proposed that from a strong initial supersaturation, a rapid nucleation or burst of particles occurs, followed by the slower absorption of diffusing atomic matter onto these nucleated particles. Their key observation was that the reduction in supersaturation after the nucleation burst strongly depletes the local availability (concentration) of constituent species, thus decreasing the rate of further nucleation, leading ultimately to a narrow size distribution of the nucleated, diffusively growing nanocrystals. Ostwald ripening may broaden the resulting distribution of nanocrystals. In Figure 3.38a this process starts at about 300s after injection. In Ostwald ripening, many small crystals initially form in a system, but they slowly disappear, except for a few that grow larger at the expense of the small crystals. The smaller crystals act as "nutrients" for the bigger crystals. This is a spontaneous process that occurs because larger crystals are more energetically favored than smaller crystals. While the formation of many small crystals is kinetically favored (i.e., they nucleate more easily), large crystals are thermodynamically favored. Thus, from a standpoint of kinetics, it is easier to nucleate many small crystals. However, small crystals have a larger ratio of surface area to volume than large crystals. Molecules on the surface are energetically less stable than the ones already well ordered and packed in the interior. Large crystals, with their greater volume to surface area ratio, represent a lower energy state.

Colloidal synthesis is by far the cheapest method and has the advantage of being carried out in benchtop conditions. For an example of a typical set-up see the apparatus in Figure 3.38b. This method is simple and can fabricate large quantities of quantum dots.

In Volume II, Chapter 8, we introduced sol-gel processing, which produces particles (typically metal oxides) by a series of hydrolysis and condensation reactions to form a sol of particles suspended

in a liquid phase (Volume II, Figure 8.2). The sol-gel technique constitutes a chemical forming process for making very small particles—say, 20–40 nm in diameter—a particle size that is virtually impossible to make by conventional mechanical grinding (Volume II, Figure 8.1). The method is used to synthesize glass, ceramic, and glass-ceramic nanoparticles. From Volume II, Figure 8.2, ultrafine and uniform ceramic powders may be formed either by grinding of a xerogel or by slowly drying the sol. The disadvantages of sol-gel processing include the toxic chemicals required for the reactions and the lengthy preparation time.

Additional liquid phase nanoparticle synthesis techniques include sonochemical processing, cavitation processing, and microemulsion processing. In sonochemistry, an acoustic cavitation process generates a transient localized hot zone with extremely high temperature and pressure gradients. Such sudden changes in temperature and pressure assist the destruction of the sonochemical precursor (e.g., an organometallic compound) and the formation of nanoparticles. The technique can be used to produce large volumes of materials for industrial applications.

In hydrodynamic cavitation, nanoparticles are generated through creation and release of gas bubbles inside a sol-gel solution.[69,70] The sol-gel solution is mixed by rapidly pressurizing it in a supercritical drying chamber and exposing it to cavitational disturbance and high-temperature heating. The erupted hydrodynamic bubbles are responsible for nucleation, growth, and quenching of the nanoparticles. Acoustic cavitation in liquids actually leads to two different types of major effects, i.e., physical phenomena such as streaming, turbulence, microjet, shear, etc. and chemical phenomena such as radical production. The collapse of cavities can indeed generate highly reactive radicals, which may induce specific chemical reactions. One easily recognizes how in the case of gas-solid reactions, the dissolution of solids is enhanced due to the turbulent mixing generated by hydrodynamic cavitation. The vigorous mixing enhances the transport of gas molecules to the solid surface resulting in an increase in the mass transfer and hence the overall reaction rate. The particle size can be controlled by adjusting the pressure and the solution retention time in the cavitation chamber. Gedanken[69] and Gogate[70] reviewed the use of sonochemistry for the fabrication of inorganic nanomaterials of various shapes, size, structure, and phases.

Microemulsions (liquid in a liquid) and micelles have been used for synthesis of metallic, semiconductor, silica, barium sulfate, magnetic, and superconductor nanoparticles.[71] In contrast to ordinary emulsions, microemulsions form upon simple mixing of the components and do not require the high shear conditions generally used in the formation of ordinary emulsions. The two basic types of microemulsions are direct [oil dispersed in water (o/w)] and reversed [water dispersed in oil (w/o)]. The technique is useful for large-scale production of nanoparticles using relatively simple and inexpensive hardware.

The diagram in Figure 3.39 explains the basic scheme for microemulsion nanoparticle synthesis. Basically, each microemulsion type (A and B) contains a reactant of the synthesis, and when they are forced together (in a reactor) exchange occurs causing the reactants to combine. Because there is limited reactant in each droplet, the size of the nanoparticle is controllable. The ability to synthesize nanoparticles in a water/supercritical fluid microemulsion was also realized.[72–75] This method promises to be a highly useful route to controlled nanoparticle synthesis because of the added control variables afforded by the tunability of the solvent quality (density) through pressure and temperature.

Liquid phase synthesis techniques in general are better than gas phase techniques (see next) for controlling the final shape and size of the nanoparticles. The ultimate size is controlled, as in the case of gas

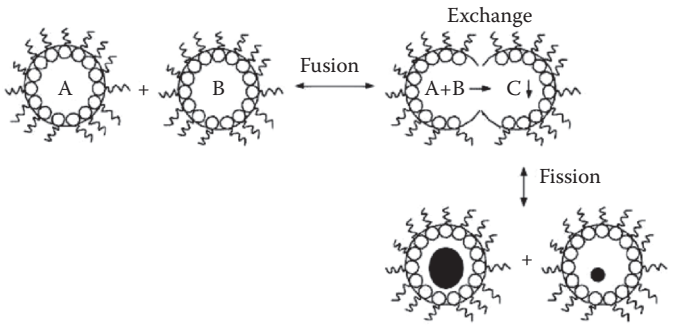

FIGURE 3.39 Microemulsion nanoparticle synthesis.

phase synthesis, by either stopping the process when the desired size is reached or by choosing chemicals that form particles that are stable, and stop growing at a certain size. These approaches are relatively low cost and high throughput, but contamination from precursor chemicals may be a problem.

Gas Phase Synthesis

Introduction

In gas phase nanoparticle synthesis a gas phase mixture is rendered thermodynamically unstable relative to the formation of the desired nanoparticles. Supersaturation is achieved by vaporizing material into a background gas and condensation to form particles is induced by cooling, e.g., by mixing with a cool gas or expansion through a nozzle. Once nucleation occurs, the remaining supersaturation is relieved by additional condensation on virgin substrate areas, or reaction of vapor phase molecules continues on deposited particles. This initiates the particle growth phase and rapid quenching after nucleation prevents particles that are too large.

In Table 3.6 we list several types of gas phase nanoparticle synthesis techniques grouped into those that use solid precursors and those that employ liquid or vapor precursors. The latter category is called *chemical vapor synthesis* (CVS), a modified chemical vapor deposition (CVD) method where the process parameters are adjusted to form nanoparticles instead of a thin film.

Gas Phase Synthesis with Solid-State Precursors

Inert-gas aggregation frequently is used to make nanoparticles from solid metals with low melting points (e.g., Bi). The metal is vaporized in a vacuum chamber and then supercooled with an inert gas stream. The supercooled metal vapor condenses into nanometer-sized particles that can be entrained in the inert gas stream and deposited on a substrate or studied in situ. Inert gases are used to avoid oxidation when creating metal nanoparticles, whereas a reactive oxygen atmosphere is used to produce metal oxide ceramic particles. The main advantage of this approach is the low contamination level. Final particle size is controlled by varying temperature, gas environment, and evaporation rate.

Pulsed laser ablation, like ion cluster beam deposition, is a nanoparticle gas phase synthesis method that uses solid precursors. Both techniques were reviewed in Volume II, Chapter 7. Pulsed laser ablation is used to vaporize a plume of material. Generally, the method can only produce small amounts of nanoparticles, but it can vaporize materials that are not easily evaporated, e.g., in the synthesis of Si, MgO, titania, and hydrogenated-silicon nanoparticles. There is a strong dependence of particle formation dynamics on the background gas. The use of pulsed laser ablation shortens the reaction time and allows for the preparation of very small particles. In 1995, at Rice University, it was reported that synthesis of carbon nanotubes could be accomplished by laser ablation.[76] A pulsed or continuous laser was used to vaporize a graphite target placed in an oven at 1200°C (Volume II, Figure 7.18). Contact with a cooled copper substrate caused the carbon atoms to be deposited in the form of nanotubes. This method has a carbon nanotube yield of around 70% and produces primarily single-walled carbon nanotubes with a controllable diameter determined by the reaction temperature. However, it is more

Table 3.6 Gas Phase Synthesis Methods for Nanoparticles

Methods Using Solid Precursors	Methods Using Liquid or Vapor Precursors
Inert and reactive gas condensation	Spray pyrolysis using different types of atomizers (e.g., pressure electrostatic, ultrasonic) and salt-assisted spray pyrolysis (SASP)
Pulsed laser ablation	Laser pyrolysis/photochemical synthesis
Ion cluster beam deposition	Low-temperature reactive synthesis
Spark discharge deposition	Thermal plasma synthesis
	Flame decomposition
	Flame spray pyrolysis

expensive than either arc discharge or chemical vapor synthesis.

Ion cluster beam technology also qualifies as a gas phase nanoparticle synthesis method. In ion cluster beam technology the cooling occurs when the vapor exits a special evaporation cell. As shown in Volume II, Figure 7.14, the heating of the evaporant in an evaporation cell with a small opening causes an adiabatic expansion from more than 100 to 10^{-5} or 10^{-7} mbar, upon exiting that cell. The expansion causes a sudden cooling, inducing the formation of atom clusters.

In spark discharge deposition, electrodes made of the metal to be vaporized in the presence of an inert background gas are polarized until the breakdown voltage is reached and an arc is formed across the electrodes that vaporizes a small amount of metal (e.g., Ni). This is the very technique that led to the discovery of carbon nanotubes in 1991 by NEC's Sumio Iijima (Volume I, Figure 3.64). Carbon nanotubes were found in the carbon soot of graphite electrodes during an arc discharge, by using a current of 100 amps. During this process, the carbon contained in the negative electrode sublimates because of the high temperatures caused by the discharge. Because nanotubes initially were discovered using this technique, it has been the most widely used method of nanotube synthesis. The yield for this method is up to 30% by weight, and it produces both single-walled and multiwalled nanotubes with lengths of up to 50 μm.

Gas Phase Synthesis with Liquid and Vapor Precursors

The entire range of reaction regimes and corresponding microstructures (epitaxial, polycrystalline, columnar, granular films, and aerogel coatings, as well as nanopowders) in going from chemical vapor deposition (CVD) to chemical vapor synthesis (CVS) of nanoparticles are illustrated in Figure 3.40.

In chemical vapor synthesis (CVS as opposed to CVD), vapor phase precursors are brought into a hot-wall reactor under nucleating condition. In CVS, vapor phase nucleation of particles is favored over film deposition characteristic for CVD. CVS constitutes a very flexible technique that can produce a wide range of materials and takes advantage of the huge database of precursor chemistries developed for CVD processes (see Volume II, Chapter 7). Examples include oxide-coated Si nanoparticles for high-density nonvolatile memory devices and tungsten (W) nanoparticles by decomposition of tungsten hexacarbonyl. The method allows for the formation of doped or multicomponent nanoparticles by the use of multiple precursors. For example, nanocrystalline europium-doped yttria is synthesized from organometallic yttrium and europium precursors. Other multicomponent particles that have been made by CVS include erbium in Si nanoparticles and zirconia particles doped with alumina.

Both in CVD and CVS, precursors are metalorganics, carbonyls, hydrides, chlorides, and other volatile compounds. The energy for the conversion

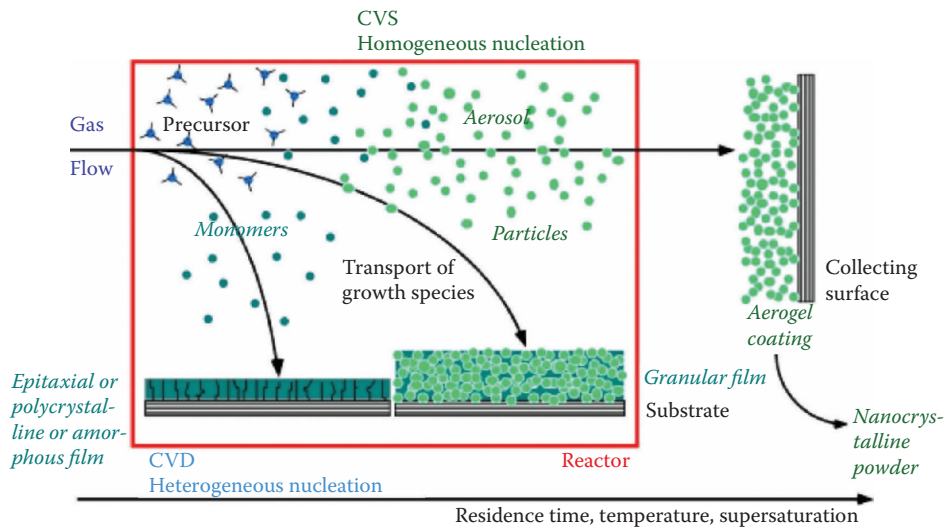

FIGURE 3.40 From chemical vapor deposition (CVD) to chemical vapor synthesis (CVS).

of the reactants into nanoparticles is supplied in hot wall (external furnace), flame (reaction enthalpy), plasma (microwave or radiofrequency), and laser (photolysis or pyrolysis) reactors.

The most important process parameters determining the quality and usability of the nanopowders are the total pressure (typical range from 100 to 100,000 Pa), the precursor material (decomposition kinetics and ligands determining the impurity level), the partial pressure of the precursor (determining the production rate and particle size), the temperature or power of the energy source, the carrier gas (mass flow determining the residence time), and the reactor geometry. The nanoparticles are extracted from the aerosol by means of filters, thermophoretic collectors, electrostatic precipitators, or scrubbing in a liquid. A typical laboratory reactor consists of a precursor delivery system, a reaction zone, a particle collector, and a pumping system. Modifications of the precursor delivery system and the reaction zone allow the synthesis of pure oxides, doped oxides, coated nanoparticles, functionalized nanoparticles, and granular films. Several CVS methods, including spray pyrolysis, salt-assisted spray pyrolysis (SASP), flame spray and electrospray pyrolysis for nanoparticle synthesis were detailed in Volume II, Chapter 9. For further reading on nanoparticle fabrication, a good resource is Jacak et al.[77] You may also want to consult Green and O'Brien.[78]

Carbon Nanostructures: Fullerenes

Introduction

Carbon, as we learn in Chapter 5, this volume, comes in an amazing number of varieties that may be grouped as crystalline, amorphous, nanoparticle, and engineered. The chemical genius of carbon is that it can combine with itself in different ways to create structures with entirely different properties. Two prominent examples of carbon structures are diamond and graphite. In pure sp^3 hybridization, four valence electrons are equally shared between neighboring carbon atoms to yield hard diamond, whereas in pure sp^2 hybridization, three in-plane covalent bonds leave a fourth delocalized electron to produce slippery graphite (see Figure 3.41 and Chapter 5, this volume: the carbon phase diagram in Table 5.9, Inset 2). In Volume I, Chapter 3, using the semiconductor band model, we explained how this same material acts as an insulator (diamond), a metal (graphite), or a superconductor (buckminsterfullerenes).

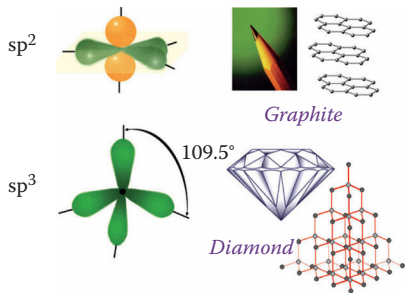

FIGURE 3.41 From graphite to diamond with carbon.[79]

In this section we only focus on fullerenes, carbon nanotubes, and graphene. Fullerenes are large, closed-cage, carbon atom clusters (Figure 3.42 and Volume I, Figure 1.29) and have several special properties that, until their discovery, were not found in any other material. Before the first synthesis and detection of the smaller fullerenes C60 and C70, it generally was assumed that these large spherical molecules were unstable. However, some Russian scientists already calculated that C60 in the gas phase should be stable and comes with a relatively large band gap. As is the case of many, important scientific breakthroughs, fullerenes were discovered accidentally. In 1985, Curl, Kroto, Smalley, and coworkers found strange results in mass spectra of evaporated carbon samples.[80] Herewith, the stability of C60 in the gas phase was proven, starting off the search for other fullerenes.

Since their discovery in 1991 by NEC's Sumio Iijima (Volume I, Figure 3.64), multiwalled carbon nanotubes (MWNTs) (Figure 3.43 and Volume I,

FIGURE 3.42 Sixty carbon atoms in the shape of a sphere—a buckyball. Every molecule combines twenty hexagons with twelve pentagons, resulting in a sphere shaped like the Buckminster Fuller geodesic sphere.

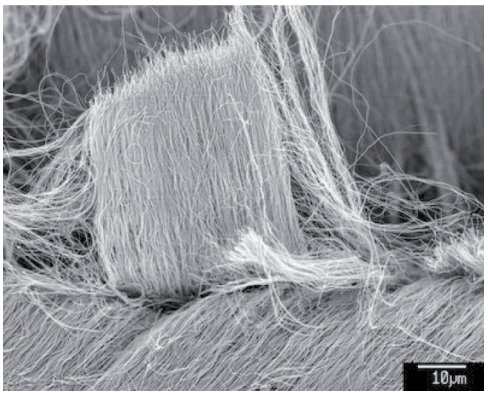

FIGURE 3.43 Multiwalled carbon nanotubes produced by the chemical vapor deposition (CVD) method. (Courtesy of the Department of Materials Science and Metallurgy, University of Cambridge.)

Figure 1.30) have been investigated by researchers all over the world.[81] With their large length (up to several millimeters) and small diameter (a few nanometers), they may be regarded as nearly one-dimensional fullerenes. Therefore, these materials possess additional interesting electronic, mechanical, and molecular properties. Carbon nanotubes, like fullerenes and graphene, profit from the intrusion of quantum phenomena and can be formed into a cylinder one atom thick in so-called "single-walled carbon nanotubes" (SWNTs) to give a wire that is perfect and without defects, much like the single-crystal whiskers we discussed in Volume I, Chapter 2.

Graphene is a flat monolayer of carbon atoms in a 2D honeycomb lattice. It is the basic building block for graphite materials of all other dimensionalities: 0D (buckyballs, C60), 1D (nanotubes), 2D (graphene), and 3D (graphite) (see Figure 3.44). Graphene is the two-dimensional crystalline form of carbon: a single layer of carbon atoms arranged in hexagons, like a sheet of chicken wire with an atom at each nexus. The familiar pencil-lead form of carbon, graphite, consists of layers of carbon atoms tightly bonded in the plane but only loosely bonded between planes; because the layers move easily over one another, graphite is a good lubricant. In fact, these graphite layers are graphene, although they had never been observed in isolation before 2004. As free-standing objects, such two-dimensional crystals were actually believed to be impossible to create—even to exist—until Russian-born physicists Andre Geim and Konstantin Novoselev at the

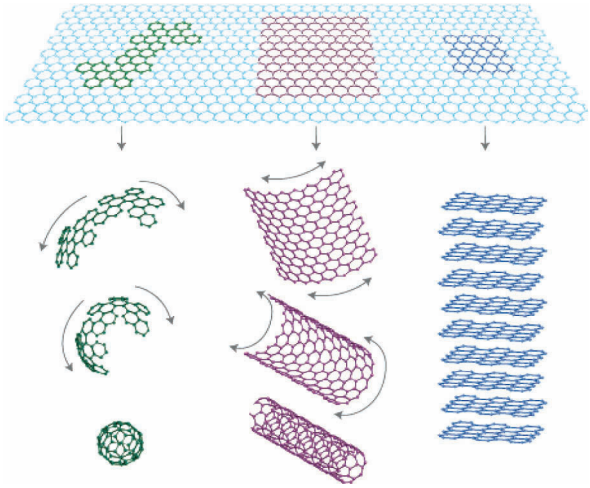

FIGURE 3.44 Graphene as the building block for graphite materials of all other dimensionalities.[94]

University of Manchester actually made free-standing graphene sheets in 2004.[82] Graphene sheets actually are easy to make but hard to see (Figure 3.45). It is now presumed that tiny fragments of graphene sheets are produced (along with quantities of other debris) whenever graphite is abraded, such as when a line is drawn with a pencil (Figure 3.45).

A summary of the many fullerene discoveries made since the discovery of C60 is presented in Table 3.7.

Buckyballs: 0D

A buckyball (short for *buckminsterfullerene*) is a 60-carbon atom molecule named for its resemblance to the geodesic spheres of architect Buckminster Fuller (Figure 3.42). Electrons in such a structure are confined in 3 dimensions and such a zero dimensional (0D) molecule or quantum dot comes with a de Broglie wavelength $\lambda_{DB} > d$ (the diameter of the particle) (see also Volume I, Table 3.11).

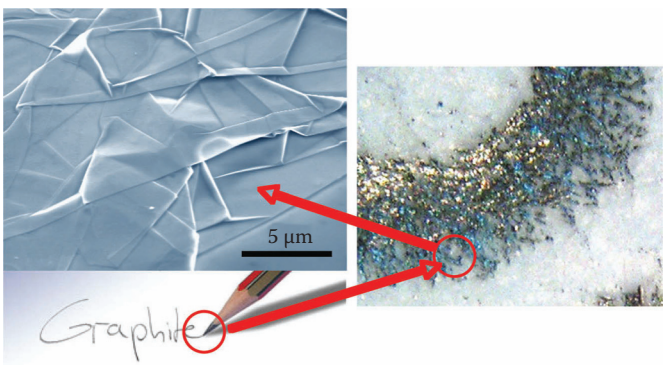

FIGURE 3.45 Easy-to-make, hard-to-see graphene sheets.[79]

Table 3.7 Short History of Fullerenes

1985: Finding of evidence for C60 in a mass spectrometry analysis of evaporated carbon samples by Kroto et al.[80]
1991: Discovery of multiwalled carbon nanotubes by Iijima[81]
1992: Conductivity of carbon nanotubes established by Mintmire et al.[83]
1993: Structural rigidity of carbon nanotubes measured by Overney et al.[84]
1993: Synthesis of single-walled nanotubes by Iijima and Ichihashi[85]
1995: Nanotubes used as field emitters by Rinzler et al.[86]
1997: Hydrogen storage in nanotubes demonstrated by Dillon et al.[87]
1998: Demonstration of the first carbon nanotube transistor by Dekker et al.[88]
1998: Synthesis of nanotube peapods by Smith et al.[89,90]
2000: Thermal conductivity of nanotubes measured by Tománek et al.[91]
2001: Integration of carbon nanotubes for logic circuits by Collins et al.[92]
2001: Intrinsic superconductivity of carbon nanotubes demonstrated by Kociak et al.[93]
2004: Discovery of stable graphene sheets by Novoselov et al.[82]

This soccer ball-shaped molecule measures just under a nanometer across and was discovered by Robert F. Curl, Jr. (Rice University), Harold W. Kroto (University of Sussex), the late Richard E. Smalley (Rice University), and some graduate students in August of 1985.[80] The professors (but not the graduate students—surprise!) received the 1996 Nobel Prize in Chemistry for this discovery. Spherical molecules like the one depicted in Figure 3.42, called *fullerenes*, come in various sizes and are identified by the letter C followed by the number of carbon atoms, for example, C60, C70, and C80.

Smalley made his early C60 buckyballs by vaporizing carbon with a laser and allowing the carbon to condense in a cold zone (see laser ablation in Figure 3.56, and Volume II, Figure 7.18).

Until C60 could be created in somewhat larger quantities, scientists were stumped in their attempts to study the new material. In 1990, Dr. Donald R. Huffman, a physicist at the University of Arizona, and Dr. Wolfgang Kratschmer of the Max Planck Institute in Heidelberg, Germany, solved this production problem with the development of the so-called "Huffman-Kratschmer reactor."[95,96] By adjusting the gas pressure in an apparatus basically consisting of an arc welder with carbon rods, they made large quantities of soot rich in buckyballs. The arc discharge technique in general was detailed in Volume II, Chapter 9 (see Volume II, Figure 9.25), and a carbon-arc discharge setup is shown in Figure 3.51 below. A graduate student of Dr. Kroto, Jonathan Hare, succeeded in separating buckyballs from the soot produced in the carbon arc by dissolving it in benzene; ordinary graphite does not dissolve, but buckyballs form a red solution. After the benzene is evaporated, the orange-brown crystals that remain are pure fullerene carbon.

Ever since their discovery, expectations have been high that these hollow, pure carbon nanostructures could be used as drug delivery agents, as environmental tracers, as antioxidants, in medical imaging, to make stronger polymers, for more efficient fuel cell membranes, as light detectors, in superconductors, and in diamond-hard coatings for hard disks. As an antioxidant in health and medicine, a buckyball can supply an electron from one of its carbon bonds and neutralize a radical's unpaired electron. In the polymer area, DuPont and Exxon Mobil are using buckyballs to develop stronger polymers. Sony is developing a more efficient fuel-cell membrane. German industrial giant Siemens developed a buckyball-based light detector, and Seagate patented buckyballs to develop diamond-hard coatings for computer disc drives. Of the many tantalizing applications involving buckyballs, imagine buckyballs filled with a specific atom or a molecule, analogous to the ferretin liver protein caging iron oxide molecules. Because of the extreme stability of these molecules, it was difficult at first to open and close buckyballs. However, by rendering one of the thirty double bonds making up a C60 cage more reactive, Wudl at the University of California, Santa Barbara, succeeded

in opening and closing the cage, contributing to a widening class of container molecules (endohedrals) tailored to fit a variety of target molecules.[97-99]

At MIT a fullerene mass production method was developed (together with a startup company, Nano-C, Inc.) in which hydrocarbons and oxygen are mixed and the hydrocarbons are burned at a low pressure. Nano-C has a prototype burner in its headquarters that can produce 1 ton of fullerenes a year. The standard atmosphere in the burner is a low-pressure mixture of oxygen and benzene, heated to over 3140°F. By manipulating conditions inside the reactor, different types of fullerenes can be produced. Nano-C claims that they obtain a yield in fullerenes of 95% obviating the usual separation step of buckyballs from soot (http://www.nano-c.com/fullerenes.html). C60 fullerenes are the least expensive fullerene and used to fetch $25 per gram. Larger fullerenes can cost thousands of dollars per gram. Nano-C says they can now make C60 fullerenes for about $4 or $5 per gram. They expect the cost to tumble below $1 with larger-scale equipment. The Frontier Carbon Corporation (FCC), headquartered in Tokyo, Japan, is the first company in the world to mass-produce fullerenes at a commercial scale, and it increased its fullerene production capacity to 40 tons/yr in April 2003 (http://www.f-carbon.com). FCC now sells fullerenes at a price one-tenth that of the existing market and has plans to decrease its price even further.

Because of the decrease in price and unique characteristics of fullerenes, some face creams and antiaging creams based on them have already entered the market (http://www.buckyusa.com). Other near-term projected industrial applications include batteries, lubricants, grinding and polishing material, polymer additives, and rubber additives.

Very few buckyball applications are financially lucrative yet. There also might be an increase in environmental concerns as, although fullerenes are found to be bactericidal, they also seem to cause brain damage in fish.[100]

Nanotubes: 1D

Carbon nanotubes (CNTs) had been observed before their "invention" in 1991. Carbon nanofibers (diameter range, 3–100 nm; length range, 0.1–1000 mm) were known for a long time as a nuisance often emerging during catalytic conversion of carbon-containing gases. In 1959, Roger Bacon produced images of carbon nanotubes,[101] and in the 1980s, Howard Tennant even applied for a patent on a method to produce them. But it was only in 1991 that Sumio Iijima, at NEC's Fundamental Research Lab, found that through carbon self-organization it is possible to deliberately fabricate those tiny graphite tubes, perhaps the smallest electrical wires ever made.[81,85] These nanotubes are called *buckytubes*, because they are structurally similar to the carbon buckyballs. CNTs can be described as a sheet of graphite, i.e., graphene rolled into a cylinder, constructed from hexagonal rings of carbon and with caps at the ends, making the shorter ones look like pills. It is possible to open those caps through oxidation: the pentagons in the end caps of nanotubes are more reactive than the sidewall, so during oxidation, the caps easily are removed while the sidewall stays intact. The first buckytubes discovered consisted of several nested, concentric cylinders with nanometer-scale diameters, called *multiwalled nanotubes* (MWNTs) (Figure 3.46). In the nested configuration MWNTs, inner and outer tubes slide and rotate easily against each other. Like Russian nested dolls, these type of structures typically feature about ten nested tubes. By 1993, Iijima and Donald Bethune at IBM independently created single-walled nanotubes consisting of just one layer of carbon atoms (SWNT) (Figure 3.47).[102] A typical

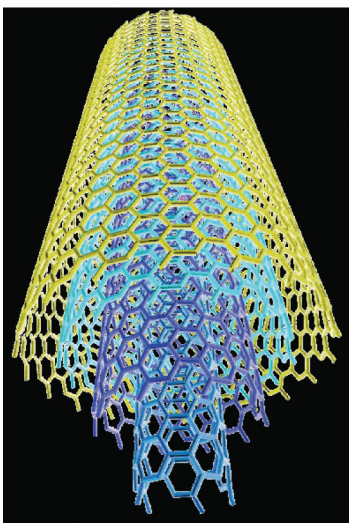

FIGURE 3.46 Artistic rendition of multiwalled nanotubes. (From A. Rochefort, Nano-CERCA, University of Montreal.)

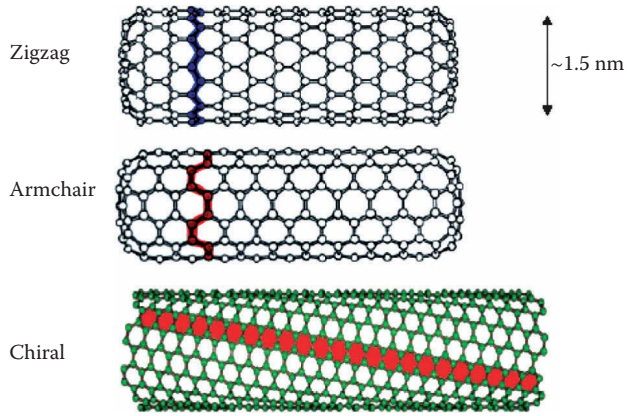

FIGURE 3.47 A single-walled carbon nanotube diameter is ~1.5 nm. Three types of lattice orientations can be identified: zigzag, armchair, and chiral nanotubes.

SWNT diameter is 1–1.5 nm, and tube lengths of several millimeters have been achieved.

Although carbon nanotubes are well ordered, STM images rarely show the sixfold symmetry of their graphene lattice. The images instead reveal the backscattering of electron waves from defects on the walls.

Nanotubes are very stiff and very stable and can be built with their length exceeding their thickness thousands of times. They fold and buckle but do not snap, and their hollow interior enables one to put materials inside.

Linear nanotubes may behave as metals or as semiconductors, depending on their diameter and the exact details of the 2D lattice orientation. Three types of lattice orientations can be identified. In armchair nanotubes, there is a line of hexagons parallel to the axis of the nanotube; in zigzag nanotubes, there is a line of carbon bonds down the center; and chiral nanotubes exhibit a twist or spiral around the nanotube (see Figure 3.47). It is the amount of twist of the lattice that determines whether a nanotube is metallic or semiconducting. Armchair nanotubes are all metallic, whereas about two-thirds of zigzag and chiral nanotubes are semiconducting (the remaining one-third are, again, metallic).

A bit more quantitative the geometry of a CNT is determined by its chiral vector (**c**) defined as follows (see Figure 3.48):

$$\mathbf{c} = n_1\mathbf{a}_1 + n_2\mathbf{a}_2 \qquad (3.13)$$

where $\mathbf{a}_1$ and $\mathbf{a}_2$ are primitive lattice vectors of graphene and n_1 and n_2 are integers (chiral numbers). The basis of this 2D lattice contains two atoms and

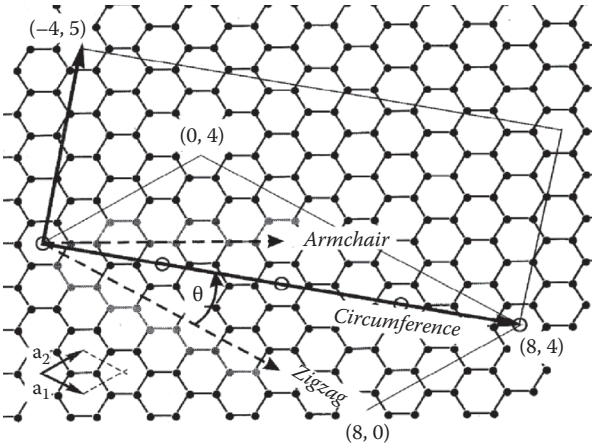

FIGURE 3.48 Graphene sheet and chiral vector.

the side length d of a hexagon in the lattice is 0.14 nm long. The chiral angle is the angle θ between the chiral vector **c** and the unit vector $\mathbf{a}_1$. If the chiral angle is 0°, $n_2 = 0$, and the nanotube is classified as zigzag. If the chiral angle is 30°, $n_1 = n_2$, and the nanotube is classified as armchair. If **c** is not along a mirror line (see Figure 3.48) the structure is chiral and these tubes, with angles between 0° and 30°, are referred to as chiral nanotubes. Chiral structures have no mirror symmetry and sort out into "left-handed" and "right-handed" versions. Due to the symmetry and unique electronic properties of graphene layers, the structure and dimensions of a nanotube strongly determines its electrical properties. For a given (n_1, n_2) nanotube, if $2n_1 + n_2 = 3q$ (where q is an integer), then the nanotube is metallic, otherwise the nanotube is a semiconductor. Thus all armchair ($n_1 = n_2$) nanotubes are metallic, and nanotubes such as (5,0), (6,4), (9,1), are all semiconducting. An alternative representation of this condition is that if $(n_1 - n_2)/3 = q$, then the SWNT is metallic. In theory, metallic nanotubes can have an electrical current density more than 1,000 times stronger than metals such as copper. The energy gap for the semiconducting fibers decreases with increasing fiber diameter d and in the limit of d_∞, we obtain the 2D case of a zero-gap semiconductor. The chirality of a SWNT can be determined by Raman spectroscopy and STM and transmission electron microscopy (TEM); STM and AFM can determine its diameter.

Also from Figure 3.48, if n is the greatest common divisor (4) of the chiral numbers n_1 (8) and n_2 (4), then the number of lattice points (open circles)

along the chiral vector is $n + 1$ (there are five open circles in Figure 3.48).

In an ordinary wire, the charge transport is diffusive, and the diffusive length of the electrons, l, is much smaller than the wire length ($l \ll L$) (see Figure 3.49a). The unique electronic properties of carbon nanotubes are due to the quantum confinement of electrons perpendicular to the axis of the tube. In that direction, the monolayer thick graphene sheet confines electrons. Around the circumference of the nanotube, periodic boundary conditions hold. For example, if a nanotube has twelve hexagons around its circumference, the thirteenth hexagonal will coincide with the first. In other words, going around the cylindrical tube just once introduces a phase difference of 2π. Because of this quantum confinement, electrons propagate along the nanotube axis, and their wave vectors point in that direction. The actual number of one-dimensional conduction and valence bands of a nanotube depends on the number of standing waves that are set up around the circumference of the nanotube. The electrons in an ideal nanotube then behave like waves traveling down a smooth channel with no atoms to bump into, and they do not undergo scattering. This allows the nanotube to pass current without resistance along its length and permits very high current densities. This type of quantum movement of an electron within a nanotube is called *ballistic transport* ($l >>> L$) (see Figure 3.49b). The contacts are part of the device and all the scattering occurs at the contacts; hence, all the voltage drops also at the contacts. The resistance, as we saw in Volume I, Chapter 3, is quantized in amounts of R = 25.8 kΩ (see also the Landauer equation: Volume I, Equation 3.274).

In metallic nanotubes, electrons can easily move from the valence to the conduction band. There is no gap between the valence and conduction band in armchair nanotubes, but as we just saw, an energy gap exists between the valence and conduction bands in about two-thirds of zigzag and chiral nanotubes. The bandgap of the semiconducting carbon nanotubes can be "tuned" from 0.5 to 1.5 eV by adjusting the diameter of the nanotube; as the nanotube diameter increases, more wave vectors are allowed in the circumferential direction and the band gap narrows. The carbon nanotube band gap is inversely proportional to the tube diameter and approaches zero at large diameters, just as for a graphene sheet (at a nanotube diameter of about 3 nm, the band gap becomes comparable to thermal energies at room temperature). The fact that the electronic structure of a carbon nanotube depends only on its physical geometry, without any doping, is unique to solid-state physics and is the basis for many of its proposed applications in electronics.

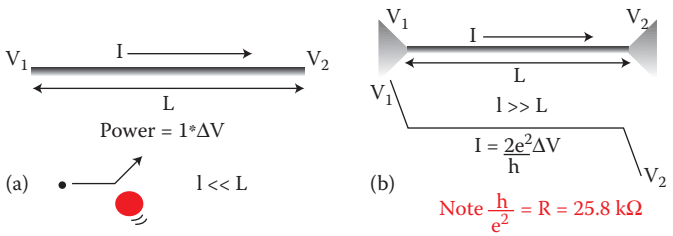

FIGURE 3.49 (a) Diffusive transport in an ordinary wire. (b) Ballistic transport in a quantum wire.

Nanotubes, we explained earlier, are made up of graphene sheets, and the unusual electronic properties of graphene arise from the fact that the carbon atom has four electrons, three of which are tied up in bonding with its neighbors. But the unbound fourth electrons are in orbitals extending vertically above and below the plane, and the hybridization of these spreads across the whole graphene sheet (see also the section below on graphene). The energy vs wavevector (**E-k**) surfaces and band diagrams of a metallic and a semiconducting carbon nanotube are compared in Figure 3.50A.

As we saw above carbon nanotubes can be viewed as a rolled up graphene sheet (Figure 3.50Aa and b). The periodic boundary condition only allows quantized wave vectors around the circumferential direction, which generates one-dimensional bands for carbon nanotubes. The nanotube can be either metallic (Figure 3.50Ac) or semiconducting (Figure 3.50Ad). If $(n_1 - n_2)/3 = q$ (with q an integer), then the SWNT is metallic. So with $n_1 - n_2 = 0$ we are dealing with a metallic tube and the bandgap is zero. And if $n_1 - n_2/3$ is not an integer we have a semiconducting tube that exhibits a forbidden band gap in the **E-k** diagram.

As we learned in Volume I, Chapter 3, carbon nanotubes have peaks in their density of states (DOS) function that are called *criticalities* or *Van Hove singularities*. These singularities in the DOS function lead to sharp peaks in optical spectra (see Figure 3.50B) and can be observed directly with scanning tunneling microscopy

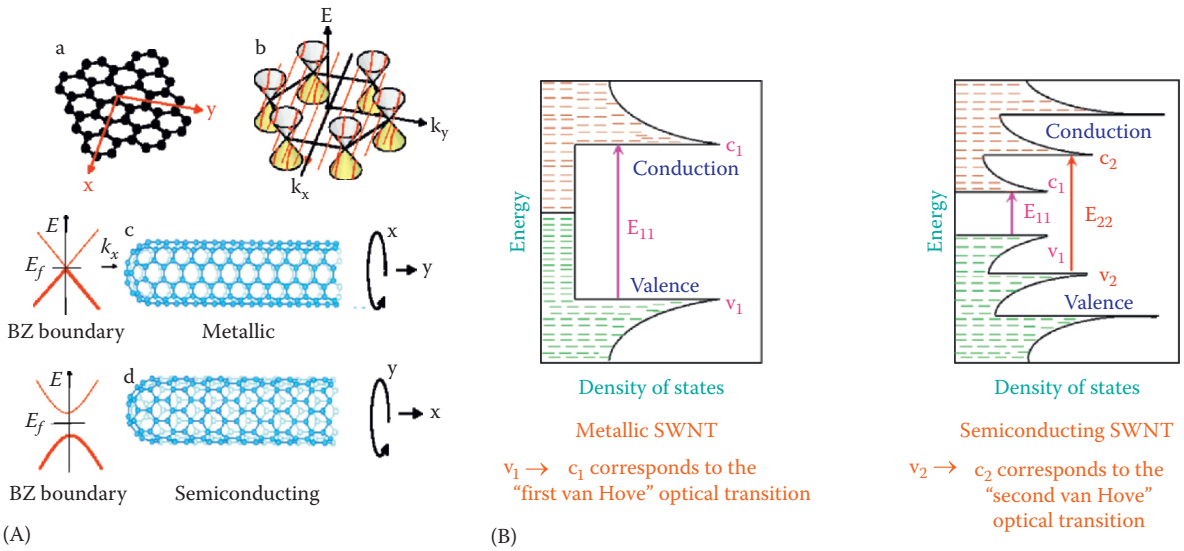

FIGURE 3.50 The E-k surfaces and band diagrams of metallic and semiconducting carbon nanotubes compared. (A) Energy vs wave vector plot. Carbon nanotubes can be viewed as rolled up graphene sheets (a,b). The periodic boundary condition only allows quantized wave vectors around the circumferential direction, which generates one-dimensional bands for carbon nanotubes. The nanotube can be either metallic (c) or semiconducting (d), depending on whether $(n_1 - n_2)$ is the multiple of 3. (B) Sharp optical transitions due to Van Hove singularities. Optical transitions between the $v_1 - c_1$, $v_2 - c_2$, etc., states of semiconducting or metallic nanotubes are traditionally labeled as S_{11}, S_{22}, M_{11}, etc. The energies between the Van Hove singularities depend on the nanotube structure. Thus by varying this structure, one can tune the optoelectronic properties of carbon nanotubes. Optical transitions are sharp (~10 meV) and strong. Consequently, it is relatively easy to selectively excite nanotubes having certain (n_1, n_2) indices, as well as to detect optical signals from individual nanotubes.

(STM) (see Volume I, Figure 3.135). At low temperatures, the derivative of the STM current with respect to voltage (dI/dV) is proportional to the density of states at the tunneling electron energy, weighted by the density of those states at the STM tip position. Since dI/dV ~ local density of states (LDOS), the LDOS is directly observed from an STM scan. In practice, during scanning tunneling spectroscopy measurements, a constant tip-sample separation is first established by fixing the set-point current at a given bias voltage. Next, the feedback of the STM is turned off and a small sinusoidal modulation is added to the DC bias voltage. The resulting current modulation (dI/dV) is then read off from a lock-in amplifier, into which the tunneling current signal from the current preamplifier is fed. The output signal from the lock-in amplifier is plotted as a function of the DC bias voltage and the tip position to generate a tunneling spectrum dI/dV (V, r), and hence the LDOS. By taking dI/dV along a line or by taking a two-dimensional dI/dV map, changes in LDOS around a impurity, or among nanotubes with different crystalline orientations can be revealed and compared with theoretical predictions. The density of states (DOS) functions for a metallic and a semiconducting carbon nanotube are illustrated in Figure 3.50B. The peaks in these DOS functions are the Van Hove singularities. In Volume I, Figure 3.135, the same DOS functions are shown in the top two plates, and the differential conductance is illustrated in the bottom two plates. Metallic carbon tubes have a constant DOS around E = 0, whereas for semiconducting ones, there is a gap at E = 0 (DOS = 0).

Carbon Nanotube Manufacture

Like fullerenes, nanotubes may be formed in macroscopic quantities in an arc discharge apparatus as described in Volume II, Chapter 9 (see Figure 9.25). In the case of a carbon arc, one refers to such a setup as a Huffman-Kratschmer reactor.[95] In a carbon arc as illustrated in Figure 3.51, two carbon rods are placed end to end with a separation distance of about 1 mm and are used as electrodes. In an enclosed volume of an inert gas (He, Ar) at a low pressure (50–70 mbar), a current of 50–100 A, driven by 20 V, creates a high-temperature arc between the electrodes. The discharge vaporizes one rod forming a deposit on the other. Producing nanotubes in high yield depends upon the uniformity in the plasma arc and also upon

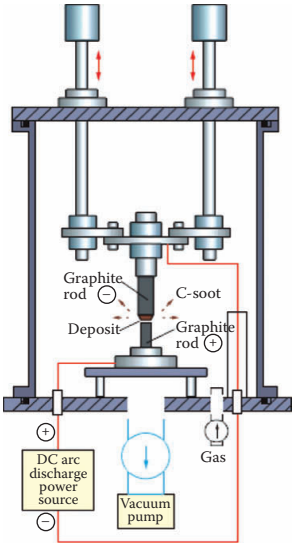

FIGURE 3.51 In the case of a carbon arc, one refers to such a setup as a Huffman-Kratschmer reactor.[95]

the temperature of the deposit on the second carbon electrode. At the extremely high temperatures of the arc plasma, a wide range of carbon materials is formed. This may include amorphous carbon, fullerenes, nanotubes, endohedrals (carbon structures with enclosures), nanocrystallites, and graphite crystals. A typical yield for nanotubes is around 30% by weight. It is the most common and arguably the easiest way to produce carbon nanotubes; however, as pointed out, it produces a mixture of items such as "soot" and catalytic metals in the end product, and the tubes are deposited in random sizes and directions.

There are a few ways of improving the process of arc discharge for producing either SWNT or MWNT (see Figure 3.52). In order to favor the production of SWNT, the anode in the apparatus is doped with a metal catalyst. The most important metals to catalyze the growth of graphitic carbon nanofibers are iron, cobalt, and nickel; chromium, vanadium, and molybdenum have also been studied. The metals have been used both as bulk particles (size typically 100 nm) and as supported particles (10–50 nm). MWNTs do not need any catalysts to grow.

By controlling the mixture of helium and argon gas, one can also control the diameter distribution of the produced nanotubes. Supposedly, this is due to the fact that the different mixtures have different diffusion coefficients and thermal conductivities.

Metal-filled carbon nanotubes (endohedrals) also have been produced with the arc-discharge method, for example, by doping a 99.4% graphite anode with a transition metal such as Cr or Ni, a rare earth such as Yb or Dy, or a covalent element such as S or Ge. A growth mechanism based on a catalytic process involving three elements, i.e., carbon, a metal, and sulfur has been proposed. The excellent protective nature of the outer graphitic cages against oxidation of the inner materials was demonstrated.[103] These carbon-coated nanoparticles are of potential importance in the study of nanowire protection against oxidation, magnetic data storage, magnetic toner xerography, magnetic inks, and ferrofluids.

To favor multiwalled carbon nanotube (MWNT) production, both electrodes in the arc discharge apparatus should be graphite (Figure 3.52). Synthesis

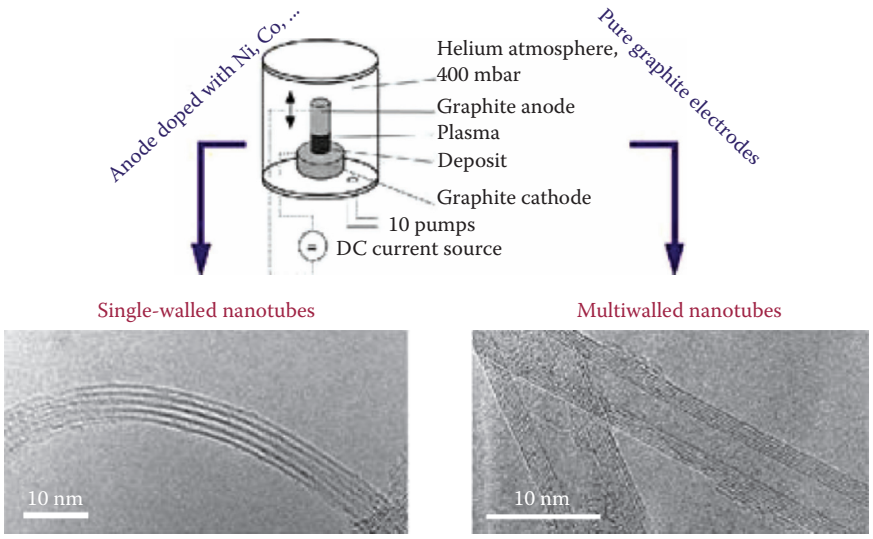

FIGURE 3.52 A carbon arc can be used to obtain single-walled and multiwalled nanotubes.

in a magnetic field and with a rotating arc discharge also improves the MWNT yield. Magnets are placed around electrodes and help align nanotubes during formation. Purification is needed in this case, which may lead to loss of structure and can cause disorder in the nanotube walls. Purification of carbon nanotubes is quite difficult because they are insoluble in organic solvents and metals are often encased in a carbon coating. Possible solutions entail acid oxidation, gas or water oxidation, filtration, and chromatography.

Besides carbon plasma arcing, other established methods to produce nanotubes are chemical vapor deposition (CVD) and laser ablation. Morinubo Endo of Shinshu University was the first to make nanotubes using CVD.[104] Pushing the field one step further, Hongjie Dai et al. at Stanford University devised a novel method for growing vertical single-walled carbon nanotubes (SWNTs) on a large scale. This group modified a plasma-enhanced chemical vapor deposition station and achieved ultrahigh-yield growth of SWNTs, thus increasing their application into commercial products.[105] By patterning a catalyst on a planar substrate they were able to control where the tubes form, for example, to make carbon nanotube arrays on a silicon wafer.[106] Typically, methane, carbon monoxide, synthesis gas (H_2/CO), ethyne, and ethene in the temperature range 700–1200 K are employed to provide the carbon atoms in the process. Dai and his colleagues discovered that the key to attaining SWNTs is to add oxygen to the CVD reaction. While carbon atoms try to form the nanotube's planar structure, hydrogen radicals are eating away at the carbon tube. Adding oxygen remedies the problem by scavenging the hydrogen radicals, creating a carbon-rich and hydrogen-deficient environment. These conditions jumpstart growth and spawn a vertical forest of nanotubes. (Dai and his colleagues were able to create 4-in. wafers blanketed with SWNTs. In addition, they devised a method for lifting the nanotubes off the original growth substrate and transferring them onto a variety of more desirable substrates such as plastics and metals—materials incompatible with the high temperatures required for nanotube growth.)

A typical CVD setup, we saw in Volume II, Chapter 7, consists of a target substrate held in a quartz tube placed inside a furnace (see Figure 3.53). The yield of this process ranges from 20% to 100%, the process is easy to scale up, and nanotubes of great length can be produced. For example, with fast-heating CVD, CNTs that are millimeters long can be grown while maintaining control over their orientation. Fast heating minimizes interaction of the growing tubes with the substrate. Using this process, Huang et al. grew a square 2D network of SWNTs guided by flow of carrier gas (Fe/Mo catalyst and CO_2 gas) (see Volume II, Figure 7.41).[108] The longest carbon nanotubes, as long as 18.5 cm, were reported in 2009. They were grown on Si substrates using an improved chemical vapor deposition (CVD).[109]

FIGURE 3.53 Plasma-enhanced chemical vapor deposition setup for nanotubes: Firstnano EasyTube 3000.

The general picture that has emerged for nanofiber formation is shown in Figure 3.54, where we contrast base growth and tip growth. In base growth, the catalyst particle can be found at the base of the nanotube, whereas in tip growth the nanoparticle is seen at the very tip of the tube. The latter seems to be the most frequent growth mode.

It is not exactly known yet how the carbon atoms in any of the manufacturingtechniques detailed here condense into tubes. Hoogenraad has proposed the following model for nucleation and growth in the case of carbon nanowires grown on Ni catalyst particles (Figure 3.55).[107] The process starts when methane decomposes into carbon and hydrogen atoms at the nickel catalyst surface (1–2). Next, H_2 molecules desorb, and carbon dissolves and forms a (substoichiometric) nickel carbide (3). This nickel carbide is metastable with respect to nickel metal and graphite so that after a short time (e.g., 10 min), the carbide phase decomposes into metallic nickel

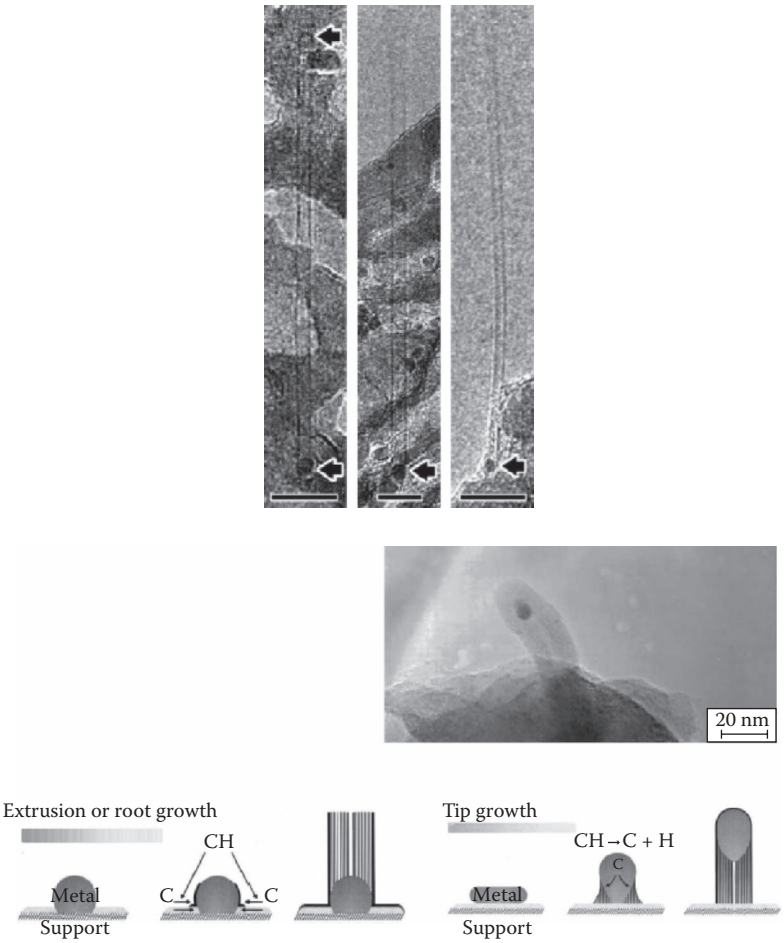

FIGURE 3.54 Base and tip growth of carbon nanotubes. Arrows point to the catalyst particle. (Hoogenraad, M.S. 1995. Utrecht University, PhD thesis. Utrecht, the Netherlands.[107])

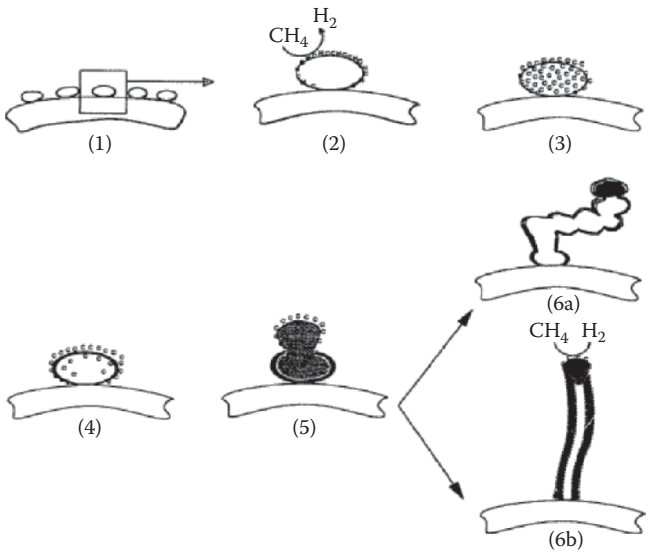

FIGURE 3.55 Mechanism for the nucleation and growth of a carbon nanofiber from methane catalyzed by a supported metal particle. (Based on the work of Hoogenraad, M.S. 1995. Utrecht University, PhD thesis. Utrecht, the Netherlands.[107])

and graphite with the graphite encapsulating the nickel particle in question (4). Hoogenraad now speculates that the metal particle is squeezed out of its encapsulation because of pressure buildup due to the formation of graphite layers at the internal surface of the graphite envelope, on the one hand, and liquid-like behavior of the metal under these conditions, on the other (5). As soon as the metal is pushed out, a fresh Ni surface is exposed to the methane and growth continues. Finally, a steady-state process occurs with either pulsed growth (6a) or smooth growth of a straight fiber (6b). This model explains why, more often than not, metal particles are found at the tip of the carbon fiber: the graphite fiber pushes the metal particle from the support and continues to grow at the back of the particle.

This type of mechanism corresponds to the vapor-liquid-solid (VLS) model as originally proposed in 1964 by R.S. Wagner and W.C. Ellis[110,140]

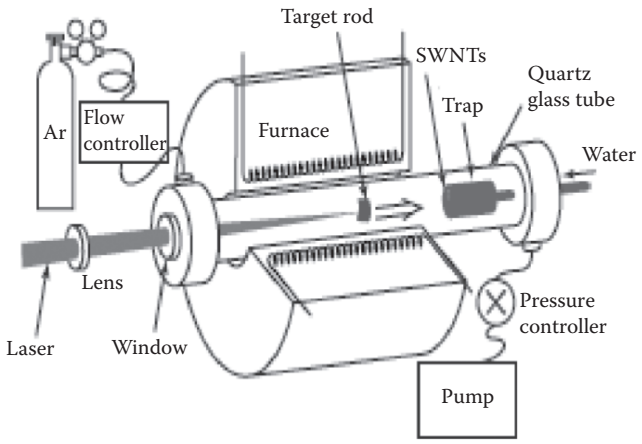

FIGURE 3.56 Laser ablation station for carbon nanotube production.[112] (With kind permission from Elsevier.)

for the Au-catalyzed Si whisker growth (see Figures 3.60 and 3.61).

Smalley made his early buckyballs by laser ablation in a furnace, as shown in Figure 3.56 (see also Volume II, Figure 7.18). The same setup can be utilized to make carbon nanotubes.

Smalley and coworkers at Rice University pioneered the use of intense laser pulses to bombard graphite rods to generate the hot carbon gas from which nanotubes settle on a copper collector. Typical yield is 70%, and the method tends to produce single-walled nanotubes. The method is quite expensive because of the use of the lasers.

In Table 3.8 we compare the pros and cons of carbon-arc discharge with chemical vapor deposition and pulse laser vaporization for the fabrication of carbon nanotubes.

Carbon Nanotube Applications

Electronic Properties

Some of the amazing properties of nanotubes are summarized in Table 3.9 below. These properties could well make carbon nanotubes (CNTs) the "Si" of this century.

It is possible for the carbon nanotube to supply the basic building blocks for an integrated circuit, as

TABLE 3.8 Comparison of the Pros and Cons of Carbon Nanotube Synthesis by Carbon-Arc Discharge with Chemical Vapor Deposition and Pulse Laser Vaporization

Method:	Carbon-arc discharge	Chemical vapor deposition	Pulse laser vaporization
Who:	Ebbesen and Ajayan, NEC, Japan 1992[113]	Endo, Shinshu University, Nagano, Japan[114]	Smalley, Rice, 1995[76]
How:	Connect two graphite rods to a power supply, place them a few millimeters apart, and throw the switch; at 100 amps, carbon vaporizes and forms a hot plasma	Place substrate in oven, heat to 600°C, and slowly add a carbon-bearing gas such as methane; as gas decomposes it frees up carbon atoms, which recombine in the form of NTs	Blast graphite with intense laser pulses; use the laser pulses rather than electricity to generate carbon gas from which the NTs form try various conditions until hitting upon one that produces prodigious amounts of SWNTs
Yield:	30–90%	20–100%	Up to 70%
SWNT:	Short tubes with diameters of 0.6–1.4 nm	Long tubes with diameters ranging from 0.6–4 nm	Long bundles of tubes (5–20 μm), with individual diameter from 1–2 nm
MWNT:	Short tubes with inner diameter of 1–3 nm and outer diameter of approximately 10 nm	Long tubes with diameters ranging from 10–240 nm	Not very much interest in this technique because it is too expensive, but MWNT synthesis is possible
Pros:	Can easily produce SWNT and MWNTs; SWNTs have few structural defects; MWNTs without catalyst, not too expensive, open-air synthesis possible	Easiest to scale up to industrial production; long length, simple process; SWNT diameter controllable, quite pure	Primarily SWNTs, with good diameter control and few defects; reaction product quite pure
Cons:	Tubes tend to be short with random sizes and directions; often needs a lot of purification	NTs are usually MWNTs and often riddled with defects	Costly technique because it requires expensive lasers and high-power equipment, but improving

Table 3.9 Some Physical Properties of Carbon Nanotubes

	Property	Remark/Comparison	Applications
Size	The average diameter of an SWNT is 1.2–1.4 nm	E-beam lithography produces lines 30 nm wide	Nanotube-tipped AFMs can trace an individual strand of DNA. The hollow structures may store hydrogen, lithium ions, or even drug molecules for slow release devices
High specific surface	>1000 m^2/g	For comparison carbon aerosol gels have a specific surface area (200–350 m^2/g)	Materials with large specific surface areas are used for energy storage as in capacitors, batteries, and fuel cells. They are also used for storage, purification, and separation of chemicals
Density	1.33–1.40 gcm^{-3} Lowest for armchair, highest for chiral	Al is 2.7 g cm^{-3}	The applications for low density materials are far ranging from consumer products such as food containers, to packaging materials, to crash protection energy absorbers
Tensile strength	Estimated to be 150 GPa	High-strength carbon steel alloys, 1 GPa. Carbon nanotubes have the greatest tensile strength of any material. It is also the stiffest known material, with a tremendously high elastic modulus (see Young's modulus)	More rugged tips for AFM and STM, superstrong composites
Resilience	Can be bent at large angle without damage	Metals and carbon fibers fracture at grain boundaries	Mechanical memory switches and nanotweezers, superstrong materials
Young's modulus	1–6 TPa (SWNT) 0.27–0.95 Tpa (MWNT)	The Young's modulus of the best nanotubes can be higher than 1000 GPa which is approximately 5x higher than steel. Reported numbers vary widely	This high Young's modulus combined with an excellent tensile strength and the lightness of carbon nanotubes, gives them great potential in applications such as aerospace (see "space elevator" in the heading of this chapter)
Current carrying capacity	Estimated at 1×10^{13} Am^{-2}	Cu wires will carry no more than 1×10^{6} A cm^{-2}	Potential for terahertz FETs
Thermal conductivity and phonon mean free path	Thermal conductivity for SWNT is as high as 3000 W/mK along the nanotube axis. The phonon mean free path length is ~100 nm	Compare this to copper, a metal well-known for its good thermal conductivity, which transmits 385 W/mK. The thermal conductivity of carbon nanotubes is dependent on the temperature and the large phonon mean free paths	Efficient heat sinking in electronics and optoelectronics
Electrical resistivity	10^{-4} ohm.cm for ropes of SWNTs at room temperature		Wiring in electronic circuitry
Field emission	Activates phosphors at 1–2 V with electrodes spaced 1 μm apart	Mo tips (Spindt cathodes, see Volume II, Figure 2.42) require fields of 50–100 V/μm	Flat-panel displays, nanovacuum tubes
Temperature stability	In vacuum up to 2800°C and 750°C in air	Metal in ICs melts between 600°C and 1000°C	High-temperature environments

Table 3.9 Some Physical Properties of Carbon Nanotubes (*Continued*)

	Property	Remark/Comparison	Applications
Quantum effects	For every nanotube circumference there is a unique band gap	Easy to manipulate electronic properties	New generation of quantum devices
Chemical sensitivity	Oxygen, halogens, and alkalis cause a drastic resistance change at room temperature	Most solid-state gas sensors only work at higher temperatures (e.g., >350°C)	Supersensitive, room temperature chemical sensors (selectivity might be an issue)
High aspect ratio	Easily 1000 : 1		The high aspect ratio of CNTs imparts electrical conductivity to polymers at lower loadings, compared to conventional additive materials, such as carbon black, chopped carbon fiber, or stainless steel fiber
Cost	~$100/g	Au, ~$10/g	High cost will make many of the above applications impossible until prices come down
Band gap	0 for metallic and 0.5 eV for semiconductors		Semiconductive type can be used as a transistor and metallic as an interconnect

For a good introductory reading on fullerenes, we suggest *The Chemistry of the Fullerenes* by Hirsch.[119] For a good introduction to nanotubes, we refer to the book *Carbon Nanotubes* by Dresselhaus et al.[120] and the special section "Carbon Nanotubes" in *Physics World*.[121]

the metallic nanotubes can act as highly conductive wires and the semiconducting nanotubes can be fabricated into transistors. Cees Dekker in Delft,[88] Paul McEuen at Cornell,[112] Phaedron Avouris at IBM,[115] and Charles Lieber at Harvard[116] all have demonstrated that single nanotubes can act as transistors. A field-effect transistor—a three-terminal switching device—can be constructed of only one semiconducting SWNT. By applying a voltage to a gate electrode, the nanotube can be switched from a conducting to an insulating state. In Volume I, Figure 1.30b, we show a single semiconducting nanotube contacted by two electrodes. The Si substrate, which is covered by a layer of SiO_2 300 nm thick, acts as a back gate. In 2002, researchers built the world's first array of transistors out of carbon nanotubes.[117]

Another carbon nanotube electronic application involves field emission. When a solid is subjected to a sufficiently high electric field, electrons near the Fermi level can be extracted from the solid by tunneling through the surface potential barrier (see Volume II, Figure 2.17). This emission current depends on both the strength of the local electric field at the surface and the material's work function (which denotes the energy necessary to extract an electron from its highest bounded state to the vacuum level). The applied electric field must be very high in order to extract an electron, a condition easily fulfilled for carbon nanotubes, because their elongated shape ensures a very large electric field concentration. For technological applications, the emissive material should also have a low threshold emission field and remain stable at very high current densities. Furthermore, an ideal emitter should be nanometer size, have high structural integrity and high electrical conductivity, exhibit a small energy spread, and demonstrate excellent chemical stability. Carbon nanotubes possess all these properties. The growth of aligned arrays of CNTs inside the pores of self-organized nanoporous alumina templates is an especially intriguing application in this regard (see Chapter 5, this volume). Govyadinov et al.[118] synthesized arrays of CNTs (deposited with catalytic CVD) in alumina pores with diameters in the sub-100-nm range and densities from 10^8 to 10^{11} tips per cm^2. These prototype CNT arrays have been used as field emitters (carbon has a low work function) and shown to exhibit field emission at a low threshold of 3–5 V/μm and emission current densities up to 100 mA/cm^2 in low-vacuum conditions.

However, a bottleneck in the use of nanotubes for field emitter application is the dependence of the conductivity and emission stability of the nanotubes

on the fabrication process and synthesis conditions. Examples of applications for nanotubes as field emitting devices are flat-panel displays (see Volume II, Figure 7.90), gas-discharge tubes in telecom networks, electron guns for electron microscopes, AFM tips, and microwave amplifiers.

Mechanical Properties

Estimates vary as to precisely how strong a single-carbon nanotube can be, but experimental results have shown their tensile strength to be in excess of 60 times stronger than high-grade steel. Depending upon the specific paper at hand, the reported numerical values for the Young's modulus range from 1–6 TPa. This scatter is known as "Yakobson's Paradox" after Boris Yakobson (Rice University) who first discussed this.[122] In a recent paper, Young Huang and co-workers address this issue and provide a resolution.[123] According to Huang et al. the errors originate in the wide scatter of assumptions about "h" the thickness of the single-walled nanotube or the graphene sheet. Theoretically, SWNTs could have a Young's modulus of between 1 and 6 TPa. MWNTs are less strong because the individual cylinders slide with respect to each other. Ropes of SWNTs are also less strong. The individual tubes can pull out by shearing, and eventually the whole rope will break. This happens at stresses far below the tensile strength of individual nanotubes. Nanotubes sustain large strains in tension without showing signs of fracture, and in other directions, nanotubes are highly flexible. Because of their flexibility, nanotubes are used, for example, in scanning probe instruments. CNTs are not nearly as strong under compression than under tension. Because of their hollow structure and high aspect ratio, they tend to undergo bucking when placed under compressive, torsional, or bending stress. Since MWNT tips are conducting, they can be used in STM and AFM instruments (Volume II, Figure 2.40). Advantages are the improved resolution in comparison with conventional Si or metal tips, while the tips do not suffer from crashes with the surfaces because of their high elasticity. However, nanotube vibration due to the large length remains an important issue, until shorter nanotubes can be grown controllably. Because of the stiffness of carbon nanotubes, they should be ideal candidates for structural applications. For example, they may be used as reinforcements in high-strength, low-weight, and high-performance composites (see below).

Energy Storage and Conversion

See Chapter 9, this volume.

Chemical Sensors and Nanoreactors

Nanotube tips can be modified chemically through attachment of functional groups. Because of this, nanotubes can be used as molecular probes, with potential applications in chemistry and biology. Because of the small channels, strong capillary forces exist in nanotubes. These forces are strong enough to hold gases and fluids in nanotubes. In this way, it may be possible to fill the cavities of the nanotubes to create nanowires. The critical issue here is the wetting characteristic of nanotubes. Because of their smaller pore sizes, filling SWNTs is more difficult than filling MWNTs. If it becomes possible to keep fluids inside nanotubes, it could also be possible to perform chemical reactions inside their cavities. In particular, organic solvents wet nanotubes easily. In this case we could speak of a nanoreactor. Table 3.10 summarizes some chemical and biological sensor applications of carbon nanotubes.

Carbon Nanotubes in Composites

One of the most important applications of carbon nanotubes is projected to be as reinforcement in composite materials. However, there have not been many successful experiments that show that nanotubes are better fillers than the traditionally used carbon fibers. The main problem is to create a good interface between the nanotubes and the polymer matrix, as nanotubes are very smooth and have a small diameter that is nearly the same as that of a polymer chain. Secondly, nanotube aggregates, which are very common, behave differently in response to loads than individual nanotubes do. Limiting factors for good load transfer could be sliding of cylinders in MWNTs and shearing of tubes in SWNT ropes. To solve this problem, the

Table 3.10 Chemical and Biological Applications of Carbon Nanotubes

System	Target Species	Salient Feature
SWNT	NH_3 and NO_2	Sensitive to 200 ppm of NO_2 and 1% of NH_3.[124]
SWNT	N_2, He, O_2, and Ar	Gas concentrations as low as 100 ppm can be detected.[125]
MWCNT	NH_3	Gas concentrations as low as 10 ppm can be detected. The sensor showed a reversible response of few minutes.[126]
Poly(*o*-anisidine)-coated CNT	HCl	Nine times increase in sensitivity compared with uncoated CNT.[127]
MWNT-SiO_2	CO_2, O_2, and NH_3	Sensor response times are approximately 45 s, 4 min, and 2 min for CO_2, O_2, and NH_3, respectively. The sensor response is reversible for O_2 and CO_2 but irreversible for NH_3.[128]
SWNT	D-Glucose	Senses D-glucose in solution phase by two distinct mechanisms of signal transduction: fluorescence and charge transfer.[129]
Poly(vinylferrocene)-derivatized MWCNT	Glucose	Glucose concentration in real blood sample can be determined.[130]

aggregates need to be broken up and dispersed or cross-linked to prevent slippage. A main advantage of using nanotubes for structural polymer composites is that nanotube reinforcements will increase the toughness of the composites by absorbing energy during their highly flexible elastic behavior. Other advantages are the low density of the nanotubes, an increased electrical conduction, and better performance during compressive load. Another possibility, which is an example of a nonstructural application, is filling of photoactive polymers with nanotubes. Poly-*p*-phenylenevinylene filled with MWNTs and SWNTs is a composite that has been used for several experiments. These composites show a large increase in conductivity with only a small loss in photoluminescence and electroluminescence yields. Another benefit is that the composite is more robust than the pure polymer. Of course, nanotube-polymer composites could be used also in other areas. For instance, they could be used in the biochemical field as membranes for molecular separations or for osteointegration (growth of bone cells). However, these areas are less well explored. The most important thing we have to know about nanotubes for efficient use of nanotubes as reinforcing fibers is knowledge of how to manipulate the surfaces chemically to enhance interfacial behavior between the individual nanotubes and the matrix material.

Conclusion

Carbon nanotubes continue to hold a tremendous promise as a structural and electronic material. Some types of nanotubes might present a danger similar to that posed by asbestos, which has tiny fibers that can get into lung tissues and cause cancerous lesions.[131] Researchers are suggesting more study and caution in handling the material.

The Rise of Graphene:*[138] 2D

Graphene is the name given to a monolayer of carbon atoms arranged into benzene rings; it is used to describe properties of many carbon-based

* Based on the paper of the same title by Geim and Novoselov[119] (*Nature Materials* 2007;6:183–91).

materials, including graphite, fullerenes, and nanotubes (see Figures 3.44 and 3.45). The graphene theory was first developed by Philip Wallace in 1947 as an approximation to help understand the electronic properties of more complex, three-dimensional graphite.[132] Landau and Peierls, 70 years ago, claimed that 2D crystals are thermodynamically unstable and that divergent contribution of thermal fluctuations in 2D crystals lattices would lead to displacements of atoms comparable to the interatomic distances and thus destroy the 2D layer. They also concluded that the melting temperature of these thin films would rapidly decrease with decreasing thickness. Furthermore, in quantum field theory and statistical mechanics, the Mermin-Wagner theorem (also known as *Mermin-Wagner-Hohenberg theorem* or *Coleman theorem*) says that crystalline order is impossible in two-dimensional structures at non non-zero temperatures, and this has been interpreted as saying that a freestanding, two-dimensional crystal would be disrupted by thermodynamic forces (hence "2D materials were presumed not to exist").[133] It was believed that because of instabilities, a 2D graphene structure would fold up, or crumple, to form a more stable 3D structure. In summary, planar graphene was presumed not to exist in the free state, being unstable with respect to the formation of curved structures such as soot, fullerenes, and nanotubes.

However, in 2004, Novoselov et al. obtained relatively large graphene sheets (eventually, up to 100 μm in size) by mechanical exfoliation (repeated peeling) of 3D graphite crystals.[82] Their motivation allegedly was to study the electrical properties of thin graphite films. As purely two-dimensional crystals were unknown before and presumed not to exist, their discovery of individual planes of graphite may be viewed as accidental. The Manchester experimental discovery of 2D crystal matter was at first put in doubt until 2005, when the groups of Andre Geim and Philip Kim of Columbia University proved that the obtained graphitic layers exhibited the expected theoretical electronic properties of graphene.[134,135] On October 5, 2010, the Royal Swedish Academy of Sciences awarded the Nobel Prize in Physics to Andre Geim and Konstantin Novoselov University of Manchester, UK, "for groundbreaking experiments regarding the two-dimensional material graphene," (http://nobelprize.org/nobel_prizes/physics/laureates/2010/press.html). Single layers of graphite were previously (starting from the 1970s) grown epitaxially on top of other materials. Epitaxial graphene also consists of a single-atom-thick hexagonal lattice of sp^2-bonded carbon atoms, as in free-standing graphene, but there is significant charge transfer from the substrate to the epitaxial graphene, and, in some cases, hybridization between the *d* orbitals of the substrate atoms and π orbitals of the graphene layer. This interaction significantly alters the electronic structure of the epitaxial graphene. The Manchester free-standing graphene on the other hand is a single-atom-thick crystal of a macroscopic size that is either suspended or interacting only very weakly with a substrate.

The electronic structure of graphene approaches the 3D limit of graphite at ten layers of graphene. Today, graphene sheets are prepared by chemical exfoliation (solution-based), epitaxial growth by CVD (same as nanotubes), epitaxy on catalytic surfaces (Ni, Pt), and mechanical cleavage. Single graphene layers are not that difficult to make (see pencil in Figure 3.45), but they are more difficult to identify. With AFM it is possible, but the throughput is very low on large areas, and SEM does not reveal the number of atomic layers. A solution involves the placement of graphene on top of a Si wafer with a carefully chosen thickness of SiO_2; in this way graphene becomes visible even in an optical microscope. An interference-like contrast appears with an SiO_2 thickness of 300 or 90 nm (see Figure 3.57).

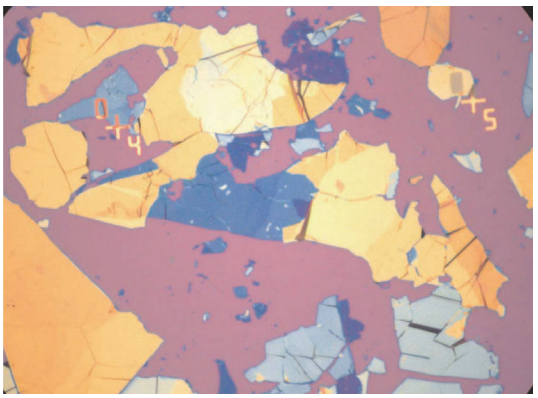

FIGURE 3.57 Graphene on SiO_2 observed in an optical microscope.[117]

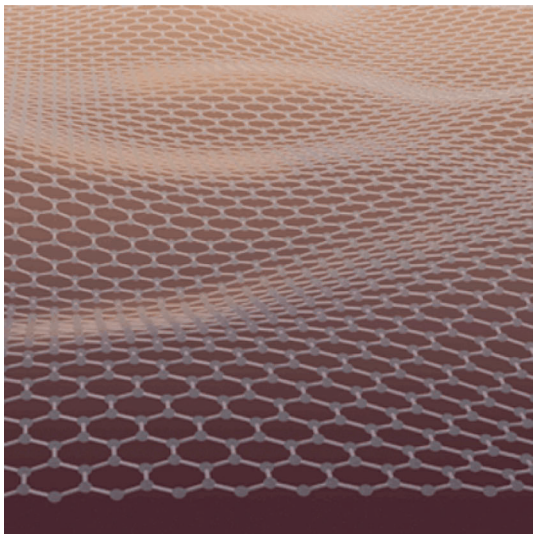

FIGURE 3.58 Graphene sheet with ripples.[119]

The atomic structure of isolated, single-layer graphene has been studied by transmission electron microscopy (TEM) on sheets of graphene suspended between bars of a metallic grid.[136] These electron diffraction patterns showed the expected hexagonal lattice of graphene but also revealed "rippling" of the flat sheet, with an amplitude of about 1 nm (see Figure 3.58). These ripples may be intrinsic to graphene as a result of the instability of two-dimensional crystals referred to above, or they may be extrinsic, originating perhaps from the ubiquitous dirt seen in all TEM images of graphene. While an infinitely large single layer of graphene would be in direct contradiction to the Mermin-Wagner theorem (see above), a finite-size 2D crystal of graphene could be stable. The observed ripples in suspended layers of graphene, it has been proposed, are caused by thermal fluctuations in the material; graphene adjusts to the thermal fluctuations, which could threaten to destroy the structure, by adjusting its bond length to accommodate the fluctuations. Within this context, it is actually debatable whether graphene is truly 2D or not, because of this natural tendency to ripple.[137]

Because graphene is somewhat tricky to make and even trickier to see and handle, most experiments have been performed not on free-standing monolayers but on two types of graphene samples: exfoliated graphene, deposited on a silicon-oxide/silicon substrate (see Figure 3.57), and epitaxial graphene, a layer of carbon atoms chemically deposited on (and chemically bonded to) a substrate of silicon carbide.

The surge of interest in the electronic properties of graphene has largely been motivated by the discovery that electron mobility in graphene is ten times higher than in commercial-grade silicon (up to 100,000 $cm^2\ V^{-1}\ s^{-1}$, limited by impurity scattering, and weakly dependent on temperature), ballistic transport is observed on the submicron scale (up to 0.3 μm at 300 K), and the quantum Hall effect can be observed at room temperature (extending the previous temperature range by a factor of 10). All these properties raise the possibility of high-efficiency, low-power, carbon-based electronics. The surprising electronic properties of graphene are ascribed to the presence of charge carriers that behave as if they are massless, "relativistic" quasiparticles called *Dirac fermions*.

A 2D graphene crystal is very different from a 3D silicon single crystal such as Si. In a semiconductor such as Si, electrons and holes interact with the periodic field of the atomic lattice to form quasiparticles. For example, in Volume I, Chapters 3 and 4, we saw how an electron moving through a conventional solid is described as having an effective mass (m_e^*) that takes into account the drag on its momentum from the surrounding crystal lattice as well as from interactions with other particles. The energy of quasiparticles in a solid depends on their momentum, a relationship described by the energy bands. In a typical 3D semiconductor, the energy bands are "parabolic."

Between them is the forbidden band gap, representing the amount of energy it takes to promote an electron from the valence band to the conduction band. The energy (E) of an electron in such a crystal depends quadratically on its momentum (p), as given by the following equation.

$$E = \frac{\hbar^2 \mathbf{k}^2}{2m_e^*} \left(= \frac{p^2}{2m_e^*} \right)$$

(Volume I, Equation 3.213)

While electron transport in most solids is accurately described by the nonrelativistic Schrödinger

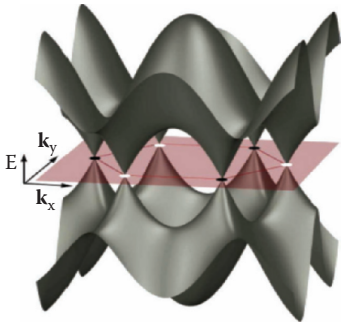

FIGURE 3.59 *E*-**k** surface of graphene. Intrinsic graphene is a semimetal or zero-gap semiconductor.

equation, graphene is quite different from most conventional three-dimensional materials. Unlike in ordinary semiconductors, graphs of the valence band and the conduction band in an *E*-**k** diagram for graphene are smooth-sided cones that meet at six points, called the *Dirac points* (see Figure 3.59). One interesting consequence of this unique band structure is that the electrons in graphene are "sort of free." The *E*-**k** relation near the Dirac points is linear for low energies, leading to zero effective mass for electrons and holes. Charge carriers in this energy range thus behave like relativistic particles (they behave like photons) described by the Dirac equation for spin 1/2 particles. The linear dispersion relationship in the low energy region is simply given by the following equation:

$$E = v_F \mathbf{k} \tag{3.14}$$

where the wave number (**k**) represents momentum and the Fermi velocity (v_F) stands in for the speed of light. Dirac fermions* travel at a constant speed—a small fraction of the speed of light.[138] Graphene has all the ideal properties to become an almost ideal component for integrated circuits. It has a high carrier mobility, as well as low noise, allowing it to be utilized as the channel in a FET. In 2008, the smallest transistor so far, one atom thick, ten atoms wide, was made of graphene.[139] IBM researchers are reporting progress in circuits based on narrow ribbons of planar graphene. The narrow graphene ribbons confine electrons in the narrow, single-planed graphene ribbons, which open up the possibility of building quantum wires and quantum wells. Narrow ribbons of graphene behave much like nanotubes and may be more amenable to manufacturing techniques such as etching. The current technology limits how thin graphene ribbons can be made. It does not allow them to be made thin enough to push to room temperature, so the work is carried out at lower temperatures.

Besides its electronic properties, graphene also is researched for its mechanical, thermal, and optical properties.

Despite all the excitement, don't expect "graphenium" microprocessors just yet. Think about carbon nanotubes, observed in 1991: they have created tremendous excitement, but today, there are no commercial CNT-based breakthrough products on the market—although they supposedly make your golf balls go straighter (a breakthrough for some golfers at least). Moreover, graphene currently is one of the most expensive materials on Earth, with a sample that can be placed on the cross-section of a human hair costing more than $1000 (as of April 2008). The price may fall dramatically, though, if and when commercial production methods are developed in the future.

Noncarbon Nanotubes and Nanowires

A nanotube, strictly speaking, is any tube with nanoscale dimensions, but generally the term is used to refer to carbon nanotubes. With a thin shell that is only one atom wide, nanotubes are hollow, giving them characteristics significantly different from those of solid nanowires made of silicon or other materials. Nanowires can be defined as structures that have a lateral size constrained to tens of nanometers or less and an unconstrained longitudinal size. At these scales, quantum mechanical effects are important. Such wires are also known as *quantum wires*. Many different types of nanowires exist, including metallic (e.g., Ni, Pt, Au), semiconducting (e.g., Si, InP, GaN, etc.), and insulating (e.g., SiO_2, TiO_2). Molecular nanowires are composed of repeating molecular units

* Dirac fermions have also been invoked to explain the quantum Hall effect in graphene, the magnetic-field-driven metal–insulator-like transition in graphite, superfluidity in ^{3}He, and the exotic pseudogap phase of high-temperature superconductors.

either organic (e.g., DNA and protein) or inorganic (e.g., $Mo_6S_{9-x}I_x$).

A major drawback to the utility of carbon nanotubes is the limited control over their chirality, which we saw above directly affects their electronic properties. At present no synthesis methods capable of controlling this feature are available, and selective synthesis of carbon nanotubes having only semiconducting characteristics remains elusive. A commonly studied noncarbon nanotube variety is made of boron nitride (BN). BN is the III-V homolog to graphene, and in this 2D lattice B and N occupy different sublattices—this lowers the symmetry and leads to new physical effects. BN nanotubes are all insulating, with a band gap of about 5 eV. Unlike carbon nanotubes, the conductive properties of BN nanotubes are more or less independent of chirality, diameter, and even the number of walls in the tube. Theoretically, the existence of silicon nanotubes with an sp^2 atomic arrangement is also predicted: creation of this type of nanotube is considered an important challenge for the future.

By making clever choices of seed crystals and growing conditions, it is possible to cause crystals to assume unusual shapes. As originally proposed by R.S. Wagner and W.C. Ellis, from Bell Labs, for the Au-catalyzed Si whisker growth, a vapor-liquid-solid (VLS) mechanism still is mostly used (Figure 3.60).[140]

As illustrated in Figure 3.61, (111)-oriented Si "whiskers" grow from a small Au particle island on a Si(111) surface when heated at 950°C and exposed

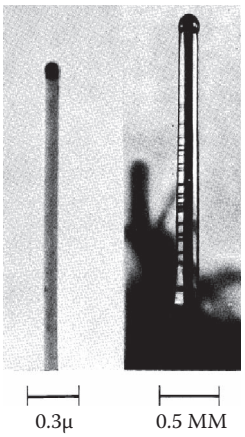

FIGURE 3.60 Si whisker growth: Au-catalyzed Si whisker growth based on a vapor-liquid-solid (VLS) mechanism.

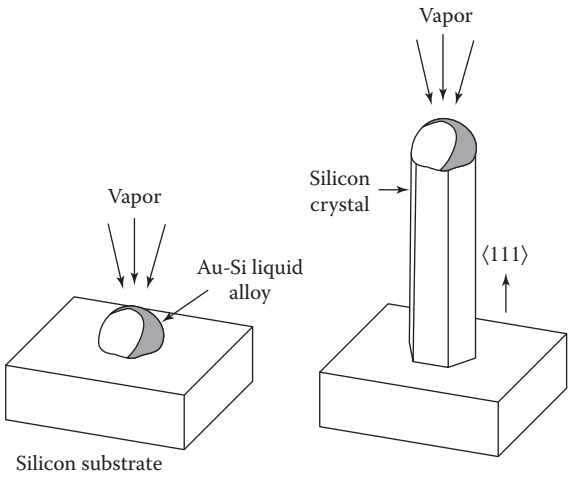

FIGURE 3.61 The vapor-liquid-solid mechanism for single-crystal Si growth.

to a flow of $SiCl_4$ and H_2 in a CVD reactor. Similar results are obtained with Pt, Ag, Pd, Cu, and Ni. When the substrate is heated up, a gold monolayer de-wets (unbinds) from the substrate in liquid form. From there, the liquid gold coalesces into nanoclusters and naturally self-assembles into gold nanoclusters. The gold acts as the catalyst in the VLS model. The liquid droplet is the preferred site for CVD deposition, and once the percentage of source material has supersaturated the nanoclusters, it begins to solidify and grow outward in a perfect single-crystal nanowire. In this growth mechanism the "impurity" is essential and remains in evidence from a small "globule" that is present at the tip of the whiskers during the growth (see Figure 3.61). The role of the impurity is to form a liquid alloy droplet at relatively low *T*. The selection of the impurity is important, as the diameter of the nanowire roughly is controlled by the diameter of the nanoclusters. The length of a nanowire is controlled by the amount of time the source is left on.

The VLS model corresponds to the model for the nucleation and growth of a carbon nanofiber from methane catalyzed by a supported metal particle shown in Figure 3.55 (based on the work of Hoogenraad[107]).

Nanoscale catalysts have been used to seed long, wire-like single crystals of compounds such as indium phosphide or gallium arsenide. The nanowire field got a shot in the arm (a rebirth, so to speak) with efforts by Charles Lieber (Harvard) (Volume I, Figure 3.65), Peidong Yang (http://www.cchem.berkeley.edu/

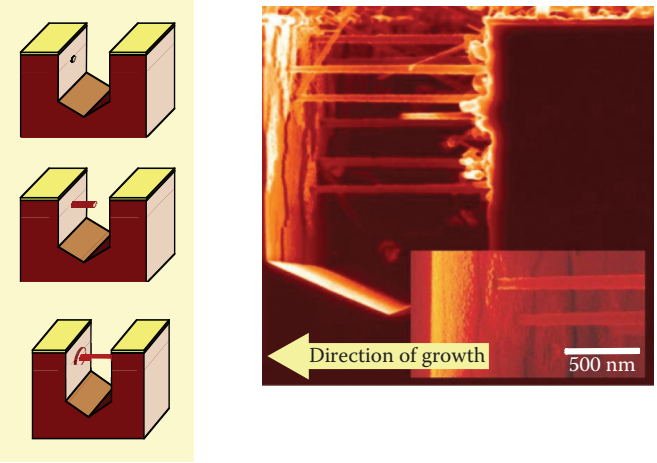

FIGURE 3.62 Lateral growth of nanowires between Si(111) surfaces. (From M. Saif Islam, S. Sharma, T.I. Kamins, and R.S. Williams, *Nanotechnology* 15;L5–L8, 2004. With permission.[141])

pdygrp/main.html), James Heath (http://www.its.caltech.edu/~heathgrp), and Hongkun Park (http://www.people.fas.harvard.edu/~hpark). Lieber's group at Harvard (http://cmliris.harvard.edu) reported arranging indium phosphide semiconducting nanowires into a simple configuration that resembled the lines in a tic-tac-toe board. The team used electron beam lithography to place electrical contacts at the ends of the nanowires in order to show that the array was electronically active.

Saif Islam et al. came up with the idea of connecting vertical Si(111) walls by growing Si nanowires laterally. Starting with a good catalyst on one wall, if there is another vertical surface in its close vicinity, the nanowire hits that surface and makes a bridge.[141] This is illustrated in Figure 3.62.

Electrochemical deposition of nanowires into a porous medium is another popular technique for making metallic nanowires. The porous medium may be porous silica, alumina, polycarbonate membranes, and even polyaniline nanotubules. Nanowire diameters as low as ~10 nm have been reported, and wire length may range from ~1 μm to >20 μm depending on the wire's diameter. Using nanoporous alumina as a template for the deposition of nanostructures of a material of choice, such as metals, semiconductors, and polymers, will be explained in Chapter 5, this volume (in Figure 5.10, the electrochemical deposition of the nanowire thermoelectric material Bi_2Te_3 is illustrated). Dresselhaus et al. show that lower-dimensional structures, such as nanowires based on Bi, BiSb, Bi_2Te_3, and SiGe nanotechnology, give additional controls that could lead to a higher ZT (see Chapter 8, this volume).[54]

TABLE 3.11 Nanowires and Their Applications

Material	Application
Si	Electronics, sensors
Cobalt	Magnetic
Germanium	Electronics, infrared detectors
Tin oxide	Chemical sensors
Indium oxide	Chemical sensors, biosensors
Indium tin oxide	Transparent conductive film in display electrodes, solar cells, organic light-emitting diodes
ZnO	UV lasers, field emission devices, chemical sensors
Copper oxide	Field emission device
Wide bandgap nitrides (GaN)	High temperature electronics, UV detectors and lasers, automotive electronics and sensors
Boron nitride	Insulator
Indium phosphide	Electronics, optoelectronics
Zinc selenide	Photonics (Q-switch, blue-green laser diode, blue UV photodetector)
Bi_2Te_3	Thermoelectric
Copper, tungsten	Electrical interconnects

Table 3.12 Nanowire Chemical Sensor Applications

Metal Oxide	Target Species	Salient Features
V_2O_5 nanofibers	1-Butylamine, toluene, propanol	Extremely high sensitivity was measured for 1-butylamine (below 30 ppb) and moderate sensitivity for ammonia. In contrast, only very little sensitivity was observed for toluene and 1-propanol vapors.[142]
SnO_2 nanobelts	CO, NO_2, ethanol	Sensitivity at the level of a few parts per billion.[143]
In_2O_3 nanowires	NH_3, NO_2	The response times have been determined to be 5 s for 100-ppm NO_2 and 10 s for 1% NH_3, and the lowest detectable concentrations are 0.5 ppm for NO_2 and 0.02% for NH_3.[144]
ZnO nanowires	Ethanol	Sensitive to ethanol concentration is in the range of 1–100 ppm. Sensitivity increases sharply as the temperature is raised from 200 to 300°C.[145]
MoO_3 nanorods	Ethanol and CO	The detection limit for ethanol and CO is lower than 30 ppm.[146]
Cd-doped ZnO nanowire	Relative humidity	Cd-doped ZnO nanowires show a clear positive temperature coefficient of resistance effect, which is quite abnormal compared with pure ZnO nanowires.[147]
SnO_2	Dimethyl methylphosphonate (DMMP)	Sensitive to 53 ppb DMMP; can be improved via doping nanobelts with catalytic additives.[148]

Advanced lithographic techniques (electron beam) are also used to pattern catalyst seeds for nanowire growth. In Table 3.11 we list some typical nanowires and their applications, and in Table 3.12, we review nanowire chemical sensor applications.

Questions

Questions by Dr. Marc Madou assisted by Mr. George O'Quinn, UC Berkeley

3.1: Explain the "fat fingers" and "sticky fingers" controversy, and suggest some possible ways that the problems associated with fat fingers and sticky fingers may be overcome.

3.2: Explain the difference between self-assembly, self-organization, and self-replication.

3.3: Why are fractal structures used consistently in nature? What benefits do these structures entail?

3.4: Make a listing of material properties that change in the nanoscale and explain why they change.

3.5: Explain the process of Stransky-Krastanov (SK) growth and how it can be used.

3.6: What effects do the chiral, zigzag, and arm-chair structures have on the properties of carbon nanotubes?

3.7: What are some important distinctions between top-down and bottom-up manufacturing (nanochemistry)?

3.8: Give some examples of bottom-up manufacturing methods.

3.9: Characterize the guiding principles involved in the growth of living organisms.

3.10: What does irreversible thermodynamics have to do with self-organization?

3.11: In the last few years, applications of quantum dots have become increasingly popular among analytical chemists. Quantum dots are now commercially available for a variety of applications, and many examples of their uses can be found in the literature. Briefly describe what quantum dots are and describe some of their applications.

3.12: Nanotechnology: hype or reality? Write one page.

Introduction

This chapter addresses packaging, assembly, and self-assembly. Under packaging of micromachines, we consider issues that differ the most from integrated circuit (IC) packaging; with micromachines one faces the paradox of needing hermetic isolation from the environment that must be sensed. This has proven to be a challenge for mechanical sensors, such as for pressure and, to a lesser extent, for accelerometers, but it is the Achilles' heel of chemical and biological sensors. We distinguish between wafer-level (batch) packaging steps and serial packaging processes and learn that micromachining itself plays an important role in transforming costly serial packaging steps into less costly, wafer-level processes.

During packaging, miniature components are put together into a housing structure in a microassembly step. This task becomes more cumbersome with smaller building blocks and will increasingly necessitate the use of parallel self-assembly techniques. Self-assembly is imperative when components are nanoscale.

Packaging

Introduction

In electronic device and mechanical micromachine fabrication, processes can be divided into three major groups.

1. First, fabrication with additive and subtractive processes, as described in Volume II. These also are called *front-end processes*.
2. Packaging, involving processes such as bonding, wafer scribing, lead attachment, and encapsulation in a protective body.
3. Testing, including package leak tests, electrical integrity, and sensor functionality.

The last two process groups incorporate the most costly steps and are called *back-end processes*. In the case of a micromachine, which often interfaces with a hostile environment and where testing might involve chemical and/or mechanical parameters, packaging and testing are yet more difficult and expensive than in the case of ICs. More than 70% of the sensor cost may be determined by its package, and the physical size of a micromachined sensor often is dwarfed by the size of its package. Most conventional packaging approaches are space inefficient, with volumetric efficiencies, even in the case of ICs, often less than 1%.[1]

Contrasting the inefficiency of human packaging methods with nature's excellence at packaging is striking. As an example, consider how DNA is packed in the nucleus of a cell. Biomolecules in a solution coil up with a gyration radius r_g given by the de Gennes formula, $r = (Lb)^{1/2}$, where L is the molecule's contour length and b is determined by the degree to which the molecule resists thermal motion.[2] The total length of all DNA in a human cell is 2 m, which is a million times the cell nucleus diameter. For b of DNA, a value of 100 nm has been determined. The resulting radius of the 2-m DNA molecule is calculated at 0.45 mm, 1000 times the nucleus diameter. How does nature pack all this into the nucleus of a cell? The answer is efficient packaging. Like a thread on a spool, DNA is wound around a set of nuclear proteins—the histones. The molecule is wound twice around one "spool" and then passes onto the next, and so on. A necklace of histones is neatly packed into a chromosome. This packaging scenario is illustrated in Figure 4.1. This way, a 0.45-mm polymer coil is squeezed into a nucleus of less than a micrometer.[3]

Packaging issues of ICs and mechanical micromachines are somewhat similar, whereas packaging of devices that are used in fluids (e.g., level sensor) or that contain liquids (e.g., some electrochemical sensors) are totally different. The latter require very

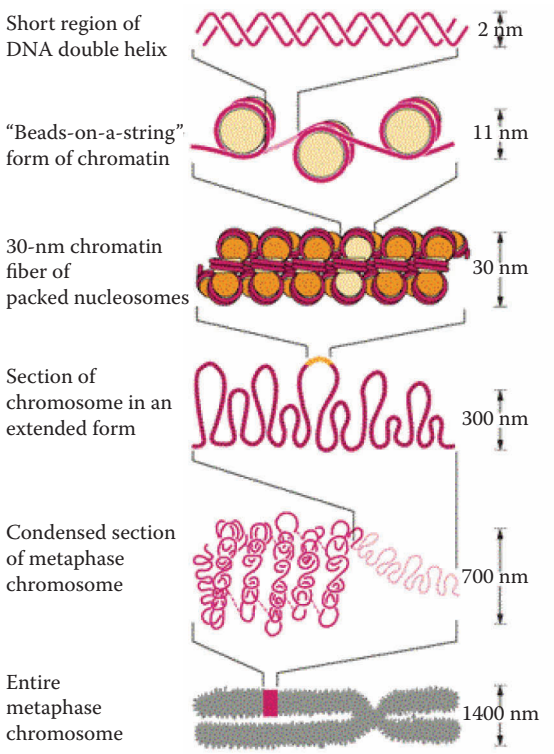

FIGURE 4.1 DNA is packaged very compactly in the cell. In eukaryotic cells, it is assembled into chromosomes, which have a hierarchical structure. The double-stranded DNA is wound twice around disc-like protein "beads" made from eight separate protein units called *histones*. The DNA-histone assembly is a nucleosome. The DNA chain, with nucleosomes all along its length, is then wound into a helix, which is itself packaged into a compact bundle in the chromosome.

different partitioning solutions and often must face biocompatibility issues as well.

Packaging in ICs and MEMS

Packaging is an essential bridge between components and their environment. In ICs, packaging provides at least four functions:

1. Signal redistribution
2. Mechanical support
3. Power distribution
4. Thermal management

In chemical and biological MEMS, the package might have several additional functions, for example:

1. Biocompatibility for in vivo devices
2. Fluidic manifold to guide liquids to different parts of the MEMS structure
3. Window/opening for analyte to interact with the chemical sensitive part of the MEMS structure

The signal redistribution is easy to understand: the electrical contacts of an IC are too closely spaced to accommodate the interconnection capacity of a traditional printed wiring board (PWB). Packaging redistributes contacts over a larger, more manageable surface—it fans out the electrical path. The mechanical support provides rigidity, stress release, and protection from the environment (e.g., against electromagnetic interference). Power distribution is similar to signal distribution except that power delivery systems are more robust than signal delivery systems, and the thermal management function is there to provide adequate thermal transport to sustain operation for the product lifetime.[1]

The various levels of packaging and their interconnections in the IC industry that we adapt here also for micromachines are summarized in Table 4.1[1] and illustrated in Figure 4.2a.[4,5] The lowest level in the IC electronics (L0 in the hierarchy) is single IC features interconnected on a single die with IC metallization lines into a level 1 IC or discrete component. Single-chip packages and multichip modules are at level 2. Levels 3 and 4 are the PWB (L3) and chassis or box (L4), respectively. Level 5 is the system itself. The hierarchy for packaging a micromachine such as a pressure sensor is illustrated in Figure 4.2b and 4.2c. For more information on advanced packaging schemes in ICs, we refer to the excellent reviews by Lyke,[1] Jensen,[4] and Lau.[6]

Packages for microelectronic systems have evolved over five decades to accommodate devices that largely have no need to interact with the environment. Packages for micromachines have all the same functions as listed for ICs but are considerably more complex, as they serve to protect from the environment while, somewhat in contradiction, enabling interaction with that environment so as to measure or affect the desired physical or chemical parameters. With the advent of integrated sensors, the protection problem became more complicated. Silicon circuitry is sensitive to temperature, moisture, magnetic field,

Table 4.1 Connection between Packaging Elements at Various Levels in the Hierarchy for ICs and Micromachines

Level	Element	Interconnected by
Level 0	Transistor within IC or resonator in MEMS	IC metallization
Level 1	ICs or discrete components such as a MEMS silicon/glass pressure sensor	Package leadframes (single-chip) or multichip module interconnection system
Level 2	Single- and multichip IC packages or a pressure sensor in a TO header in MEMS	Printed wiring boards
Level 3	Printed wiring boards	Connectors/backplanes (busses)
Level 4	Chassis or box	Connectors/cable harnesses
Level 5	System itself, e.g., a computer (IC-based) or a gas alarm system (MEMS-based)

electromagnetic interference, and light, to name just a few items. The package must protect the onboard circuitry while simultaneously exposing the sensor to the effect it measures. For example, in an in vivo integrated sensor, a true hermetic seal is necessary to protect the circuitry from the effects of blood, and the housing needs to be biocompatible as well. The housing also might be equipped with a fluidic manifold, for example, to guide the analyte to the sensor surface. Sometimes the circuit itself can be used to reduce packaging concerns, for example, to transmit data about effects which cannot be screened out, as in the removal of a temperature effect from a pressure signal. But more frequently, integration of electronics with MEMS, especially when dealing with measuring chemical or biological signals,

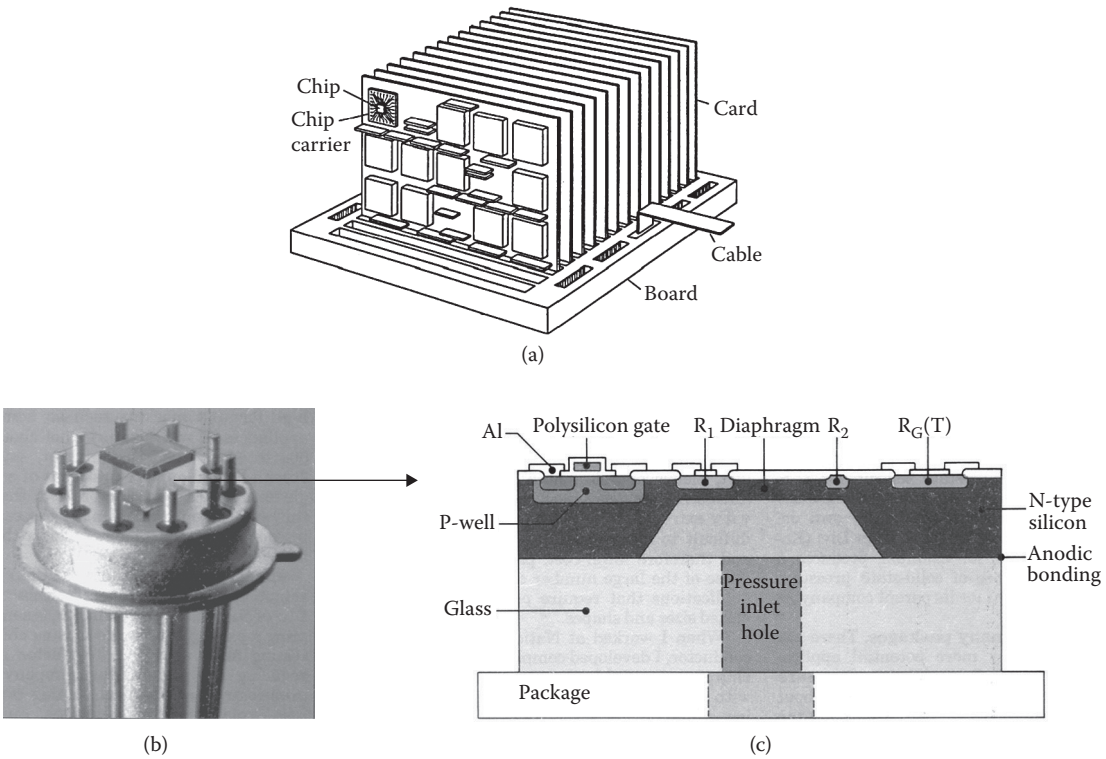

FIGURE 4.2 The packaging hierarchy in the integrated circuit (IC) world and in micromachining. (a) A large electronic unit with ICs. Transistors on the IC are level L0. The IC itself is level L1. The chip carrier is level L2, and the printed wiring board (card) is level L3. The chassis (or box) is level L4. Level 5 (L5), not shown, is the system itself, e.g., a computer. (From Jensen, J. R. 1989. In *Microelectronics processing,* ed. D. W. Hess and K. F. Jensen, 441–504. Washington, DC: American Chemical Society. With permission.[4]) (b) and (c) A micromachined unit: piezoresistive pressure sensor from NEC. L0, diaphragm on die; L1, Si/glass piece; L2, sensor mounted in TO header.

causes more problems than it solves. A package must also provide communication links, remove heat, and enable handling and testing. The material used must be one that will afford physical protection against normal process handling during and after assembly, testing, and prescribed mechanical shock. Chemical protection is also required during assembly and in practical usage. For example, during the process of installing dice on substrates, the package undergoes a series of cleanings and, under normal usage, the package may be exposed to oxygen, moisture, oil, gasoline, and salt water. The package must also be capable of providing an interior environment compatible with device performance and reliability; for example, a high-Q* resonator might need a good vacuum. Physical sensors usually have a physical barrier layer or fluid; for example, a pressure transmission fluid interposed between the sensing Si elements and the environment outside, making the encapsulation problem less severe.

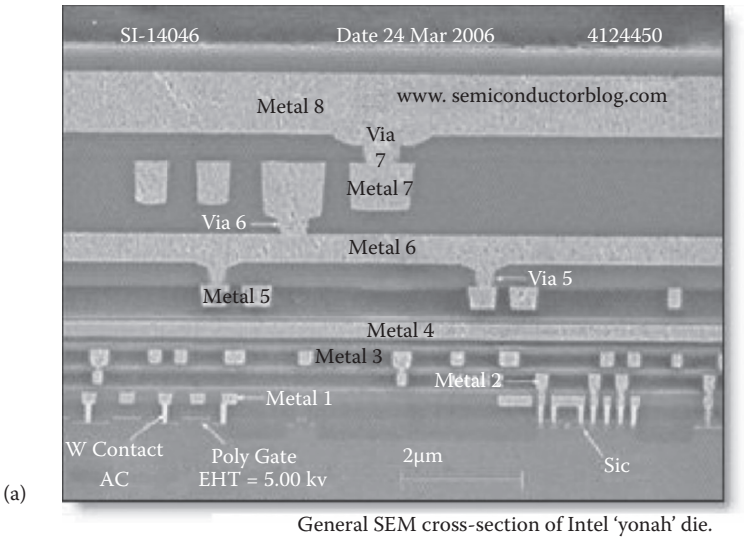
The sensor community is still searching for the perfect way to protect sensors from their environment while at the same time probing that environment. The packaging problem is the least severe for a physical sensor such as an accelerometer, which can be sealed and protected from all chemical environment effects while probing the inertial effects it measures. The problem is most severe for chemical and biological sensors, which must be exposed directly to an unfriendly world. Generalizing, chemical and biological sensors have been orders of magnitude more difficult to commercialize than physical sensors, in no small part because of packaging problems. In the latter case, problems are especially severe with electronic components and sensors integrated on the same side of a single Si substrate. For that reason, chemical and biological sensors are better made with hybrid MEMS. In hybrid MEMS, MEMS and electronics are fabricated in separate processes and put together afterward within a common package. Making a hybrid device or putting the electronics on the other side of the wafer often provides better protection of the electronics from the environment. The challenges in packaging chemical and biological MEMS are further compounded by the fact that these devices usually are less expensive than ICs or physical MEMS sensors and that they are often disposable.

* As we will learn in Chapter 8, this volume, there are two different common definitions of the Q factor of a resonator (see "Quality Factor" in Chapter 8). One is via the energy storage where the Q factor is given as 2π times the ratio of the stored energy to the energy dissipated per oscillation cycle, or equivalently the ratio of the stored energy to the energy dissipated per radian of the oscillation. The other definition is via the resonance bandwidth in which the Q factor is the ratio of the resonance frequency f_0 and the full width at half-maximum (FWHM) bandwidth Δf of the resonance. Both definitions are equivalent only in the limit of weakly damped oscillations, i.e., for high Q values.

Front-End and Back-End Processes

During the front-end processing phase, an IC or MEMS is created on a silicon substrate (referred to as a wafer). During the back-end processing phase, the IC chips created during the front-end processing phase are encapsulated into packages and thoroughly inspected before becoming completed products. The front-end and back-end processes are preceded by a design phase and by the mask creation in which the function of the IC is defined, the electric circuit is designed, and a mask for IC manufacturing is created on the basis of the design.

In this chapter we are primarily concerned with the more expensive, serial back-end processes. The back-end process used to start after the last of the IC fabrication steps, i.e., to make the interconnections within an underlying IC (from level 0 to level 1 in Table 4.1). Unfortunately, things are not that simple anymore; lately making internal IC connections has become so complicated that even within that process one talks about front end and back end of the line steps. As advanced ICs contain more than a 100 million transistors, the importance of internal IC connections is steadily increasing. As shown in Figure 4.3a, eight metal layers already are quite common. The old standard for making these metal lines was using insulating layers made of silicon dioxide, via formation by plasma etching of holes, covering the whole surface with tungsten (W), polishing the tungsten down to the silicon dioxide, leaving the vias filled with tungsten plugs, and finally sputtering an aluminum layer and selective etching it to leave the connecting Al lines. As we saw in Volume II, Chapter 8, the more advanced process for constructing interconnections in ICs uses the "dual damascene" technique (see Figure 4.3b). This process, as we glean



General SEM cross-section of Intel 'yonah' die.

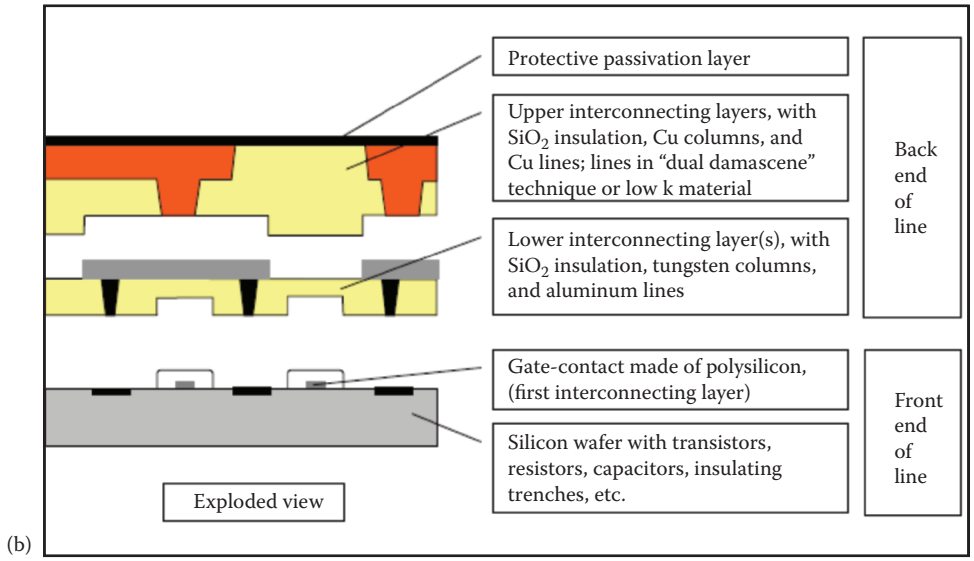


FIGURE 4.3 The back-end process usually takes of at the back end of the integrated circuit (IC) line, which makes the interconnections within an IC (from level L0 to L1). In the case of very complex interconnecting schemes such as the dual damascene, one also talks about back-end and front-end processes with the interconnecting scheme. (a) Eight-metal complementary metal-oxide-silicon chip. (b) Dual damascene technique is used to connect upper interconnecting layers with lower connecting layers (back end of line) and transistors on the wafer (front end of line).

from Figure 4.3b, is itself split up in a back-end and a front end of the line. In the dual damascene process, the last step in the front end of the line is a first interconnecting layer made up of poly-Si for the gate contacts. The back end of the IC interconnection process then starts with an insulating layer, either again made of silicon dioxide or from inorganic or organic materials with lower dielectric constants (so-called *low-k materials*). Next comes the creation of beds for lines and vias in two subsequent photoimaging process steps followed by plasma etching of the insulating layer. In a subsequent process step, the whole surface is covered with copper, and chemical mechanical polishing (CMP) removes the copper down to the top side of the insulating layer (see Figure 4.3b and Volume II, Figure 8.41).

CMP has developed into a very important step in the process chain of wafer fabrication (see Volume II, Chapter 1, Figure 1.66 for a CMP setup). The CMP slurry contains 1) chemistry to modify, e.g., oxidize, the top layer, and 2) abrasive particles to remove the modified material. CMP serves to planarize

insulating layers, to remove tungsten or copper, to define vias and lines, and to back grind the wafer to make thin flexible chips.

The resulting flat chip surface now features input/output (I/O) pads that are of rectangular shape and made from the metal of the top layer, i.e., from aluminum or copper (in GaAs chips, gold is used for contacts). These exposed metal surfaces are slightly alloyed to increase hardness and longtime stability. The chip surface, except the I/O pads and the dicing lines, are covered by a passivation made from silicon oxide and silicon nitride. Historically, this passivation was a crucial step in the development of plastic packages. Plastic packaged chips are not as well protected from humidity as chips in hermetically sealed housings.

Testing the outcome of a wafer process depends on hundreds of parameters that all have to be tightly controlled during production. All materials and parameter settings are recorded to allow the back tracing of deviations. Processed chips still on a wafer are difficult to test, because measurements at high frequencies with hundreds of contacts are difficult and expensive. Therefore, only a so-called *static test* at low frequencies is performed to do a first wafer screening, perhaps in a manual probe station with needle tips and a microscope, as shown in Figure 4.4.

The packaged chip—with its built-in (shielded) fan out of the contacts—is the best location in the fabrication chain to do a full testing of the device (L2; see below). But before we can mount the chip in its package we need to dice it.

FIGURE 4.4 Optical microscope with needle-tip manipulators.

Dicing

One of the final steps in front-end processing of an IC or three-dimensional (3D) microstructure fabrication and the first in back-end packaging is sawing the finished Si wafer into individual "dice." After the wafer is probed (see above; Figure 4.4), it is mounted onto sticky tape and put onto the dicing saw (Figure 4.5). A typical saw blade consists of a thick hub with a thin rim impregnated with diamond or carbide grit. Rotating at a speed of several thousand revolutions per minute, the blade encounters the Si wafer at a feed rate on the order of a centimeter per second, sawing partially or completely through the wafer. After dicing, the elastic plastic sheet can be stretched to distance the chips in case the saw kerf went all the way through the Si wafer.

Except when cutting a silicon-glass bonded wafer combination, standard IC cutting practices regarding surfactants, cleanliness, and blade width/depth ratio apply to MEMS wafers as well. Typical kerf widths are 50–200 µm, while typical roughness along the kerf edge is 10–50 µm. The restrictions of mechanical sawing include this roughness, which precludes the fabrication of smooth structures along the outside edge of the die. In addition, the vibration inherent in the sawing process makes it difficult to securely hold down dice during sawing if these dice are less than 0.5 mm on a side. For smaller dice, micromachining is necessary for edge definition and separation of individual devices. In the latter case, anisotropically etched V-grooves extending almost through the depth of the wafer separate the individual dice, which might be broken apart by applying a small mechanical force. Alternatively, the dice

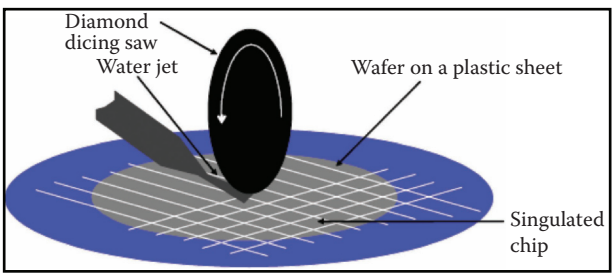

FIGURE 4.5 Dicing operation.

are etched completely free at the moment critical components (e.g., a pressure-sensitive membrane) have reached the specified thickness (see V-groove Thickness Control in Volume II, Figure 4.44).

Most mechanical sensors and actuators are equipped with a bonded cap or cover (Si, glass, etc.), protecting them during dicing. In the case of surface micromachined devices, a final sacrificial release etch (see Volume II, Chapter 7) is performed after the dicing is complete. This procedure ensures that there are no free mechanical structures during the dicing, but it implies also that the microstructures must be freed on individual dice, making for a more costly device. The TI DMD™ arrays described in Volume II, Example 7.2 are handled this way: they are diced first, and then the organic sacrificial layer is etched in an oxygen plasma. The cap approach is not applicable in the case of flow sensors, and chemical and biological sensors or other devices that require direct contact with their surrounding environments.

Level 1 Packaging (L1) and Level 2 Packaging (L2)

Introduction

Level 1 devices are packaged with leadframes (single-chip), transistor outline (TO)-headers, or multichip module interconnection systems, and the resulting devices are then packed onto printed wiring boards (see Table 4.1). Micromachining deviates most dramatically from ICs in the nonstandard nature of packages from level 2 up. In the case of some sensors, standard TO-5 and TO-8 headers still might be useful, but in most cases the package dictated by the specific application is of a much more complex nature.

Single-Device Packaging

A typical package for single chips with 100 and more leads is the quad flat pack (QFP) illustrated in Figure 4.6. The process steps necessary to build such a QFP are the stamping or etching of a leadframe, gluing the chip to the leadframe (also named die bonding), wire bonding the chip to the leadframe, overmolding everything except the outer leads and cutting and bending the leads to gull-wing shape. In the cross-section of the QFP, in Figure 4.6b, the different elements of a QFP are visible: the chip, the leadframe and the glue, the gold wires, the overmolding, and the final form of the leads. This package is now ready to be soldered to a printed wiring board.

Leadframes are stamped or etched strips of metal sheets (Figure 4.7). Chips can be mounted in one or several rows on the large central pads. The outside dimensions of the strips—width, length, and the holes at the edge—are standardized. The basic material is an iron-nickel-alloy. The inner leads, the lands for the gold wire, have to be gold or silver plated. The outer leads are pretinned for the later soldering to the printed wiring board. An auxiliary rectangular line circumventing the main package is needed to seal the overmolding form. This line is stamped out after overmolding.

The die is glued to the large central pad of the lead frame with a conductive epoxy resin. Precise mounting of the chips is required to facilitate the subsequent wire bonding. The glue has to be cured before wire bonding starts. Because standard glues cure in tens of minutes, rather than in seconds, the curing is quite a disturbing factor in a production line. Batches of leadframes have to be placed in a curing oven.

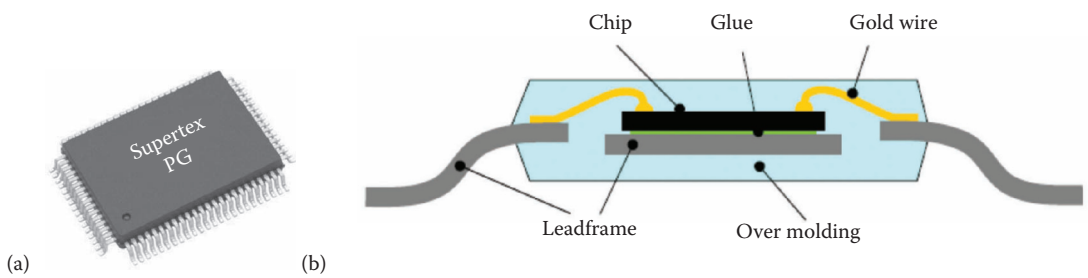

FIGURE 4.6 (a) An eighty-lead plastic quad flat pack (QFP) ready for soldering to a printed wiring board (PWB). (b) A QFP in cross-section.

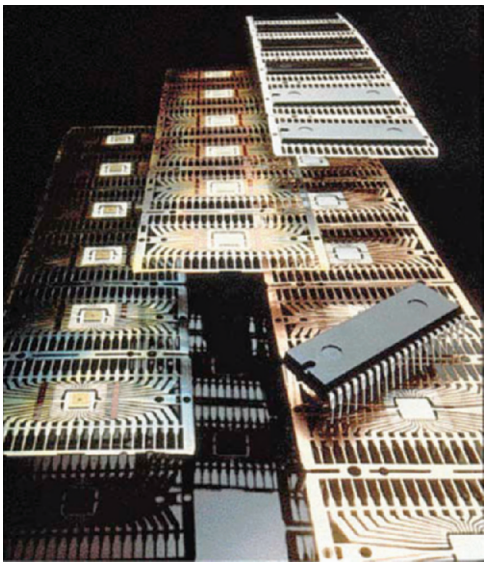

FIGURE 4.7 Leadframes are stamped or etched strips of metal sheets.

The QFP shown in Figure 4.6 is a relatively old packaging scheme introduced in the 1980s. The dual inline package (DIP), what most people envision when they think of an IC "chip," was developed even earlier (in the 1960s) (Figure 4.8a). In a DIP, the leads are perpendicular to the body of the package, making them ideally suited for insertion mounting onto printed wiring boards (PWBs) using plated through-holes.

A QFP is an example of surface mount technology (SMT). In SMT, the leads do not penetrate the PWB surface, and ICs are mounted, by reflow solder technology, on both sides of the PWB, resulting in higher-density electronics. In the industry, SMT has largely replaced the through-hole technology construction method of fitting components with wire leads into holes in the circuit board. An SMT component usually

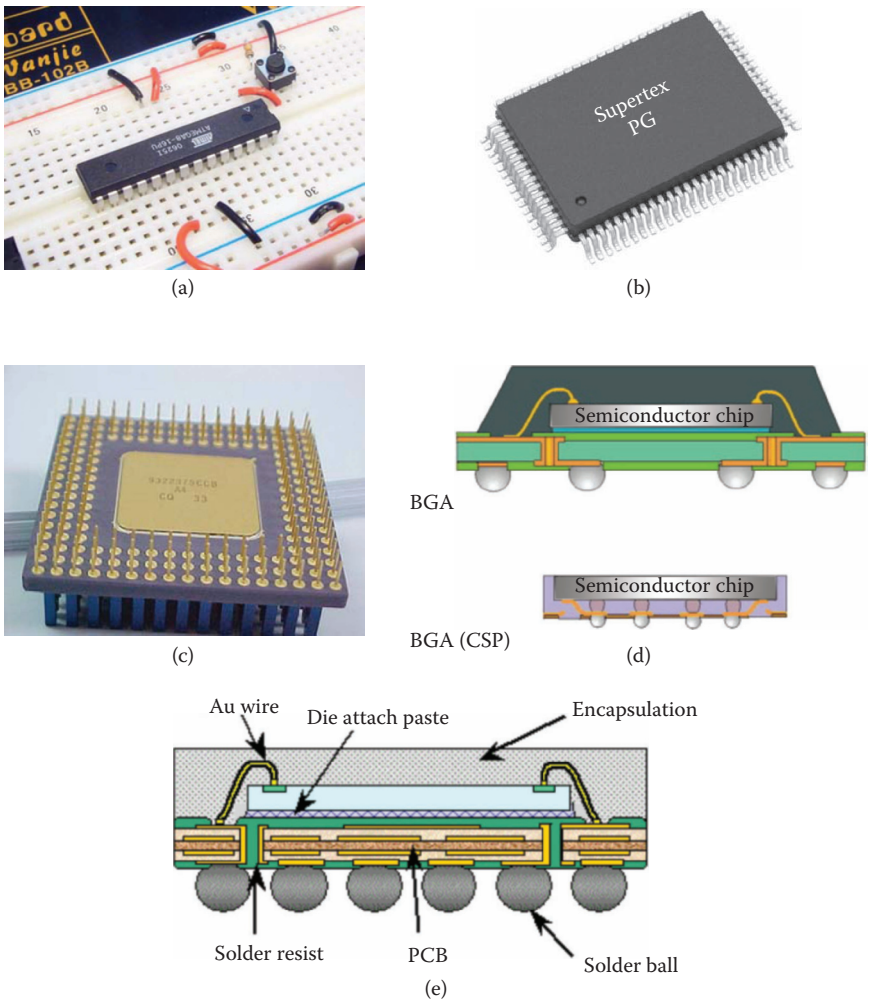

FIGURE 4.8 Packaging options. (a) The dual inline package (DIP), developed in the sixties. (b) The quad flat pack (QFP) was developed in the 1980s. It is a first example of surface mount technology. (c) Pin grid arrays (PGAs) were also developed in the 1980s. (d) Ball grid array (BGA), developed in the early 1990s as a replacement for QFPs, including a BGA implemented as chip scale packaging (CSP). (e) Detail of chip scale package (CSP).

is smaller than its through-hole counterpart because it has either smaller leads or no leads at all. The QFPs (see above and Figure 4.8b) and pin grid arrays (PGAs; Figure 4.8c) were developed in the 1980s. There are leadless or leaded ones and come in plastic or ceramic bodies. With contacts on all four sides, up to ~200 I/Os are possible with QFPs, and PGAs can have up to ~600 I/Os. Ball grid arrays (BGAs) (Figure 4.8d) were developed in the early 1990s as a replacement for QFPs. They feature solder bumps in a matrix on the bottom of the package. They have a higher density, smaller footprint, and shorter electrical paths (i.e., faster signal propagation) but are more expensive than QFPs. BGAs are the natural choice for multichip module (MCM) packaging (see below). Chip scale packaging (CSP) was developed in the late 1990s (see bottom drawing labeled "BGA (CSP)" in Figure 4.8d and Figure 4.8e). CSP is a general term for all semiconductor packaging schemes that aim to be almost the same size as the chip itself (typically about 1.2 times the bare chip). In CSP, the package is an extension of the bare IC and permits easier handling, testing, and assembly. In one version of CSP, the BGA packaging scheme is modified with electrodes that are directly installed on the bottom of the IC. [See bottom drawing labeled "BGA (CSP)" in Figure 4.8d and Figure 4.8e.]

A simple single die mounting method, often used in MEMS, is in a header, as shown in Figure 4.9, where we show the bulk silicon micromachined piezoresistive accelerometer manufactured by TRW NovaSensor (Fremont, CA) in a TO-5 header.

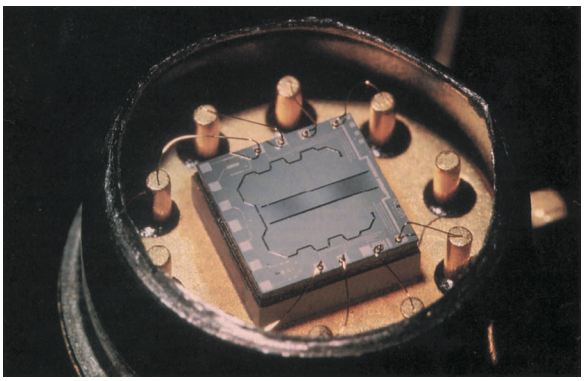

FIGURE 4.9 Commercially available Si accelerometer based on hybrid technology; bulk-micromachined 50-g accelerometer bonded into a TO-5 header. Signal conditioning electronics are on a separate chip. (Courtesy of TRW NovaSensor.)

After dicing a MEMS sensor die, the die attachment step to the header follows. In a typical header, gold-plated pins are hermetically sealed to the header base with glass eyelets, which provide a hermetic feed through with both high electrical and mechanical integrity. To protect the mounted sensor, a metal can is hermetically resistance-welded to the header. Since the thermal expansion coefficient of the package material to which the die is attached typically differs substantially from that of Si and glass, the die attachment must compensate for this. The three methods used the most for die attach are eutectic (Au-Si alloy), epoxy, and silicone rubber, in order of highest to lowest stress.[1,4] The next step in the process consists of the electrical connection to the Si sensor. Gold or aluminum wire is bonded by thermosonic, thermocompression, or wedge-wedge ultrasonic wire bonding (see "Wire Bonding", this chapter). The fine gold wires in the TO-5 package illustrated in Figure 4.9 are barely visible. Wire bonding occasionally damages MEMS components during packaging, as the applied ultrasonic energy, typically at a frequency between 50 and 100 kHz, may start the oscillation of suspended mechanical microstructures. Coincidentally, many micromachined structures have resonant frequencies in the 50–100 kHz range, increasing the risk of structural failure during wire bonding.

The TO-5 packaged accelerometer in Figure 4.9 is an example of a relatively simple packaging solution; typically MEMS packaging is a lot more challenging. Indeed, an accelerometer can be completely shielded from its environment, whereas many other MEMS sensors must be exposed directly to the environment they are sensing.

It is imperative that sensor elements are not subject to undesirable mechanical stresses originating from their packaging structure. Slow creep in the adhesive or epoxy that bonds the silicon die to the package housing, for example, may lead to long-term drift. Corrugated structural members, as used by Jerman,[7] decouple the sensor from its encapsulation, reducing the influence of temperature changes and packaging stress. Corrugated members have been implemented, for example, in single-crystal silicon, polysilicon, and polyimide. The technique was described in Volume II, Chapter 7, as one of the

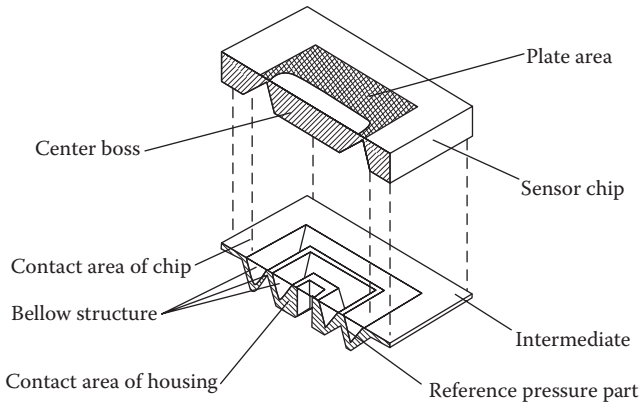

FIGURE 4.10 Stress release bellows. A corrugated intermediate Si piece decouples the sensor from its housing. (From Offereins, H. L., H. Sandmaier, B. Folkmer, U. Steger, and W. Lang. 1991. In *6th International Conference on Solid-State Sensors and Actuators [Transducers '91],* 986–89. San Francisco. With permission.[10])

methods to control stress in micromachined structures. The stress-decoupling, corrugated bellows either surround the sensor structure itself[8,9] or the sensor chip is mounted via an intermediate with a bellow structure to the housing.[10] The latter implementation is sketched in Figure 4.10.

Thermal management in MEMS involves cooling heat-dissipating devices, especially thermal actuators, but also includes understanding and controlling the sources of temperature fluctuations that may adversely affect the performance of the device. Thermal modeling must include both the die and its package. To facilitate heat flow from die to package, a die-attach scheme must be used that exhibits high thermal conductivity.

The last assembly step, after die attachment and electrical contacting, involves the protection of the silicon die and electrical leads. This is especially important for sensors and actuators that are to be used in intimate contact with harsh environments. Various methods are available, including the following:[1,4]

1. Vapor-deposited organics for mildly aggressive environments {e.g., 2–3-μm thick low-pressure chemical vapor-deposited [LPCVD] parylene [poly(*p*-xylene)]}. A negative aspect of this form of passivation is that the added layer often makes the die too stiff for accurate sensing or actuating functions.
2. Silicone oil over the die for medium-isolated pressure sensors.
3. Coating of the die surface with soft substances such as silicone gel. Hardening of the gel over time is a major problem. Silicones do not form a moisture barrier, and the exact mechanism by which they protect the die as a surface coat is not understood.[11]
4. SiC (e.g., deposited with plasma-enhanced chemical vapor deposition) for harsh environments.[12]
5. A plastic or ceramic cap for particle and handling protection.
6. A welded-on nickel cap with pressure port.

Multichip Packaging

A multichip module (MCM) is a chip package that contains two or more bare chips mounted close together on a common substrate. Shorter tracks between the individual chips increase performance and eliminate much of the noise that external tracks between individual chip packages pick up. There are four main categories of MCMs based on the substrate used:

1. Laminated (MCM-L): Constructed of plastic laminate-based dielectrics and copper conductors using PWB technology. These are the lowest cost MCMs.
2. Ceramic (MCM-C): Constructed on cofired ceramic or glass-ceramic substrates using thick-film (screen printing) technologies.
3. Deposited (MCM-D): Uses a dielectric layer over a ceramic, glass, or metal substrate, and thin film interconnects are created on the dielectric layer. These are the highest-performance MCMs.
4. Si-based (MCM-Si): Uses a silicon substrate with tracks created in the silicon like regular ICs. Transistors can also be formed in the substrate.

ICs and micromachined chips may be packed laterally or they may be stacked on top of one another. In the latter case, individual dice, blocks of dice, and entire wafers may be stacked with electrical interconnections either made by wires (see Figure 4.11)

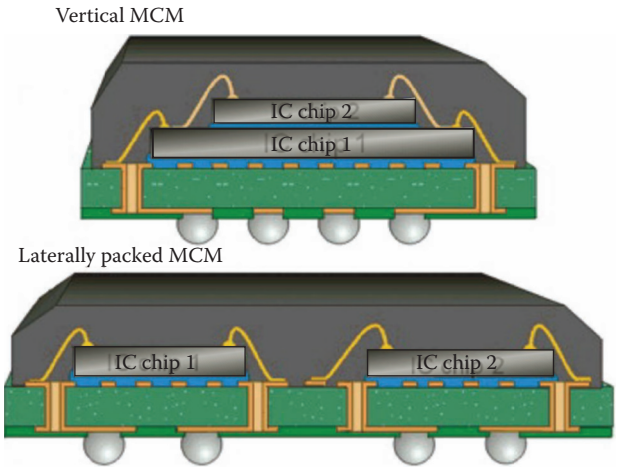

FIGURE 4.11 Schematic of a two-chip MCM.

or interconnects running vertically from plane to plane.[13] A commercial example of a four-chip MCM is shown in Figure 4.12.

MCMs increase the interconnect density on printed circuit boards and speed up the processing time. Multichip modules are an important supporting technology for MEMS, as most MEMS are better partitioned into separate sensing and electronic parts rather than being built monolithically in Si. MCM also allows complementary metal-oxide-silicon (CMOS) and bipolar technologies to be used in the same package.

Instead of the wire bonds shown in the MCMs in Figure 4.11, flip-chip bonding often is used to make contact to the chip. In flip-chip bonding, as its name implies, the die is bonded, facedown, on its substrate without the use of connecting wires (see "Electrical Connection Methods" and Figure 4.13). Electrical contacts are made directly between plated solder bumps on bond pads on the die and metal pads on the packaging substrate. The intimate spacing between the die and the substrate (<200 μm) presents two major advantages. With wire bonding, the pads on the die must always be positioned on the periphery to avoid crossing wires, but with flip-chip bonding, the bond pads may be placed over the entire die. This results in a significant increase in density of possible I/O connections (up to 700 simultaneously I/Os). Second, the effective inductance of each interconnect is minuscule because of the short height of the solder bump compared with that of a gold wire. These are the reasons why the integrated circuit industry has adopted flip chip for high-density, fast electronic circuits. Flip-chip mounting is equally attractive to the MEMS industry. Again, the ability to closely package a number of distinct dice on a single-package substrate with multiple levels of embedded electrical connections represents a major advantage. This approach may be used, for example, for bonding to electrically connect and package three dice, including an accelerometer die, a yaw-rate sensing die, and an electronic application-specific integrated circuit (ASIC) onto one ceramic substrate to build a fully self-contained navigation system. A similar unit could be built with wire bonding, but it would be significantly larger and its reliability would be questionable given the large number of "loose" gold wires within the package.[14] In the next section we explain how a typical flip-chip process works.

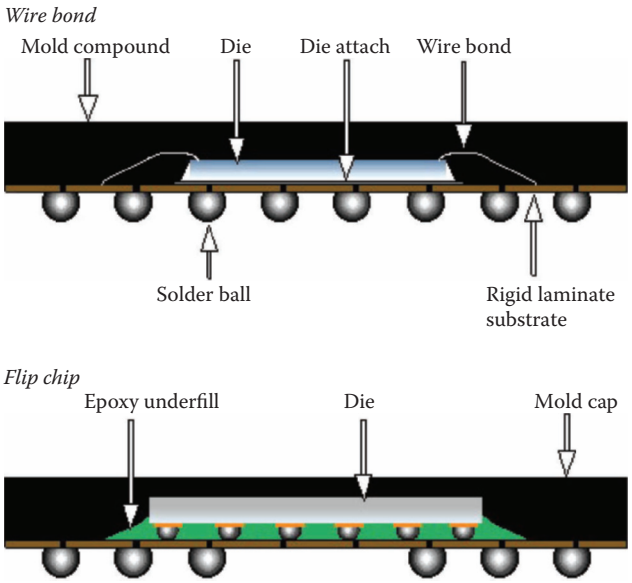

FIGURE 4.13 Flip-chip versus wiring bonding.

Electrical Connection Methods

Introduction

The three most used electrical connection methods between a chip and a substrate are illustrated in Figure 4.14. They are wire bonding, tape automated bonding (TAB), and flip-chip bonding.

Wire Bonding

The pads on a chip and the pads on a substrate (e.g., a leadframe, but also a printed wiring board or ceramic substrate) often are interconnected by wire bonding. A gold, copper, or aluminum wire is bonded between each bonding pad of the chip and the corresponding pad on the substrate. There are two major types of wire bonding: ball-wedge and wedge-wedge bonding. In gold ball-wedge bonding, a gold wire is fed through a ceramic capillary, as shown in Figure 4.15. The protruding wire end is melted by an electrical spark to form a ball, which is bonded to the first pad. This operation requires both ultrasonic excitation of the capillary and heat application to the substrate (200°C). The capillary guides the gold wire now to the second pad, where it forms a wedge and cuts the wire in a single step. The wire has to be clamped to cut it, and ultrasound action and heat application also are necessary to achieve good adhesion of the wedge to the second pad. Copper ball-wedge bonding is also possible when the copper wire is flushed by an inert gas during ball formation. Copper wires can be used instead of gold wires. They fit well to the copper pads of the most recent ICs, and their electrical conductivity is higher. Copper wires also are stiffer than gold wires and exhibit less wire sweep during overmolding. After the mounting and bonding, process steps to establish corrosion protection and mechanical protection of the chip are needed, either by hermetic sealing of the assembled board or locally by "glob top" sealing with a droplet of sealing material, e.g., epoxy. Wire bonding of bare chips is used in hybrids, most often with a ceramic substrate. Chip on board is also used with glass/epoxy laminates in some consumer applications (pocket calculators, watches, smart cards, etc.), and occasionally in professional applications.

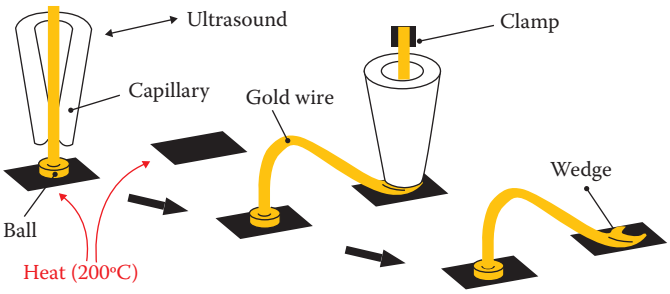

FIGURE 4.15 Gold ball-wedge bonding.

An aluminum ball cannot be formed as easily in air as it can with gold because aluminum oxidizes immediately in air (much faster even than copper). Another technique, wedge-wedge bonding, has to be used as illustrated in Figure 4.16. Aluminum is

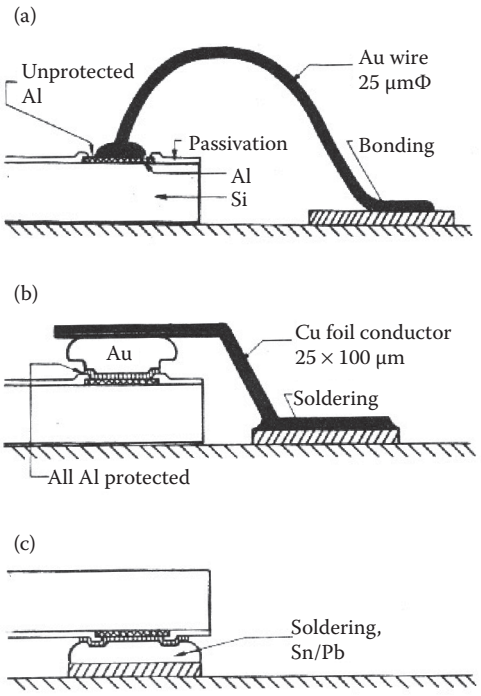

FIGURE 4.14 The three most used electrical connection methods between a chip and a substrate: (a) wire bonding; (b) tape automated bonding (TAB); (c) flip-chip bonding.

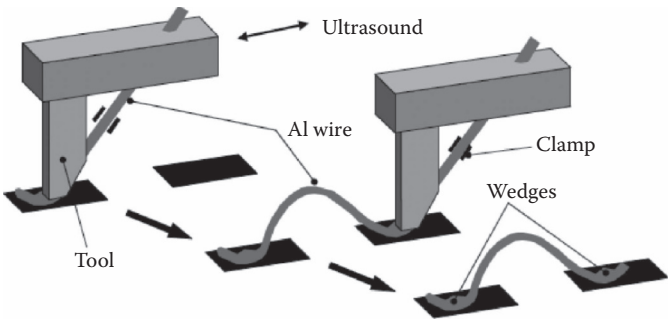

FIGURE 4.16 Wedge-wedge bonding of aluminum wire.

a soft metal, but its oxide at the surface is very hard and has to be broken by the ultrasound action of the wedging tool. Aluminum bonding can be performed with the substrate at room temperature. This is a huge advantage when bonding to a standard PWB substrate with a low glass transition, i.e., softening temperature (T_g) of around 150°C. The wedging tool used for aluminum bonding is directional, and it has to be rotated for different bonds in different directions. It is also larger than the capillary in ball-wedge bonding, so it needs more room on its back side and cannot reach into deep holes between components.

Tape automated bonding (TAB) is illustrated in Figures 4.14b and 4.17. It uses a leadframe made from a fine film of copper conductor on a dielectric film such as polyimide for interconnections between chip and substrate. The conductor patterns in the leadframe are imaged using a photolithography process from a continuous copper layer on the dielectric carrier film. The TAB leads connecting the die and the tape are the inner lead bonds, while those that connect the tape to the package or to external circuits are known as the outer lead bonds (see Figure 4.17). The mounting is done such that the bonding sites on the die, usually in the form of bumps or balls made of gold or solder, are connected to fine conductors on the tape, which provide the means of connecting the die to the package or directly to external circuits (Figure 4.17). To facilitate the connection of the die bumps or balls to their corresponding leads on the TAB circuit, holes are punched on the tape where the die bumps will be positioned. The conductor traces of the tape are then cantilevered over the punched holes to meet the bumps of the die. The leads are soldered to the substrate with a specialized tool called *thermode* ("impulse soldering"). Finally, the bare chip is encapsulated with epoxy or plastic (glob topped). The main advantage of TAB is the tight pitch of the circuit. Line pitches of 45 μm are achievable (22.5-μm lines/spaces). This allows for high-density circuits. TAB is in widespread use in liquid crystal displays, electronic watches, and other high-volume consumer products. Other TAB applications are VLSI circuits with a high lead count and other high-end needs.

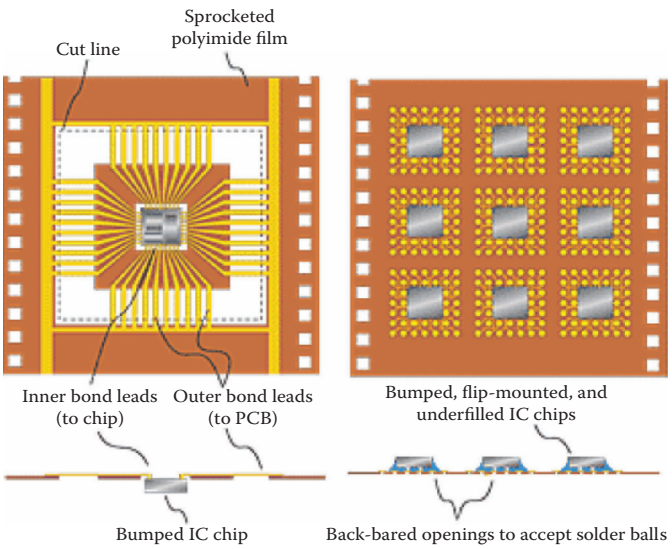

FIGURE 4.17 Tape automated bonding (TAB) takes advantage of flexible base films to make interconnections from the chip to a printed wiring board.

Flip-Chip Bonding

The concept of the flip-chip bonding process, with the semiconductor chip assembled facedown onto a substrate, is ideal for limited size applications because there is no extra area needed for contacting on the sides of the component (see Figure 4.13). Flip chip is carried out by mounting the chip upside down on the substrate, after having deposited solder bumps on all interconnection pads of the chip. The chip is then soldered directly onto the substrate, which requires close thermal matching of the chip and substrate. To make solder bumps on the die, a typical process involves sputter deposition of a thin titanium adhesion layer over the aluminum bond pad metal, followed by sputtering of a copper seed layer. The titanium and copper are patterned with photoresist to form a pedestal for the solder bump. Before the solder bump itself is formed, a thicker layer of copper is first electroplated on the patterned pedestal. The solder bump, typically a tin-lead alloy, is electroplated over the electroplated copper. On the substrate side, solder paste is screen-printed in patterns matching the landing sites of the solder bumps on the die. Pick-and-place robots position the die, facedown, and align the solder bumps to the solder-paste pattern on the substrate. Heating in an oven or under infrared radiation melts the solder, and the bond is created. Often an underfill step is required to fill the void space between the die and

the package substrate with epoxy. The underfill not only adds mechanical strength to the assembly but also protects the connections from environmental hazards. Underfill adhesive may be dispensed along one or more edges of the die and is drawn into the space under the die through capillary action. Heat-curing the underfill adhesive completes the assembly process.

Conductive adhesives are a viable alternative to tin-lead solders for flip chip joining. Conductive or nonconductive adhesives may attach a gold stud bumped chip to a substrate. The conductive adhesives used are either isotropic, conducting in all directions, or they are anisotropic, conducting in a preferred direction only. In Figure 4.18 we show a schematic drawing of flip chip bonding with isotropically conductive adhesives (ICAs) and anisotropically conductive adhesives (ACAs). In either case, the adhesives act as the electrical and mechanical joining agents.

Isotropic conductive adhesives consist of an adhesive binder filled with conductive particles that are normally in contact with each other and provide a low electrical resistance in all directions. Generally, the polymer resin is an epoxy and the conducting particles are silver. The adhesive may be dispensed by stencil printing onto the substrate bond pads, or the bumped die may be dipped into a thin layer of the adhesive, coating only the bumps. Stencil printing of the conductive adhesive limits minimum pad pitch to about 90 µm. Since dipping places adhesive only on the bump surface, the minimum bump spacing is smaller than for stenciling, to pad pitches of 60 µm or less. After the isotropic conductive adhesive is heat cured, a nonconducting underfill adhesive is applied to completely fill the under-chip space.

Anisotropically conductive adhesives are pastes or films that are filled with metal particles or metal coated polymer spheres to a concentration that ensures electrical insulation in all directions before bonding, but after bonding the adhesive becomes electrically conductive in the z-direction. Anisotropically conductive adhesives have the ability to connect finer-pitch devices.

Also, nonconductive adhesives can be used for flip chip bonding, in this case the joint surfaces are forced into intimate contact by the adhesive between the component and substrate.

In general, the pad pitch of the die is finer with adhesive flip-chip than possible with solder flip-chip. The cleaning step is not as rigorous as with solder-based systems; it eliminates process steps such as coating the interconnect pads with solder and eliminates the use of lead. On the downside, the electrical conductivity of ICAs and ACAs is inferior to that of tin-lead solders. ICAs have about 1

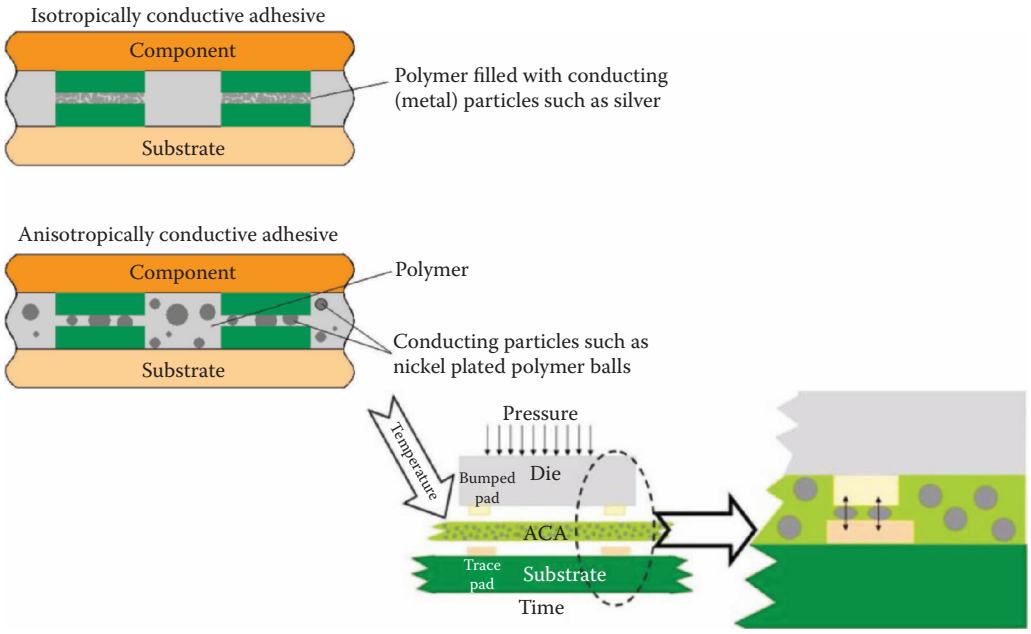

FIGURE 4.18 Schematic drawings of flip-chip joints made with conductive adhesives.

magnitude greater volume resistivity than eutectic tin-lead solder.

Flip-chip technology gives the highest packaging density of the different interconnection methods described here. It gives excellent electrical characteristics and high reliability when properly used, but it is a very demanding technology both to establish and operate. Initial costs are high, favoring high-volume or high-end applications. The performance in high-frequency applications is superior to other interconnection methods, because the length of the connection path is minimized. Also, reliability is better than with packaged components because of the decreased number of connections. Flip-chip technology is potentially cheaper than wire bonding because bonding of all connections takes place simultaneously, whereas with wire bonding one bond is made at a time. In practice, however, this price benefit is not always achieved because of immature processes, e.g., the cost of die bumping with current processes can be significant, especially in low volumes. Today flip-chips are widely used for watches, mobile phones, portable communicators, disc drives, hearing aids, LCD displays, automotive engine controllers, and mainframe computers.

Flip-chip mounting is not compatible with all MEMS devices. For example, there is a risk of damaging the thin diaphragm of a pressure sensor during a flip-chip process.

In what follows we review the different options for through-wafer electrical interconnects. Most methods work for Si only, but others may also be used to form vias in polymers, glass, and ceramics.

Making Vias through Silicon

At first glance, chemical etching is the simplest way to form holes (vias) through Si. The author applied this method for the fabrication of an electrochemical sensor array bonded to a bottom Si chip carrying the electronics (see Volume II, Figures 4.92 to 4.96). Unfortunately, the aspect ratio, length versus diameter, is low, less than 1, so integration is limited by the space between the holes.

With dry etching of vias, problems used to include a lack of sufficiently fast etch rates and sufficient selectivity over the mask. However, advances in high-density plasma sources now allow for etch rates up to 4 µm/min, a selectivity of Si versus SiO_2 of over 150 (70:1 for resists), and aspect ratios of 30:1.[15,16] Along this line, Chow et al. present a through-wafer electrical interconnect fabrication process compatible with standard CMOS processing.[17] In this pre-CMOS process step, a high-density SF_6 plasma (Bosch process; see Volume II, Chapter 3) is used to etch circular holes of 18–25 µm in a 400-µm-thick wafer. By etching from each side, the aspect ratio capability required of the etching process is halved.

Another via alternative is laser drilling. With laser drilling, an aspect ratio of 1:50 can be reached, and relatively high drilling speeds (e.g., 10 holes per second) are possible at a power density of 10^{11} W/cm^2.

Ultrasonic drilling makes for cleaner vias than laser machining, which, unless there is a reactive gas involved or a femtosecond laser, leaves debris on via rims. The ultrasonic technique is limited to "large" diameter holes (100 µm and up). Laser-machined holes are compared with ultrasonically drilled holes in Volume II, Figure 6.21. In all the techniques for making a through-wafer electrical interconnect thus far described, after the hole is created, a metal or highly doped polysilicon must be deposited for electrical connection. In the case of a conductive substrate, the walls of the hole must be passivated first, for example, by growing a thermal oxide. Most methods described to deposit the metal in the vias combine sputtering and electroless or electroplating.

Localized, very deep (throughout the thickness of a wafer) doping of Si is possible by temperature gradient zone melting (TGZM).[18] In this case, via formation and metal deposition become one and the same process. An example is the fabrication of Al interconnects through a Si wafer. At sufficiently high temperatures, aluminum will form an alloy with Si. If the Si substrate is subjected to a temperature gradient, the molten alloy zone will migrate to the hotter side of the wafer. In practice, Al thermomigration in Si starts with electron beam deposition of a thick layer of Al (>5 µm) and photolithographically defining the aluminum into the desired pattern on one side of the Si wafer. The wafer is then radiatively heated from the other side to temperatures considerably higher (1000–1200°C)

than the eutectic temperature to form the molten zone. The one-sided heating imposes a thermal gradient of up to 50°C/cm across the molten zone, resulting in a highly aluminum doped (2×10^{19} cm^{-3}) zone of single-crystal Si. Because of the speed (the zone moves through the silicon on the order of 10 μm/min), wafers can be doped through their thickness in minutes. With TGZM, the concomitant side diffusion is a few micrometers compared with millimeters for solid-state diffusion.

In principle, this technique offers very exciting opportunities for novel 3D structures, as connections can be made front to back on a Si wafer. However, the lines through the silicon, being active junctions, are light sensitive, and the Al on the exit side can turn very rough. Also, because the process is so extreme, it needs to precede the implementation of any other structure on the wafer.

Bonding of Layers in MEMS

Introduction

Wafer bonding is a technology that has found widespread use in IC as well as MEMS fabrication. It allows the permanent bonding of two wafers. Applications include packaging, fabricating 3D structures, and forming multilayer devices. In MEMS, more often than with ICs, one needs to bond a variety of materials together, including Si to a glass pedestal (e.g., in pressure sensors), Si to Si (in many multistack MEMS devices), and polymer to polymer (e.g., in fluidic devices).

Assisted Thermal Bonding or Anodic Bonding

Field-assisted thermal bonding, also known as anodic bonding, electrostatic bonding, or the Mallory process, is commonly used for joining glass to silicon. The main utility of the process stems from the relatively low process temperature (the temperature limit for IC processed Si substrates is about 450°C). Since the glass and Si remain rigid during anodic bonding, it is possible to attach glass to Si surfaces, preserving etched features in either the glass or the silicon. This method is mostly applicable to wafer scale die bonding (L1).

A bond can be established between a sodium-rich glass, say Corning #7740 (Pyrex), and virtually any metal.[19] Besides Pyrex, Corning #7070, soda lime #0080, potash soda lead #0120, and aluminosilicate #1720 are suitable as well.[20] In the case of Si, Pyrex is most commonly used. Bonding can be accomplished on a hot plate in atmosphere or vacuum at temperatures between 180°C and 500°C. Typical voltages, depending on the thickness of the glass and the temperature, range from 200 to 1000 V. The operating temperatures are near the glass-softening point but well below its melting point, as well as below the sintering temperature of standard AlSi metallization. At the most elevated temperatures, the wafers are bonded in 5–10 min, depending on voltage and bonded area.[20] Compared with Si fusion bonding (see below), anodic bonding has the advantage of being a lower-temperature process with a lower residual stress and less stringent requirements for the surface quality of the wafers. Figure 4.19 represents a schematic of an anodic bonding setup and an image of the actual operation. Generally, one places a glass plate on top of the Si wafer and makes a pinpoint contact to the uppermost surface of the glass piece, which is held at a constant negative bias with respect to the electrically grounded silicon. The bonding is easy to follow: looking through the glass, the bonded region moves from the contact cathode pinpoint outward and can be detected visually through the glass by the disappearance of the interference fringes. When the whole area displays a dark gray color, the bonding is complete.

A constant current, instead of constant voltage, could also be used but is avoided, since dielectric breakdown may occur after the bonding is complete and the interface becomes an insulator (see bonding mechanism below). The contacting surfaces need to be flat (surface roughness $R_a < 1$ μm and warp/bow < 5 μm) and dust-free for a good bond to form. The native or thermal oxide layer on the Si must be thinner than 200 nm. The height of metal lines crossing under the bonded area should be less than 600 Å, or 1000 Å for hermetic sealing. The thermal expansion coefficients of the bonded materials must match in the range of bonding. In Figure 4.20, we show the thermal expansion coefficient of Si, a borosilicate

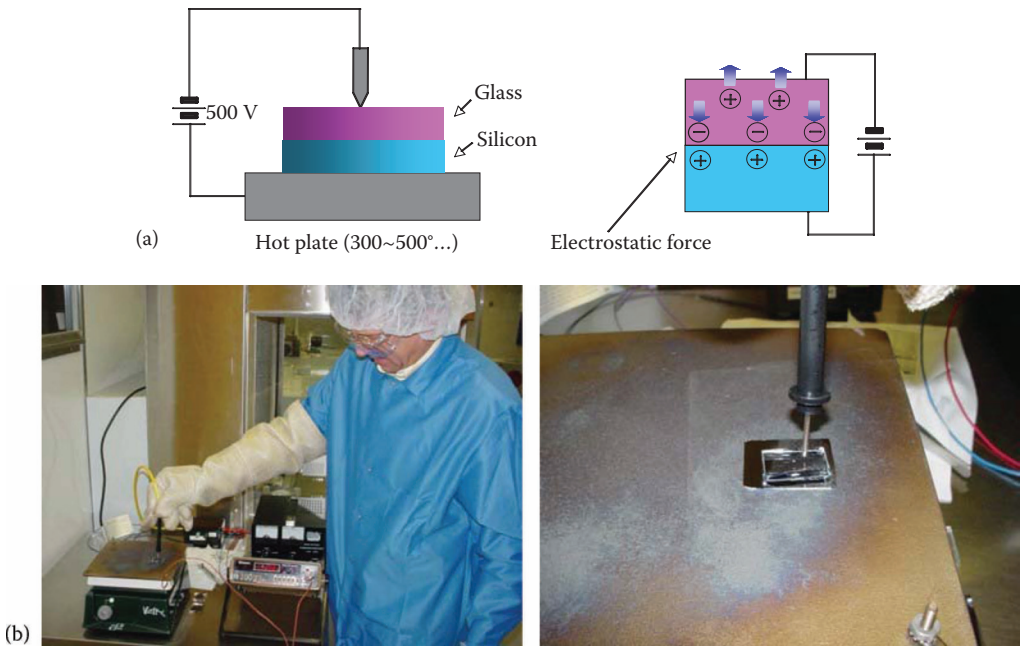

FIGURE 4.19 (a) Principle sketch of anodic glass-to-Si bonding. Control parameters are temperature (300–400°C), bias voltage (700–1200 V), time (~2 min), and materials (glasses, Si, SiO_2). (b) Actual anodic bonding process on a simple hot plate.

glass, and a Pyrex-like glass (HOYA's SD-2) as a function of temperature.[21] The curves of borosilicate glass and silicon single-crystal wafer cross at about 240°C. When anodic bonding is performed at 400°C, the difference of the expansions at high temperature creates residual stress in the Si chip during cooling to room temperature.

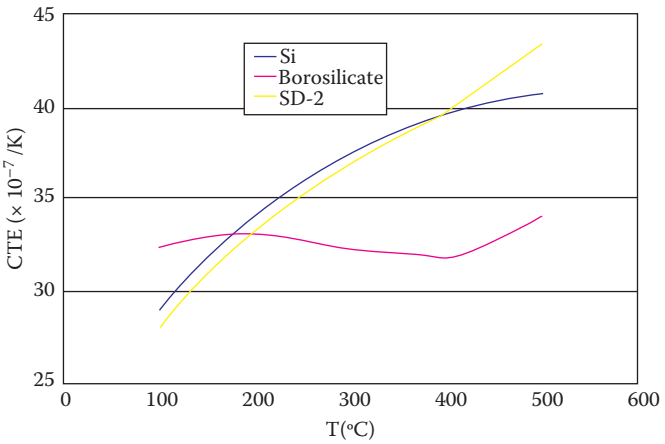

FIGURE 4.20 Thermal expansion coefficients of Si, borosilicate, and a Pyrex-like glass, HOYA's SD-2, a substrate engineered to minimize the distortion or bowing effect caused by the thermal mismatch between the two wafers. CTE, coefficient of thermal expansion. (From Peeters, E. 1994. *Process development for 3D silicon microstructures, with application to mechanical sensor design*. PhD thesis, Catholic University of Louvain, Belgium.[21])

Above 450°C, the thermal properties of the materials begin to deviate seriously; therefore, the process should be limited to 450°C. One also expects that Si would be under compression for seal temperatures below 280°C and under tension for temperatures in excess of 280°C.[21] Wafer curvature measurements indicate, however, that the transition from concave 7440 glass/Si sandwiches (Si under compression) to convex sandwiches (Si under tension) lies around a seal temperature of 315°C.[21,22] This indicates that other non-negligible, stress-inducing effects add an additional compressive component. As we learned before, for most applications tensile stress is preferred over compressive stress, and a considerable safety margin toward higher bonding temperatures must be respected to avoid buckled Si membranes and bridges.

The anodic bonding mechanism is not yet completely understood. Electrochemical, electrostatic, and thermal mechanisms and combinations thereof have been suggested to explain bond formation, but the dominant mechanism has not been clearly defined. It is suggested that at elevated temperatures, the glass becomes a conductive solid electrolyte, and the bonding results through the migration of sodium (Pyrex contains approximately 3–5% sodium) toward the cathode (see Figure 4.19). As

it moves, it leaves a space charge (bound negative charges) in the region of the glass/silicon interface. Most of the applied voltage drop occurs across this space charge region, and the high electrical field between the glass and Si results in an electrostatic force, which pulls the glass and Si into intimate contact. During this charging process, the electric field is high enough to allow a drift of oxygen to the positive electrode (Si) reacting with silicon and creating Si-O bonds. The elevated temperatures and high electric field thus result in covalent bonds forming between the surface atoms of the glass and the silicon. A good quantitative discussion on the many important effects in anodic bonding is by Anthony.[23]

Field-assisted bonding has also been applied to bond GaAs to glass. Corning #0211 is used at 360°C, and a bias of 800 V is applied for 30 min to complete the bonding process. It is well known that GaAs forms very poorly adhering oxides, leading to poor anodic bonding; prebaking of the glass at 400°C for 15 h in a reducing atmosphere (H_2 and N_2) is reported to lead to better bonding.[24] Von Arx et al. bonded glass capsules to a smooth polysilicon surface to form a hermetically sealed cavity large enough to contain hybrid circuitry of a biocompatible implant.[25]

The high electrical field and the migration of sodium make anodic bonding of glass plates to Si a rather difficult technology. The mismatch in thermal expansion coefficient between the glass and the Si causes both thermally induced and built-in mechanical stress. In addition, the viscous behavior of the glass results in degraded long-term stability of the components. As a result of these problems, several modifications of the basic technology have been introduced (see below). A typical commercial instrument for anodic bonding is from Electronic Visions Co.'s 500 Series-Wafer Bonding Systems (e.g., the EV560).

Field-Assisted Thermal Bonding Modifications

The pinpoint method for anodic bonding, as illustrated in Figure 4.19, requires a very high bias voltage and a long period of time to bond areas far removed from the cathode point, since the electrical field in the glass substrate diminishes fast as the distance from the pinpoint cathode increases. At NEC, a Ti mesh bias electrode is deposited over the whole glass wafer to accomplish faster bonding. Because of the mesh assistance, the whole wafer may be Si bonded at 400°C and 600 V in less than 5 min, compared with over an hour at the same temperature and voltage without the mesh.[26]

Another modification of anodic bonding by Sander[27] involves deposition of intermediate layers of Si dioxide and aluminum to screen the underlying Si from harm from the high electrical fields. First, Si dioxide is thermally grown on the Si surface. Then, a layer of aluminum is deposited on the oxide surface. Finally, a piece of glass is bonded to the aluminum. This technique produces a good hermetic seal, but the soft aluminum may be expected to creep after bonding, producing drift in the sensor output. In addition, the aluminum is not corrosion resistant for in vivo applications, so that the bond area may corrode rapidly. A similar modification of glass-to-silicon bonding also uses a sandwich structure, but a layer of polycrystalline silicon (polysilicon) is deposited on the oxide surface instead of aluminum, and a piece of glass is bonded to the polysilicon (see also Von Arx et al.[25]).

It is also possible to anodically bond two Si wafers with a thin intermediate sputtered[28,29] or evaporated[30] borosilicate glass layer (4–7 μm thick). Because two Si wafers are used, there are fewer problems associated with mismatch in thermal expansion coefficient. In addition, since the glass layer is very thin, the voltage necessary for the bond is usually no more than about 50–100 V. Using a thin intermediate film makes the devices akin to a monolithic structure. Residual stresses and thermal expansion coefficient mismatches only have minor effects on device performance. The surfaces of the Si to be bonded should be polished, and one of the two wafers should be coated with the thin glass layer. This intermediate layer may be sputtered from a Pyrex target, resulting in a rather slow process. Hanneborg et al., for example, report a growth rate of 100 nm/h at a pressure of 5 mTorr argon and sputtering power of 1.6 W/cm^2.[29] The films, as deposited, are highly stressed and must be annealed before bonding at the annealing point of 565°C in a wet oxygen atmosphere.[20] With a 4-μm-thick sputtered

glass layer, 50 V and a temperature of 450–550°C suffices to create a hermetic bond. With sputtered layers below 4 µm thick, a thermally grown SiO_2 must be included between the glass and the silicon to avoid electrical breakdown during anodic bonding. The bond strength with Pyrex as an intermediate layer, measured by pulling the wafers apart, ranges from 2 to 3 MPa. As the Pyrex thin films etch very slowly in KOH, they can be used as a mask material for anisotropic etching.[31] Esashi et al.[32] report room temperature anodic bonding using a 0.5–4-µm-thick film sputtered from a Corning glass #7570 target. This glass has a softening point of 440°C compared with 821°C for Pyrex, and bonding is completed within 10 min with 30–60 V applied. A pull test reveals a resulting bond strength in excess of 1.5 MPa. Application of pressure up to 160 kPa on the wafer sandwich apparently supports the bonding process; at a pressure of 160 kPa, the minimum voltage to achieve bonding drops by a factor of 2. The slow deposition rate of glass sputtering presents a major disadvantage for this technique, but evaporated glass layers can be deposited with much higher rates up to 4 µm/min and could provide a solution; unfortunately, in this case pinholes tend to reduce the breakdown voltage.[30]

Field-assisted bonding between two Si wafers, both provided with a thermally grown oxide film, is also reported to be successful. Both Si wafers must be covered with 1 µm of oxide. Bonding of a bare Si wafer to a second wafer with oxide failed because of oxide breakdown under very small applied bias. Temperatures range from 850°C to 950°C, and a voltage of 30 V must be applied for 45 min at the chosen bonding temperature.[33]

Silicon Fusion Bonding

The ability to bond two Si wafers directly without intermediate layers or applying an electric field simplifies the fabrication of many devices. This direct bonding of silicon to silicon, Si fusion bonding (SFB), is based on a chemical reaction between OH groups present at the surface of the native or grown oxides covering the wafers. The bonding relies on the tendency for both very smooth and flat surfaces to adhere, and heat annealing to increase bond strength. The method is of great interest for the fabrication of silicon-on-insulator (SOI) structures. The processes involved in making these bonds are simpler than other currently employed bonding techniques, the yields are higher, the costs are lower, and the mechanical sensors built according to this principle exhibit an improved performance. Finally, as demonstrated in Figure 4.21, the size of an SFB-type device can be almost 50% smaller than that of a conventional anodically bonded chip.

Wafer bonding may be achieved by placing the surfaces of two wafers in close contact and

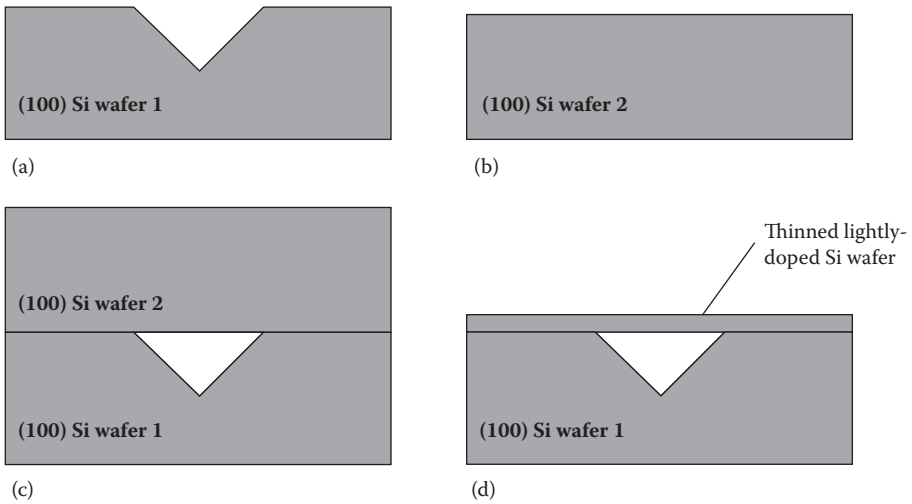

FIGURE 4.21 Silicon fusion bonding enables smaller-footprint microelectromechanical system devices to be fabricated. (a) Etch a silicon wafer to create a square pit (inverted pyramid). (b) A plain second silicon wafer is cleaned and ready for fusion bonding to the first wafer. (c) Bond the two wafer using fusion bonding. (d) The second wafer is then thinned down from the back side using either mechanical-chemical polishing or etching.

inserting them in an oxidizing ambient at temperatures greater than 800°C. It may be noted that the term *silicon fusion bonding* is somewhat misleading; the fusion point of Si at atmospheric pressure is 1410°C, well below the relevant process temperatures.[31] The quality of the bond depends critically on temperature and the roughness of the surface. Flatness requirements are much more stringent than for anodic bondings, with a microroughness R_a < 10 or 40 Å and bow < 5 µm versus 1 µm R_a and bow < 5 µm in anodic bonding. Because of the high temperature involved, active electronics cannot be incorporated before the bonding takes place (the temperature limit for bonding IC-processed standard Si substrates is about 420–450°C; see "IC Compatibility" in Volume II, Chapter 7). Higher temperature (above 1000°C) is usually required to get voidless and high-strength bonding.[34] Bond strength up to 20 MPa has been reported. The application of a small pressure during the bonding process further increases the final bond strength.[35] The bonding can be carried out successfully with one oxidized Si wafer to another bare Si wafer, two oxidized wafers, or two bare Si wafers, and even between one wafer with a thin layer of nitride (100–200 nm) and one bare wafer or two wafers with a thin layer of nitride. The same fusion-bonding technique can be applied for bonding quartz wafers, GaAs to Si, and Si to glass. Provided that the surfaces are mirror smooth and can be hydrated, the bonding process proceeds in an identical fashion as for Si-Si bonding (see Schmidt[36] and references therein).

According to most references, before fusion bonding, the oxidized Si surfaces must undergo hydration. Hydration is usually accomplished by soaking the wafers in a H_2O_2-H_2SO_4 mixture, diluted H_2SO_4, or boiling nitric acid. After this treatment, a hydrophilic top layer consisting of –OH bonds is formed on the oxide surface. An additional treatment in an oxygen plasma greatly enhances the number of –OH groups at the surface.[37] Then, the wafers are rinsed in deionized water and dried. Contacting the mirrored surfaces at room temperature in a clean-air environment forms self-bonding throughout the wafer surface, with considerable bonding forces.[38] In a transmission infrared microscope, a so-called *bonding wave* can be seen to propagate over the whole wafer in a matter of seconds. The bonded pair of wafers can be handled without danger of the sandwich falling apart during transportation. A subsequent high-temperature anneal increases the bond strength by more than an order of magnitude. The self-bonding is the same phenomenon described under stiction of surface micromachined features (see Volume II, Chapter 7).

At present, the fusion bonding mechanism is not completely clear. However, the polymerization of silanol bonds is believed to be the main bonding reaction:

$$\text{Si–OH} + \text{HO–Si} \rightarrow \text{H}_2\text{O} + \text{Si–O–Si} \qquad \text{Reaction 4.1}$$

Figure 4.22 shows the suggested bonding mechanism, including the transformation from silanol bonds to siloxane bonds. Silanol groups give rise to hydrogen bonding, which takes place spontaneously even at room temperature and without applying pressure, as long as the two wafers are extremely clean and smooth.[38]

Measurements of bond strength as a function of anneal temperature indicate three distinct bond strength regions, according to Schmidt.[36] For anneal temperatures below 300°C, the bond strength remains the same as the spontaneous bond strength measured before the anneal. For self-bonded

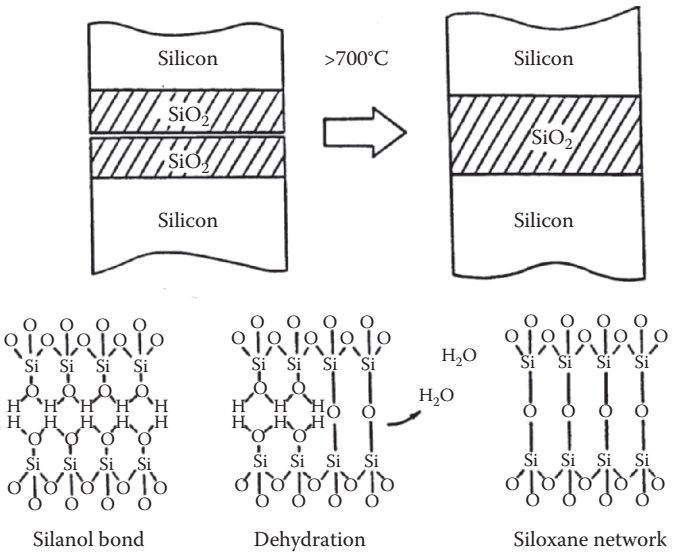

FIGURE 4.22 Schematic illustration of the silicon-to-silicon bonding by fusion and a proposed mechanism.

wafers with hydrogen bonding between the silanol groups of opposite surfaces, Tong et al.[39] measured an activation energy of 0.07 eV for temperatures <110°C—fairly close to the theoretical value of around 0.05 eV for hydrogen bonding. At about 300°C, according to Schmidt, the –OH groups form water molecules, and the voids that are sometimes observed at this temperature are believed to be due to water vapor formed in the process.[40] Stengl et al. report that the formation of voids can be avoided by first contacting the wafers at a temperature of 50°C.[41] The voids tend to disappear also at temperatures above 300°C, while the bond strength increases and then levels out. It is assumed that in this regime, Si-O-Si bonds (siloxane) start forming between the surfaces (Reaction 4.1). Tong et al.[39] found a pronounced increase of interface energy of room-temperature, self-bonded hydrophilic Si/Si, Si/SiO_2, and SiO_2/SiO_2 wafers after storage in air at room temperature and up to 150°C for periods between 10 and 400 h. The interfacial energy increase is ascribed to the generation of additional –OH groups due to a reaction with water and the strained oxide and/or Si below 100°C, as well as the formation of stronger siloxane bonds, which, this group claims, already forms from temperatures below 150°C. They find that the siloxane groups have a much higher bond energy with an activation energy of 1.8–2.1 eV.[39] After prolonged storage, interface bubbles were observed that seem to contain hydrogen and hydrocarbons. At the highest temperatures (>800°C), Schmidt finds the bond strength starts increasing again, and at 1000°C, the bond is reaching the fracture strength of single-crystalline silicon: 10–20 MPa. In this third region, it has been suggested that surfaces can deform more easily (oxide flow), bringing them into better contact.[36] At these temperatures, oxygen also diffuses into the Si lattice. Multiple Si wafers can be fusion bonded together. In some applications, up to a total of seven wafers have been bonded together.

Recall that for fusion bonding, surfaces have to be chemically activated to prepare for the bond. This is quite an undesirable step because the chemicals needed for surface preparation often are not compatible with other micromachining materials. Another way to activate the bonding surface and to make it hydrophilic is to use a plasma activation step. The plasma slightly roughens the surface and increases the number of –OH groups, in a manner similar to hydrophilic chemical activation. The plasma activation is a dry process that is much more compatible with many micromachining process flows. Also, because it is a dry process, it is compatible with released devices (no stiction problems). The bond still needs to be annealed, just as in regular fusion bonding, but the anneal temperatures and times required for a strong bond are much less (400°C vs. 1100°C), possibly because of the slightly roughened surface.

It should be noted that spontaneous bonding of Si wafers also has been claimed with hydrophobic surfaces. It was suggested that such low-temperature bonding is due to van der Waals forces, whereas hydrogen bridging is involved in hydrophilic surfaces. The bonding energy obtained with hydrophobic wafers was as low as 26 mJ/m^2, but after annealing at 600°C, the bonding energy reached a value of 2.5 J/m^2, only attainable at 900°C with hydrophilic wafers.[42] This is in contradiction with most other research done, which concludes that the wafers must be hydrophilic for SFB.

Early on, it was reported that Si_3N_4 was a non-bondable surface.[43] Based on Reaction 4.1, one would assume that the low-temperature direct bonding of Si_3N_4 could take place only if oxidation of the nitride introduced silanol groups. Indeed, an oxidized surface of nitride was reported to bond at high temperatures consistent with Si fusion bonding.[44] Unexpectedly, Bower et al.[45] demonstrated extremely strong bonds between Si wafers coated with a smooth, clean layer of LPCVD Si_3N_4 at temperatures ranging between 90°C and 300°C. A 500-Å-thick nitride was first deposited in the LPCVD reactor and then, without breaking the vacuum, activated in an ammonia stream for several minutes. This group speculates that a chemical reaction such as the following is responsible for bonding where the released hydrogen diffuses from the bonding interface:

$$\equiv Si{-}(N_xH_y) + (N_xH_y){-}Si \equiv \rightarrow \equiv Si{-}(2N_x){-}Si \equiv + yH_2$$

Reaction 4.2

Fracture occurs at about 2 MPa. In a further extension of this work, it was found that an NH_3 plasma

treatment of Si, SiO_2, and TiN for 5 min or longer also provided direct bondable surfaces. Using Si_3N_4 as an intermediate layer, Bower and coworkers bonded Si to Si, Si to SiO_2, and Si to GaAs.[46] This low-activation energy bonding allows bonding of optoelectronic components such as GaAs with completed electronic circuitry on Si with Al metallization in place.

Thermal Bonding with Intermediate Layers

When incorporating an intermediate layer between two substrates, many thermal bonding techniques are feasible. If the intermediate layers can be patterned by lithography, both L0 and L1 packaging becomes possible. Anodic bonding occurs uniformly, but the high fields are detrimental to field-effect devices. Some intermediate layer materials with a low melting point [e.g., phosphosilicate glass (PSG)] do not need electric field for bonding, but the thickness and uniformity are hard to control. An ideal method would require neither an electrical field nor high temperatures and would be very uniform. With films that become soft at low temperatures, all features on the wafer may be covered smoothly as long as they are not a significant fraction of the intermediate film thickness itself.

LPCVD PSG has been used for Si-to-Si wafer bonding. Fusion of two Si wafers coated with 1–2-µm-thick PSG layers is fast. Excellent bonding results, provided the wafers are clean and reasonably flat. Unfortunately, the bonding process occurs at a high temperature of 1100°C for 30 min.[47]

Several suppliers of glass materials offer low-temperature sealing glasses known as glass frits or glass solders. Corning Glass Works, for example, has introduced a series of glass frits (#75xx) with sealing temperatures ranging from 415°C to 650°C.[48] These glasses are applied by a variety of methods, including spraying, screen-printing, extrusion, and sedimentation. After the glass is deposited, it needs to be preglazed to remove the organic residues produced by vehicle and binder decomposition (see "Types of Inks/Pastes and Applications" in Volume II, Chapter 9). The substrate-glass-substrate sandwich is then heated to the sealing temperature while a slight pressure is applied (>1 psi). Devitrifying glasses and thermoplastic, vitreous glasses are offered. The devitrifying glasses are thermosetting, and they crystallize during the sealing procedure, thereby changing their mechanical properties. The vitreous glasses are thermoplastic, melt at a lower temperature than devitrifying glasses, and flow during sealing, but their material properties do not change after sealing is completed. An important problem today remains the uncertainty regarding the mechanical and chemical behavior of these glasses.[27] Moreover, almost all of the low-melting-point formulations of glass frits contain some lead, which is a major drawback because the European Union and Japan are forbidding the use of lead in all electronics manufacturing in the coming years.

Ko et al.[20] used RF sputtering from a target made from a Corning 7593 glass frit to obtain a thinner (8000 Å) and more uniform intermediate glass film for bonding. The sputtered glass did not need glazing. Annealing at 650°C in an oxygen atmosphere resulted in an excellent bond strength of two Si wafers coated with these films.

Legtenberg et al.[49] used a thin film of atmospheric pressure chemical vapor-deposited (APCVD) boron oxide with a softening temperature of 450°C. However, boron oxide is hygroscopic and does not present a viable solution. Field et al.[50] used boron-doped Si dioxide, which also becomes soft at 450°C. The doping is performed in a solid source drive-in furnace. The bond seal is hermetic, and a crack propagates right through the material rather than along the bonded surface. A problem with this method is the sensitivity of the film to phosphorous contamination.

Spin-on-glass (SOG) was reported by Yamada et al.[51] and Quenzer and Benecke[52] In Yamada et al.'s effort, SOG [$Si(OH)_x$ (with $2 < x < 4$)] was coated on the wafer surface to be bonded. After the 50-nm-thick film was baked at a temperature of 250°C for 10 min, the wafers were contacted and pressurized in vacuum at 250°C for 1 h. The bonding was already strong after this step, but wafers were further annealed for 1 h at 1150°C in air to sinter the SOG layer and to improve the breakdown voltage of the layer. Quenzer et al. used sodium silicate as an intermediate layer. The wafers were made hydrophilic in an RCA1 cleaning step, and the glass was spun on from a dilute sodium silicate solution. The film thickness was between 3 and 100 nm, and

annealing at 200°C produced good bonds between bare Si wafers, Si wafers with native oxide, thermal oxide, and Si nitride. No need for further annealing is mentioned in this work.

To bond the unpolished back side of a Si die to another Si part, an aqua-gel based on a hydrophilic pyrogenic silica powder (grain diameter smaller than 7 nm) and polyvinyl alcohol (PVA) as a binder may be used. In this scheme, the adhesion depends on hydrogen bonding between the −OH groups of the PVA, the SiO_2 grains, and the Si surfaces. No special surface treatment is required, and the bonding can be achieved in 15 min at room temperature. Bond strength is in excess of 1 MPa. This new technique works for bonding Si to Si, Si to SiO_2, SiO_2 to SiO_2, and glass to Si or SiO_2. Surprisingly, this technique was also shown to work for bonding III-V materials. This type of bonding is proposed for the fashioning of multichip-on-silicon packaging (L2 level).[53]

Silicon microstructures can be sealed together by eutectic bonding. Eutectic films are alloys of two materials and act as the "glue" or solder to bond two wafers. Solder is a form of eutectic alloy that is commonly used in building printed circuit boards. Solder has been used since antiquity to bond metal surfaces to one another. It is an alloy with a low melting point, typically containing tin or indium, used to join electrical components to a circuit board or to join metal objects together. In Au-Si eutectic bonding, one applies a contact force and increases the temperature beyond the Au-Si eutectic temperature (363°C). This results in diffusion of silicon into the gold (not diffusion of gold into silicon) until the Au-Si eutectic composition is reached (19 atomic percent Si). The Au-Si eutectic bonding takes place at a temperature of 363°C, which is well below the critical temperature for Al metallized components, and Au is a quite commonly used thin-film material. These are good reasons to select the Au-Si eutectic, but other material combinations are possible. It is possible to bond bare Si against Au-covered Si, or Au-covered Si against Au-covered Si. Another alternative is to use Au-Si preform with a composition close to the eutectic concentration. Eutectic bonding in MEMS packaging is demonstrated below, in Figure 4.37, where we illustrate a wafer-to-wafer transfer of an encapulsation package. Tiensuu et al. have demonstrated a mean fracture strength of the Au-Si bond of 148 MPa.[54] This compares well with fusion bonding with a typical bond strength of 5–15 MPa.

There are some considerable disadvantages associated with Au-Si eutectic bonding. It is difficult to obtain complete bonding over large areas, and even native oxides prevent the bonding to take place and eutectic preform (e.g., with Au-Sn) bonding is reported to introduce substantial mounting stress in piezoresistive sensors, causing long-term drift due to relaxation of the built-in stress.[20]

Bonding with Organic Layers

Two silicon wafers also can be bonded using an intermediate polymer film that forms the "glue" between the two. Polymers such as polyimide, or "epoxy" can be used; if the glue can be deposited in a uniform film and has good adhesion to Si, it can be used to bond the two wafers together. One of the issues with polymers is that as they are baked to harden them, they produce vapors of solvents within them, and these vapors create voids, which tend to push the two wafers apart. Therefore, polymers that tend to outgas very little are desired. One of these materials is benzo-cyclobutene (BCB), which is used as an insulator in building integrated circuits. BCB can be spin deposited and then patterned like photoresist. Thus, it is possible to create fine features on one wafer that can then be used to bond to a companion wafer. BCB patterns retain their shape after bonding, and the bond strength is very high (one needs to destroy the BCB to break the bonded wafers). It is also possible to use another polymer, such as Parylene, which is simply a plastic. When heated, the plastic joins the two wafers together. Parylene is a very inert, tough, and easy to deposit polymer. It is used extensively in implantable biomedical systems. It can be evaporated at room temperature (0.1–10 μm range) and when deposited it is conformal, uniform, and pinhole-free.

A most interesting option for packaging is through lithographic patterning of thick resist layers. Prominent new candidates for packaging micromachines are thick ultraviolet photoresists, such as AZ-4000 and SU-8, reviewed in Volume II, Chapter 1, as well as LIGA resists such as PMMA.

Using polymers, very low bonding temperatures are possible. The bond strength can be quite high, no metal ions are present, and the elastic properties can reduce stress. One can envision that with thick enough polymer layers, packaging as part of the front-end processing will become possible (up to level 2). Disadvantages include impossibility of hermetic seals (see Figure 4.29), high vapor pressure, and in cases where a high Young's modulus and low hysteresis is required poor mechanical properties.

An example of photopatterned bonding is provided by the flexible polysiloxane interconnection between two substrates demonstrated by Arquint et al.[55] UV-sensitive cross-linking of polysiloxane layers with a thickness of several hundred micrometers is used to pattern the polymer onto the first substrate, and a condensation reaction is used to form a chemical bond to the second surface. The procedure is illustrated in Figure 4.23.[55]

Good bonding results with photopatternable resists also have been obtained by den Besten et al.,[56]

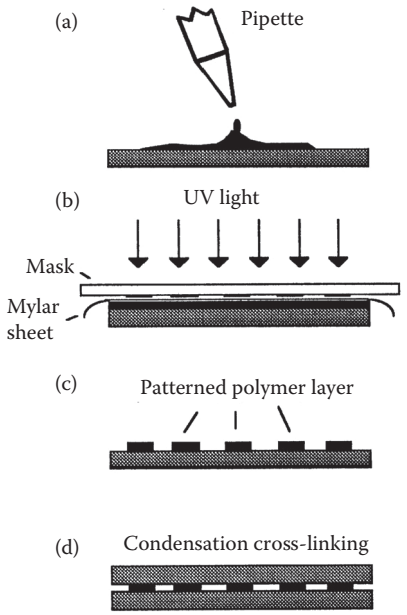

FIGURE 4.23 Procedure for silicon/polymer/silicon bonding: (a) Monomer solution is deposited either by spin coating or casting; (b) exposure to ultraviolet light for photopolymerization; (c) polymeric pattern is developed in xylene; (d) second wafer is pressed onto the polymeric pattern and left for humidity-induced polymerization in ambient air (10 h). (From Arquint, P., P. D. van der Wal, B. H. van der Schoot, and N. F. de Rooij. 1995. In *8th International Conference on Solid-State Sensors and Actuators (Transducers '95)*, 263–64. Stockholm, Sweden. With permission.[55])

who used negative photoresist at a bonding temperature of 130°C. In an important potential application, UV-curable encapsulant resins have been employed for wafer-level packaging of ion-sensitive field effect transistors (ISFETs).[57]

Bonding of Plastic to Plastic

A major concern of polymer-based MEMS, especially in microfluidic devices, is how to bond plastic parts together. This bonding or application of plastic lids to plastic microparts can be achieved using adhesives or tapes, plastic welding (e.g., hot plate and ultrasonic welding), and selected organic solvents (i.e., partially dissolving the bonding surfaces and evaporating the solvent). In our laboratory, several of these techniques have been tried, including vacuum-assisted heat bonding, bonding with double-sided adhesive tape, and water-soluble polymer-assisted bonding. Figure 4.24 shows a cross-section of microchannels bonded by these three methods. For large features (several hundred micrometers to millimeters), conventional plastic welding techniques such as hot plate, ultrasonic, and infrared (IR) welding can be used. Applying vacuum before welding may reduce voids at the welded interface, and consequently, lower pressure and temperature can be used in welding. This minimizes the molten polymer from flowing into the bonded channels (see Figure 4.24a). Ideally, small overflow traps should be designed along the edge of the channels (as shown in Figure 4.25) to completely prevent the channels from being blocked by the molten polymer during welding. For smaller channel sizes (less than 100 μm), the design and fabrication of overflow traps become difficult. Double-sided adhesive tape can be a useful way for microbonding, as shown in Figure 4.24b. The main disadvantage is that the presence of an adhesive tape tends to change the channel size and channel wall properties. This is the technique we often used in the assembly of the compact disc (CD) fluidic platform (see Chapter 5, Figure 5.28). For very small channels (less than 1 μm), prefilling the channels with a water-soluble polymer (serving as a sacrificial material), drying the polymer, sealing the plate with channels to a cover lid by either welding or adhesive bonding, and then washing out the water-soluble polymer turns out to be a viable way to

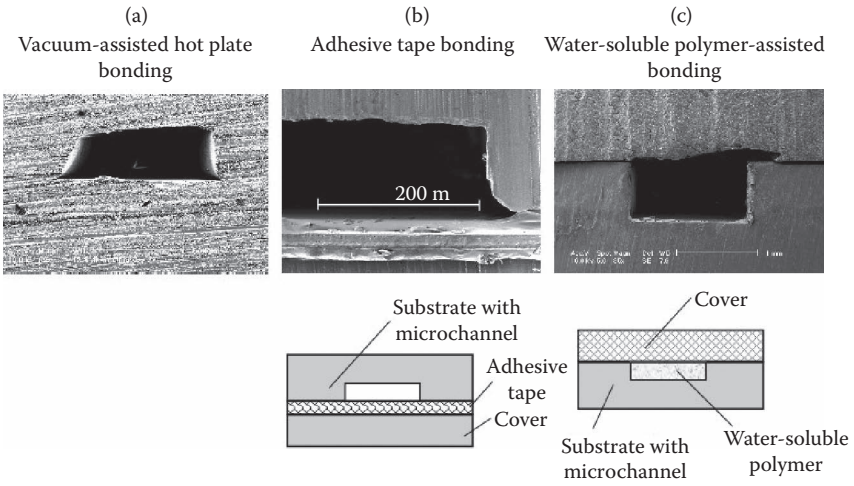

FIGURE 4.24 Scanning electron microscope cross-section of bonded microchannels by three different methods (see text). (Courtesy of Dr. Marc Madou and Dr. James Lee, Ohio State University.)

prevent channel blockage during bonding (see Figure 4.24c). This method, however, is more tedious and may not always be applicable. Development of low-cost, high-speed, and reliable bonding techniques for microfluidic devices remains an important and challenging issue in bio-MEMS fabrication.

Polydimethylsiloxane (PDMS), introduced in Volume II, Chapter 2, is the most common example of a group of polymers known as silicones. Silicones are used as a component in silicone grease and other silicone-based lubricants, as well as in defoaming agents, damping fluids, heat transfer fluids, cosmetics, hair conditioner, and other applications; they are also the primary component in Silly Putty. PDMS is used extensively in microfluidics research to create channels, valves, pumps, and other components that make up microfluidic systems. As we saw in Volume II, Chapter 2, the molecular structure of PDMS is made up of a backbone of siloxane with two methyl groups attached to each silicon atom. The backbone is terminated with either a methyl group or hydroxyl group. PDMS can be reversibly and irreversibly bonded to a variety of substrates. Without pretreatment, PDMS bonds reversibly to glass structures with a bond strength that can survive fluidic pressures of ~4 psi, enough for many microfluidics applications. Activating the PDMS surfaces with a plasma treatment before bonding can create an irreversible bond. The plasma treatment temporarily replaces one of the methyl groups of the PDMS with a silanol group. This activation typically lasts for tens of minutes. If the surface of an activated PDMS layer comes in contact with another activated surface, the silanol groups combine to create a siloxane bond and a water molecule, similar to the hydrophilic fusion bonding process described above. There is no need to anneal this bond because the high permeability of the surrounding polymer allows the water molecule to diffuse away easily (although heat speeds the process up). Irreversible PDMS bonds can stand pressures of up to 70 psi.

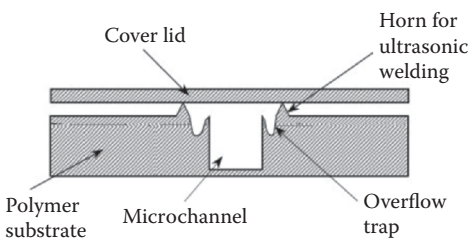

FIGURE 4.25 Schematic of ultrasonic welding with overflow trap. (Courtesy of Dr. Marc Madou and Dr. James Lee, Ohio State University.)

The bonding processes detailed here are summarized in Table 4.2. A good review of polymer micromolding, including polymer bonding, is that of Becker and Gärtner.[58]

Alignment during Bonding

Obtaining good alignment between the device wafer and support substrate (e.g., glass or another Si wafer) during bonding poses some extra challenges, because a transfer from aligner to annealing furnace

Table 4.2 Comparison of Bonding Techniques

	Anodic	Fusion	Glass Frit	Eutectic	Solder	Parylene	PDMS

generally is required after alignment. One technique used for bonding alignment is to generate holes in both the device wafer and the substrate, followed by putting them in a specially designed fixture to perform the bonding. The accuracy achievable with this option is only around 50 µm, though. Higher alignment accuracy (~2.5 µm) can be achieved by using a bonding machine equipped with an in situ optical alignment setup. Aligned wafer bonding has been worked on extensively by Bower et al.[59] They used an infrared aligner modified to hold two imprinted wafers face to face while projecting an infrared image of the surfaces to a viewing screen (see Figure 4.26).[59] An array of V-grooves etched into the surface of the Si wafers was then precisely aligned, and the wafers were brought in contact for initial bonding. The

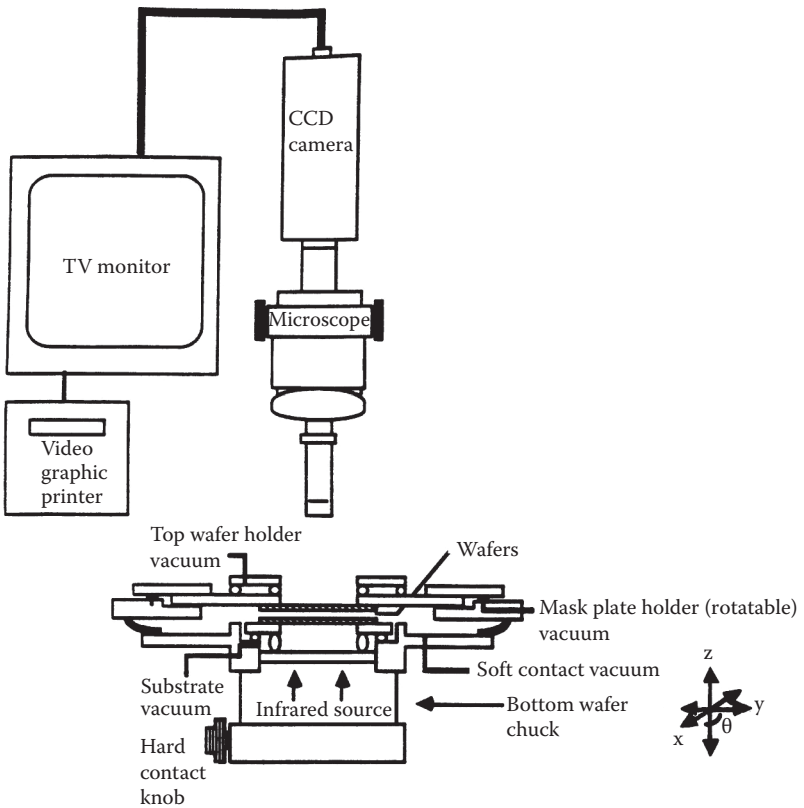

FIGURE 4.26 Alignment fixture for bonding. The schematic diagram shows the infrared aligner system used for wafer bonding. Wafer holders are designed with a large opening at the center to allow maximum infrared energy to pass through to the camera. (Courtesy of Dr. R. Bower, University of California, Davis.)

(111) planes that define the walls of the V-groove create a shadow image without the necessity of metal features commonly used for two-sided backside alignment. The initial bonding is nothing more than the normal soft contact provided by the aligner itself. Hydrogen bonds are formed between the two surfaces in intimate contact. These relatively weak bonds of about 0.05 eV are sufficient to hold the two pieces firmly together without relative displacement during the transport from the aligner to the annealing furnace. Subsequent high-temperature annealing (950°C for 30 min) was used to strengthen and complete the chemical bonding. The aligned-wafer technique also can be used when dealing with dissimilar substrates.

Shoaf and Feinerman[60] developed an alignment technique to assist in precise Au-Si eutectic bonding of Si structures. A (100)Si wafer is anisotropically etched to create V-grooves around the periphery of the structure to be bonded. Gold is deposited onto one of the wafers prior to dicing into individual dice. Optical fibers are placed into the orthogonal V-grooves, as demonstrated in Figure 4.27, and used as precision location keys for assembly prior to bonding. The entire structure is placed on a hot chuck at 400°C for bonding, and the fibers are removed after bonding. Results have shown a maximum misalignment of 5 μm for a 1 × 1 cm die. This technique allows a sensor die to be precisely bonded to an electronics die without the aid of a microscope or micropositioners.

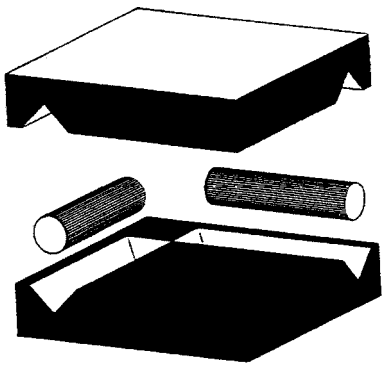

FIGURE 4.27 Schematic representation of the anisotropically etched V-groove/optical fiber alignment technique. Optical fibers are placed into the V-grooves of the bottom Si die. A second die with etched V-grooves is then placed on top of the first die. The fibers act as precision locating keys and align the two Si dice. (From Shoaf, S. E., and A. D. Feinerman. 1994. Aligned Au-Si eutectic bonding of silicon structures. *J Vac Sci Technol* A12:19–22.[60])

Imaging and Bond Strength and Package Hermeticity Tests

Methods for imaging a bonded pair of Si wafers include infrared transmission (voids larger than 20–30 μm can be seen this way), ultrasound (qualitative information about the bond quality), and x-ray topography. The most common mechanical techniques to characterize bond strength are illustrated in Figure 4.28.[36] Both the burst test (Figure 4.28a) and the tensile/shear test (Figure 4.28b) yield important engineering insights for sensor construction but do not yield information about the detailed nature of the bond because of the complicated loading of the interface.[36] In the Maszara method,[61] a thin blade is inserted between the bonded wafers and a crack is introduced (Figure 4.28c). The length of the crack, measured by infrared imaging, gives a value for the surface energy inferred through knowledge of the sample and blade thickness and the elastic properties of the wafer. This method has the advantage of creating a well-defined loading on the bonded interface. Unfortunately, the surface energy is a fourth

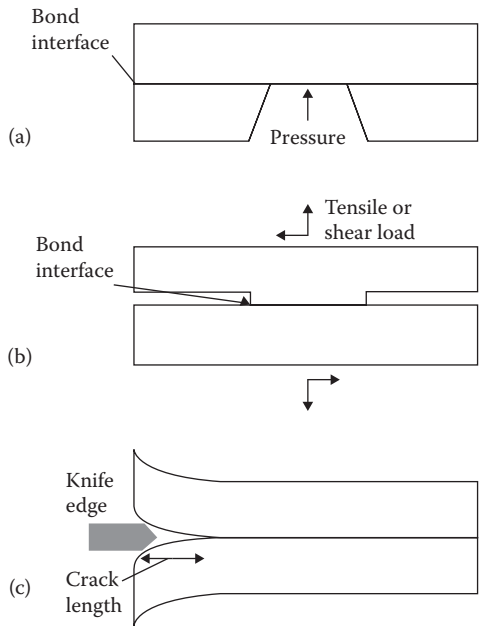

FIGURE 4.28 Three methods for bond strength measurements. (a) Burst test. (b) Tensile and shear test. (c) Maszera test. (From Schmidt, M. A. 1994. In *Technical Digest: 1994 Solid State Sensor and Actuator Workshop,* 127–30. Hilton Head Island, SC. With permission.[36])

power of the crack length and uncertainties in measuring that length make for large errors.

The hermeticity of sealed cavities in packaging is important for physical protection purposes and, in some cases, for the performance of the sensor inside. The word *hermetic* means airtight, so a good hermetic seal does not let gasses, vapors, or liquids pass across it. Some materials are better than others at creating hermetic seals because their molecules (or atoms) are more closely spaced together. Hermeticity is an important parameter for micropackaging because certain MEMS devices need vacuum to operate and ICs need a dry environment to maintain their reliability. For example, the quality factor, Q, of a resonator, the vacuum reference of an absolute pressure sensor, and the cavity of a pneumatic infrared sensor (i.e., a Golay cell) all are critically dependent on a good hermetic package. Testing the hermeticity of electronic devices usually is carried out by helium leak detection. While this technique, with a minimum detectable leak rate of 5×10^{-11} to 5×10^{-10} Torr L/s, is appropriate for testing of relatively large packages, it is unacceptable for nearly every Si sensor application (it is not valid for package sizes under 1000 nL). Nese et al. have introduced Fourier transform infrared (FTIR) spectroscopy for measuring the gas concentration inside a sealed Si cavity using N_2O as a tracer gas.[62] Although the sensitivity for leakage is about the same as with a helium leak detector, the method is accumulative, so by prolonging the exposure times, the sensitivity can be increased, which is not possible with the dynamic helium leakage testing method.

Although anodic bonding may be carried out in a vacuum chamber, the pressure inside a Si cavity differs from the chamber pressure because of gas generation, probably oxygen, during bonding. To control cavity pressure for critical damping of packaged micromechanical devices, Minami et al.[63] used nonevaporable getters. Getters are agents that counteract harmful contaminants within a sealed package; they may include solids, liquids, gases, and combinations thereof. The solid nonevaporable getter used by Minami et al.[62] is a Ni/Cr ribbon covered with a mixture of porous Ti and Zr-V-Fe alloy that absorbs gases after activation at 400°C and is built into the microdevice. These authors monitored the effectiveness of their method to control cavity pressure by measuring deflection of a thin membrane covering the cavity.

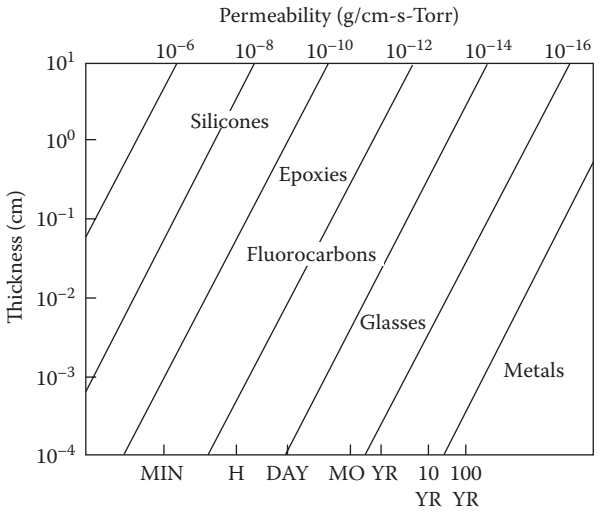

FIGURE 4.29 The calculated time for moisture to permeate various sealant materials (to 50% of the exterior humidity) in one defined geometry. Organics are orders of magnitude more permeable than materials typically used for hermetic seals. (From Striny, K. M. 1988. In *VLSI Technology,* ed. S. M. Sze, 566–611. New York: McGraw-Hill. With permission.[64])

Figure 4.29 shows the relative capabilities of several materials to exclude moisture from the encapsulated components over long periods. Organic materials are not good candidates for hermetic packages; for almost all high-reliability applications, the hermetic seal is made of glass or metal. Plastic packaging for integrated circuits (ICs) is governed by several industry standards that have evolved over the years; plastic packaging for MEMS, on the other hand, is not yet governed by any standard. For the simplest mechanical sensors, standard or slightly modified IC plastic packages are used. New plastic packaging technologies and their standardization for MEMS will begin only once the volume of MEMS products approaches a larger fraction of that of ICs.

For measuring moisture penetration in a package, temperature-accelerated soak tests may be performed. Moisture penetration can be followed, for example, with an integrated on-chip dew-point sensor.[25] Striny[64] points out that the cost or difficulty of obtaining a truly hermetic seal for a particular package often is prohibitive. In that case, in addition to polymer lid sealing, surface die coats, for example

with silicones, are applied. From Figure 4.29,[64] we can conclude that silicones do not act as a moisture barrier; the exact mechanism by which they protect the die when applied as a surface coat is not yet well understood.[65]

Examples of MEMS Packages

Introduction

Pressure sensors and accelerometers typically fit in standard packages, but few other MEMS devices do. Examples of nonstandard packages that we have already discussed include the catheter-based electrochemical sensor shown in Volume II, Figures 4.92 to 4.96, where a dual-lumen catheter forms the basis of the packaging scheme, and the thin-film magnetic head illustrated in Chapter 1, Figure 1.1d, this volume. The very fragmented nature of micromachining applications and the nonstandardness of the package necessitate a design approach starting from the package.

Cap-on-Carrier and Cap-on-Chip

In Figure 4.30, two MEMS packaging schemes are compared. The cap-on-carrier packaging method (L1) (Figure 4.30a) is suitable for accelerometers, gyroscopes, and other motion detectors that can be hermetically sealed. It is the prevalent method in industry today. The cap-on chip is an on-chip packaging method (Figure 4.30b), also called *chip scale packaging* (CSP), that is the preferred approach, as the packaging can be made part of the front-end batch manufacturing process and may be much smaller. The two approaches are contrasted in Figure 4.31.

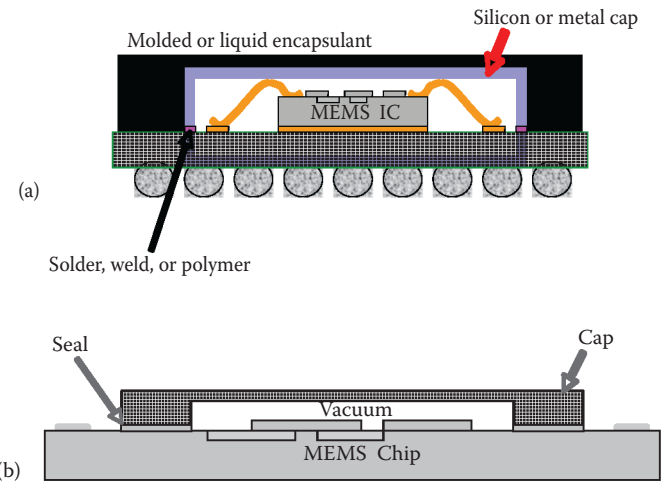

FIGURE 4.30 Cap-on-carrier (a) and cap-on-chip (b) compared.

One reoccurring problem in MEMS packaging is how to protect sensitive movable mechanical structures during dicing. The dicing process is very harsh, and any loose structure might break off. Fortunately, in most MEMS process sequences, the step where movable structures are released is the final so-called *release step* (typically, a sacrificial material is etched away to free the movable part; see Volume II, Chapter 7). By carrying this release step out after dicing, breakage of sensitive MEMS structures is avoided.

But individual die-level release is expensive and slow. Released dice, as shown in Figure 4.31, are packaged in ceramic or metal cavity packages. These packages often are large and expensive. Alternately, one does the MEMS release at the wafer level and then wafer-level packages the devices before dicing. Wafer-level packaging must follow the wafer-level release, again to avoid damaging the MEMS. The process is called *CSP* with caps-on-chip. These caps may be made of glass or another Si piece and typically are still quite bulky (millimeters rather than tens or hundreds of micrometers). These bulk wafer caps are

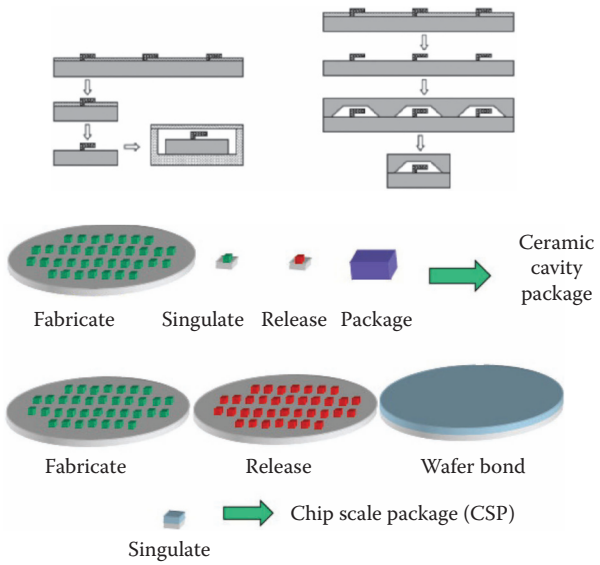

FIGURE 4.31 Microelectromechanical systems (MEMS) are either diced, then released and finally packaged in ceramic or metal cavity packages. Or one does the MEMS release at the wafer level and then wafer-level package the devices before dicing. The latter process is called *chip scale packaging* (CSP).

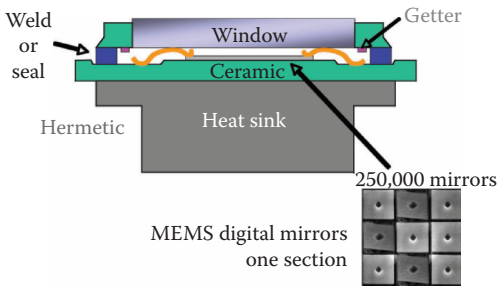

FIGURE 4.32 Packaged Digital Mirror Device™ from Texas Instruments utilizes a vacuum hermetic package with a transparent optical window. The package also includes a getter to adsorb any residual moisture.

the current industry standard, used, for example, in Motorola accelerometers, Bosch gyroscopes, Clarisay SAW filters, and Radant MEMS switches. The bulk wafer caps are robust, hermetic, and implemented on a wafer-level, but they require a large on-chip area for the seal ring. Below, we review a number of alternative wafer-level cavity sealings, i.e., cap-on-chip techniques such as the microassembled HEXSIL caps, techniques that are today mostly in the research and development phase. They all have a considerable smaller footprint than the bulk caps discussed here.

The Digital Mirror Device™ from Texas Instruments, discussed in Volume II, Example 7.2, utilizes a vacuum hermetic package with a transparent optical window as shown in Figure 4.32. The package also includes a getter to adsorb any residual moisture. This package is an example of a special type of cap-on-carrier package.

Next-Generation Cap-on-Chip Cavity Sealing

Introduction

Many microdevices have been fabricated making use of some type of cavity sealing or cap-on-chip technique. Cavity sealing can serve as a batch-compatible zero- and first-level packaging technique by encapsulating a die feature (L0) or a whole die at a time (L1). In bulk micromachining (Volume II, Chapter 4) and Si fusion-bonded (SFB) surface micromachining (Volume II, Chapter 7), cavities are fabricated by bonding, respectively, a glass plate (anodic bonding) or Si wafer (fusion bonding) over etched cavities in a bottom Si wafer. The Si and glass layers bonded typically are rather thick and do not lend themselves well to die feature level packaging. In polysilicon and selective epitaxy surface micromachining (see Volume II, Chapter 7), on the other hand, sealing cavities often is a more integral part of the overall fabrication process, and both die and die features might be packaged this way. These and other lithography-defined packages, such as those involving ultraviolet patternable polymers, lend themselves to inexpensive batch solutions and represent a new technology area where micromachining could provide solutions for the MEMS and IC industries.

Sealing of Polysilicon and Silicon Nitride Cavities

In Figure 4.33a, we illustrate how a polysilicon vacuum shell encapsulates a polysilicon resonator element. The micromachined surface package (microshell) illustrated is much smaller than typical bulk-micromachined packages. Microshells can be made by defining thin gaps (~100 nm) between the substrate and the perimeter of the structural elements by etching away a sacrificial layer sandwiched

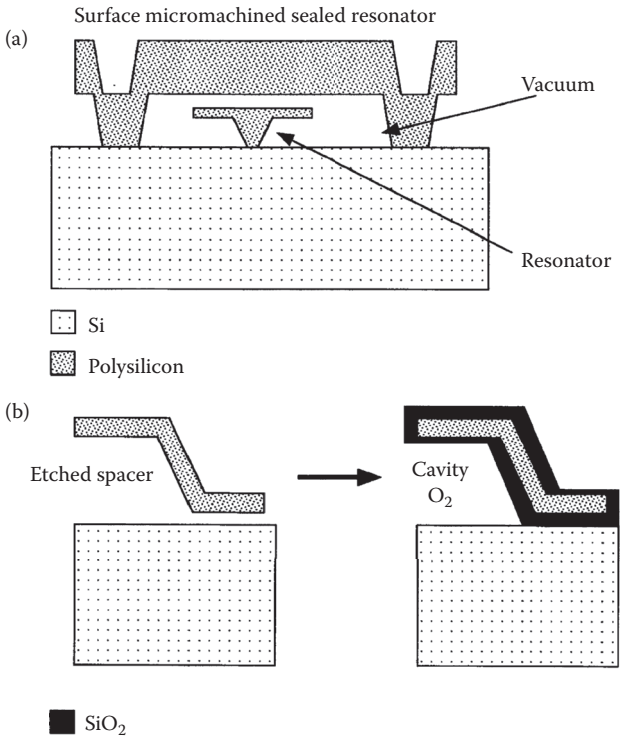

FIGURE 4.33 Sealed cavities in surface micromachining. (a) Typical sealed cavity with a resonator structure inside. (b) Reactive sealing.

between the two and then sealing the resulting gaps. In so-called *reactive sealing*, demonstrated in the schematic fabrication sequence in Figure 4.33b, thermal oxidation of the polysilicon and Si substrate at 1000°C seals the narrow openings left after removal of the spacer phosphosilicate glass (PSG).[66–68] Reactive sealing is possible even in vacuum because of the reaction of oxygen, trapped inside the cavity.

Alternatively, sealant films, such as oxides and nitrides, can be deposited over small etchant holes,[67,69] as illustrated in the fabrication sequence in Figure 4.34A. In the latter case, the cavity is sealed by low-pressure chemical vapor-deposited (LPCVD) silicon nitride. The excellent coverage of this method ensures that the nitride closes the etch channel quickly before too much deposition in the chamber itself can take place. Typical deposition conditions during the sealing step are 850°C and 250 mTorr, so the residual pressure in the microshell, at room temperature (assuming ideal gases) should be about 67 mTorr. Some researchers have reported residual pressures of 200–300 mTorr.[70] Eaton and Smith[71]

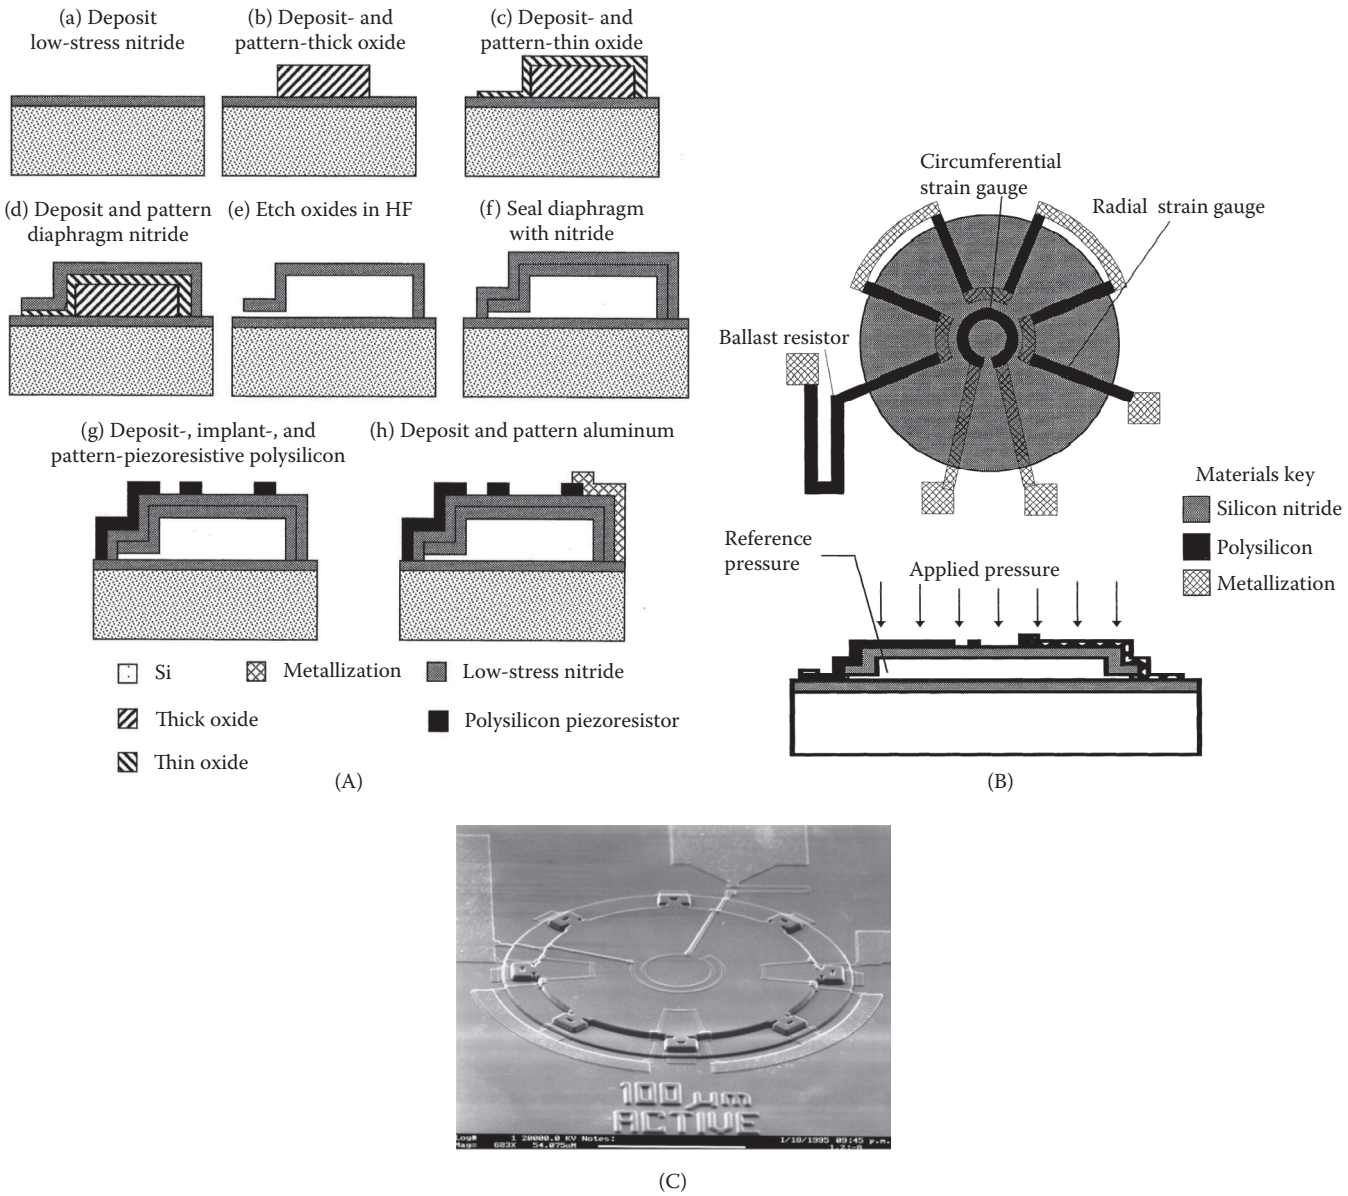

FIGURE 4.34 Absolute pressure sensor.[70] (A) Schematic fabrication sequence of vacuum shell with low-pressure chemical vapor-deposited Si nitride sealing. established that the resulting cavity pressure is stable for a given membrane, but the residual pressure is variable and nonrepeatable across a substrate and even less from substrate to substrate.

The fabrication time of packaging shells often makes for a long process. The sacrificial material inside the shell is removed very slowly given the poor access via narrow etch holes to it by the etchant. Lebouitz et al. at the University of California, Berkeley, introduced an interesting means to speed up the fabrication of microshells.[72] The process is outlined in Figure 4.35. Permeable polysilicon windows (see Volume II, Chapter 7) are used as an etch access for removing the underlying sacrificial PSG. Using concentrated HF, shells 3 μm high and as wide as 1 mm have been cleared of PSG in less than 120 s. Subsequent low-pressure hermetic sealing using low-stress Si nitride leads to deposition of less than 100 Å inside the package.

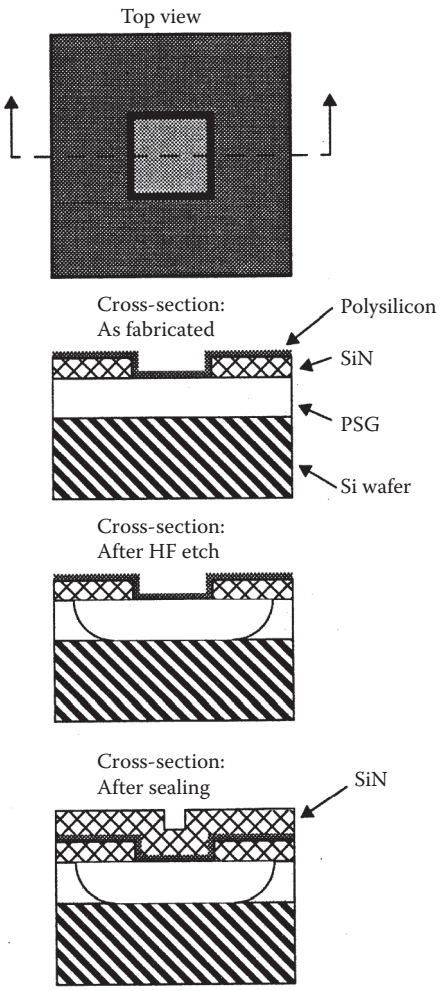

FIGURE 4.35 Schematic of etch access window design, operation, and sealing. [From Lebouitz, K. S., R. T. Howe, and A. P. Pisano. 1995. In *8th international conference on solid-state sensors and actuators (Transducers '95)*, 224–27. Stockholm, Sweden. With permission.[72]]

Sealed cavities, as shown here, lend themselves well to pressure sensing applications. Depending on the atmosphere to which the chip is exposed to during the sealing process, gauge, vacuum, or absolute pressure sensors can be created.[73,74] The process outline in Figure 4.34A actually illustrates the case of an absolute pressure sensor with a Si_3N_4 membrane.[71] The sensor consists of a circular Si nitride diaphragm, which forms the top of a sealed vacuum cavity, providing the pressure reference. Polysilicon strain gauges are fabricated on top of the diaphragm and the measured resistance changes are, to first order, directly proportional to the applied pressure. In Figure 4.34B, we show a schematic of the sensor, and in Figure 4.34C, we feature an scanning electron microscope (SEM) microphotograph of a finished device.

Of reactive sealing and sealant films, the reactive sealing process is by far the most elegant and highest in performance. The first commercial absolute polysilicon pressure sensor, incorporating a reactively sealed vacuum shell, was introduced for automotive applications in 1995 by SSI Technologies, but it is not a product offering anymore.[75] Another application of the above type of sealed surface shells is the vacuum packaging of lateral surface resonators. Most resonator applications share a need for resonance quality factors from 100 to 10,000. However, the operation of comb-drive microstructures, as shown in Volume II, Figure 7.76, in ambient atmosphere results in low-quality factors of less than 100 due to air damping above and below the moving microstructure.[76] Vacuum encapsulation is thus essential for high-Q applications. It also has been shown that lateral comb-drive microresonators,[77] besides their use in commercial accelerometers, have potential applications in areas such as mechanical filters for signal processing,[78] noncontact electrostatic voltage sensing,[79] and rotation-rate sensing.[80]

Epitaxial Deposition Cavity Sealing

Deposition of a set of epitaxial Si layers with varying doping has shown to afford the formation of a hermetically sealed surface cavity.[81] The cavity, in this

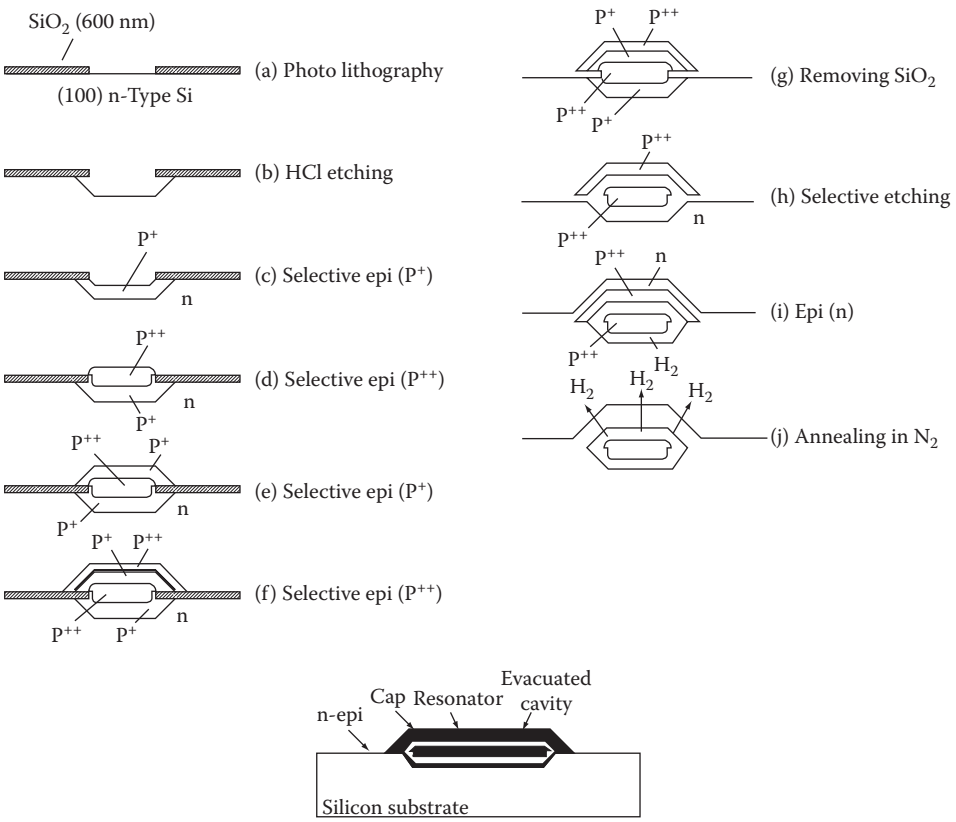

FIGURE 4.36 Epilayer-based fabrication process of a vacuum-encapsulated resonant beam. Process from (b) to (f) is carried out in one batch epitaxial process. For process step details see text. (From Ikeda, K., H. Kuwayama, T. Kobayashi, T. Watanabe, T. Nishikawa, T. Yoshida, and K. Harada. 1990. Silicon pressure sensor integrates resonant strain gauge on diaphragm. *Sensors Actuators A* A21:146–50. With permission.[82])

example of selective epitaxy surface micromachining, is formed by selective etching of p^+ epitaxial Si over more heavily doped Si p^{++} layers. The process is illustrated in Figure 4.36. The fabrication starts with a HCl dry etch at 1050°C in an epireactor through a hole in an oxide mask (Figure 4.36, steps a and b). Then follows a selective epitaxial growth of silicon in the following sequence: doped p^+, p^{++}, and p^+, p^{++} as indicated in Figure 4.36, steps c, d, e, and f. These steps are all carried out in the same epireactor, simply by changing the concentration of the B_2H_6 dopant. The next step consists of stripping of the oxide in HF (Figure 4.36, step g), followed by selective electrochemical etching in hydrazine (step h). In this electrochemical etching step, the n-substrate is passivated against the etching by the imposed potential and the p^{++} structures by the boron etch-stop mechanism. At this juncture, one ends up with a microbridge covered by a cap, both made out of single-crystalline, heavily boron-doped Si (p^{++}). The cap finally is sealed by growth of an n-type epitaxial layer (Figure 4.36, step i). The residual hydrogen in the cavity, after sealing, is diffused through the epitaxial layer by high-temperature annealing in a nitrogen ambient, resulting in a residual pressure inside the cavity of 1 mTorr (step j).[81,82] To make a pressure sensor that incorporates such an encapsulated resonator in a suspended membrane, one has to fabricate a membrane by etching from the back side of the wafer; a rather trivial step compared with the process just described. In the particular device shown here, the resonance of the encapsulated beam is activated by a Lorentz force and detected by measuring the resulting inductance.

Microassembled Caps or HEXSIL Cavity Sealing

Researchers at the University of California, Berkeley (UCB) developed another vacuum encapsulation method suitable for L0 and L1 level

packaging involving the wafer-to-wafer transfer of micromachined caps as demonstrated in Figure 4.37a.[83] Reactive sealing requires a temperature of 1000°C, and thick SiN sealing requires 850°C. Moreover, in the latter technique some sealant gas deposits on the encapsulated microdevices.

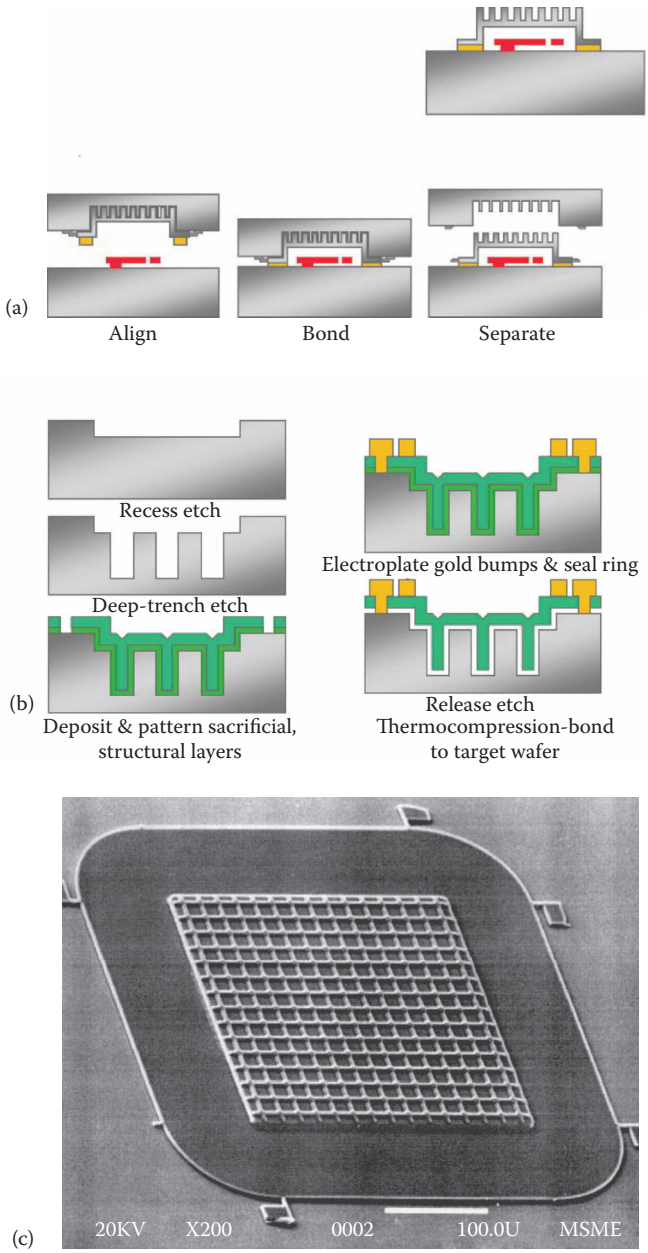

FIGURE 4.37 Wafer-to-wafer transfer of encapsulation structures. (From Hok, B., C. Dubon, and C. Ovren. 1983. Anodic bonding of galium arsenide to glass. *Appl Phys Lett* 43:267–69. With permission.[24]) (a) Principle of the wafer-to-wafer transfer method of encapsulation caps. (b) Fabrication of the tethered caps in a HEXSIL process. (c) Scanning electron microscope micrograph of a transferred cap.[82] (Courtesy of Dr. M. Cohen, University of California, Berkeley.)

In the alternative UCB packaging method, tethered cap structures are sealed down to the substrate employing a low-temperature Au-Si eutectic bond (the gold-silicon eutectic at 363°C is safely below that for aluminum-silicon). The encapsulation caps are made in the HEXSIL* process, as demonstrated in Figure 4.37b (see Volume II, Chapter 7, for details on the HEXSIL process). The caps have the general shape of a top hat and are suspended by breakaway polysilicon flexures in the handle wafer. The brim of the hat is coated with 0.7 µm of gold. The HEXSIL wafer with the embedded caps is positioned ($\Delta x <$ 10 µm) over the Si wafer with the active devices to be encapsulated. In situ annealing in vacuum by infrared heating forms the eutectic bond between the Si of the bottom wafer and the gold rim of the cap. The transfer occurs at a chamber pressure of 10^{-5} Torr, with 10 psi of mechanical pressure applied to the wafer sandwich. When the handle wafer is withdrawn, the polysilicon flexures break, leaving the caps sealed to the substrate wafer. In some limited test runs in a laboratory setting, a transfer yield of 100% was obtained for arrays of thirty caps. The HEXSIL mold wafer is reusable. An example of a transferred encapsulation cap is shown in the SEM micrograph in Figure 4.37c. To summarize, in the microassembled caps process, microcaps are fabricated on a donor wafer and transferred to a target wafer by wafer bonding and separation. The thin seal ring on the cap requires very little real estate (~1% of a bulk cap). The process potentially might be much less expensive than wafer-bonded caps as well.

Many of the newfound ways of hermetically sealing and bonding different layers and making contacts between them increasingly interest IC manufacturers. An important opportunity for micromachinists is to transfer the developed 3D machining technologies to the newest generations of 3D ICs.

Assembly and Self-Assembly

Introduction

Assembly is used to build complex products from relatively simple parts and to integrate incompatible

* HEXSIL is the acronym for hexagonal honeycomb poly-Si.

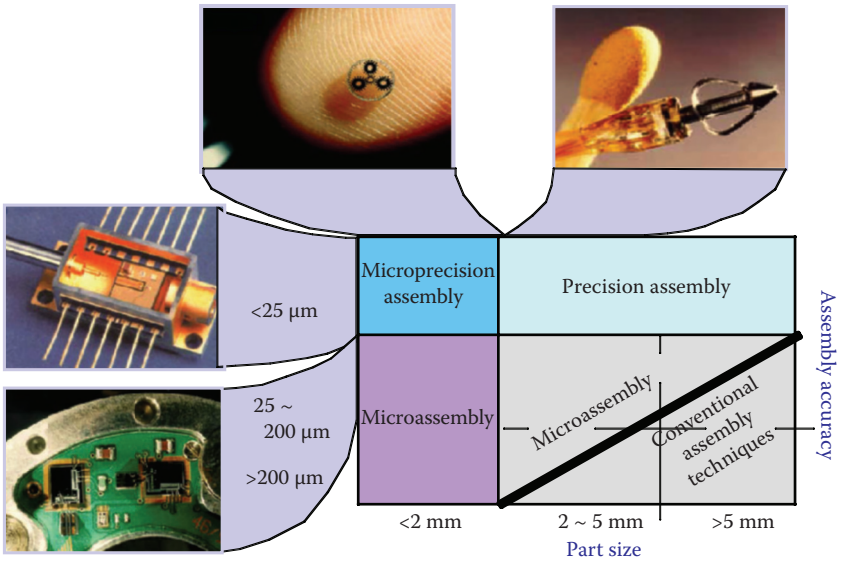

FIGURE 4.38 Assembly processes: part size assembled and assembly accuracy. (Courtesy of Kory Ehmann.)

manufacturing processes. Today, IC and MEMS assembly is mostly carried out by humans with tweezers and microscopes or with pick-and-place robots.[84] Micro- and mesoscale assembly processes handle objects from several micrometers to several millimeters in size. In Figure 4.38, we consider part size and assembly accuracy.

The current challenge is to assemble smaller and smaller components from different technologies with micro- and nanoprecision. The application field of micro- and nanoprecision assembly lies well beyond conventional or microscale assembly, with part dimensions larger than 2 mm (see Figure 4.38). The various micro- and nanoassembly approaches, divided into serial and parallel processes, are summarized in Table 4.3. In serial micro- and nanoassembly, parts are picked up and placed together on a substrate or workpiece one by one. Table 4.3 covers many methods enabling serial manipulation of very small parts/particles, including individual atoms for nanoassembly. Unless one can manipulate many parts/particles in parallel, most of these techniques will remain research tools rather than manufacturing options. In parallel micro- and nanoassembly, where parts are assembled simultaneously, we distinguish between deterministic and stochastic assembly.[84] In the former, the relationship between the part and its destination on a substrate is known in advance. In the latter, this relationship is unknown or random; parts "self-assemble" during a stochastic process driven by some motive force.

Stochastic self-assembly is an attractive option to integrate dissimilar process technologies. To achieve self-assembly, bonding forces must be present, the bonding must occur selectively, and the assembling parts must be able to move so that they can come together. Stochastic assembly often encompasses vibration of the parts in combination with electrostatic, fluidic, and other forces that operate on singulated parts in various media (fluids, air, or vacuum). After reviewing scaling issues of the assembly process, several examples of micro- and nanoassembly are presented. The smaller the building blocks, the higher the need for stochastic self-assembly, as handling the individual components becomes more and more of a mechanical challenge, and the process would be too slow. Nature, building on the nanoscale, does rely heavily on self-assembly (Chapter 2), and DNA-assisted self-assembly is an early attempt at co-opting nature for human manufacturing endeavors.

The best way to grab microparts is to use a microgripper, where grasping forces and jaw size match the requirements. Many kinds of microgrippers have been built. In Volume II, Figure 7.88, we show an example of a microgripper made of high-aspect-ratio molded polycrystalline silicon. The white bar at the bottom of the picture represents 100 μm. The actuator is an electrically heated

thermal expansion beam, which causes the compound lever linkage to move the tips. Such grippers have been used to seize various microscopic objects, including 2.7-µm-diameter polystyrene spheres, dried red blood cells, and various protozoa.

Scaling of the Assembly Process

Scaling effects in microassembly represent a daunting task. The newest pick-and-place robots with submicrometer resolution must be used, as conventional robots that pick, transport, and place small parts have a control error of 100 µm at best, which would translate in relative errors of 100% on micrometer-sized parts. It might be difficult to pick up large objects with a robot gripper, but small parts (<1 mm and masses less than 10^{-6} g) are difficult to release, as adhesion forces between gripper and object are significant compared with gravitational forces at that scale.[84] In Chapter 7, this volume, on scaling, we will indeed learn that in the microdomain, surface forces such as adhesion dominate over volume forces such as gravity or inertia. Adhesive forces involved in pick-and-place include surface tension due to moisture on the part and gripper, van der Waals forces (significant for gaps below 100 nm), and electrostatic attractions (e.g., induced by triboelectrification).

In Figure 4.39, we compare the magnitude of attractive surface forces (electrostatic, van der Waals, and surface tension) with the gravitational force as a function of part size, assuming a sphere (part)-plane (gripper) interaction. It is observed that in the microworld, surface forces dominate over gravitational influence. At 1 µm the gravitational

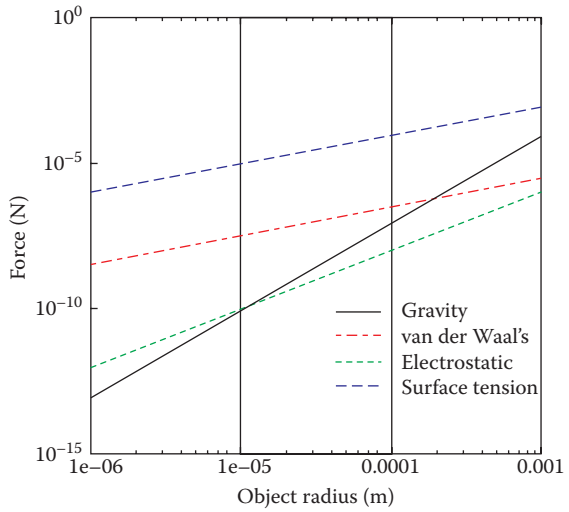

FIGURE 4.39 Comparison of the magnitude of attractive surface forces, i.e., electrostatic, van der Waals, and surface tension, with the gravitational force as a function of part size, assuming an interaction between sphere (part) and plane (gripper).

force is the least important force of the four, and at 10 µm the gravitational force equals the electrostatic force.

The electrostatic force is caused by charge attraction. Between a charged spherical object and a conductive plane it is approximated as follows:

$$F_{el} = \frac{\pi}{4\varepsilon_0}\frac{\varepsilon-\varepsilon_0}{\varepsilon+\varepsilon_0}d^2\sigma^2 \qquad (4.1)$$

where

d = the diameter of the particle
σ = the charge density on the surface
ε_0 and ε = the air's and the plane's dielectric-constants, respectively

The distance *z* between the sphere and the plane is assumed to be very small (Figure 4.40).

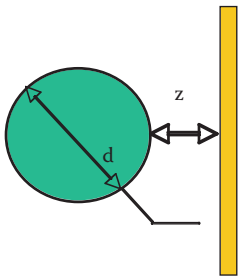

FIGURE 4.40 The electrostatic force between a spherical particle and a wall.

It is difficult to ensure that parts and grippers are electrically neutral because of the friction force and the difference in contact potentials between part and gripper. The gripper is typically coated with conductive coatings and grounded (the electrostatic force between two good insulators at 1 µm is 10^6 Pa!).

We already know that van der Waals forces may cause sticking together of MEMS parts and that this stiction may become permanent (see Volume II, Chapter 7, on stiction in surface micromaching). The van der Waals force is an atomic force caused by momentary movements of electrons, i.e., dipoles (see Volume I, Chapter 7). The sphere-plane van der Waals force is calculated as follows (see also Volume I, Table 7.8):

$$F_{vdw} = \frac{Hd}{12\,z^2} \qquad (4.2)$$

with the Hamaker constant *H* (see Volume I, Chapter 7, Table 7.6 for some typical values), the object diameter *d*, and the object-plane distance *z* (it is again assumed that $z \ll d$). This force becomes significant at less than 100 nm and increases with contact area (remember the popular study of Gecko Setae, with a force as high as 60 µN on a single seta; see Volume I, Chapter 7). Rough surfaces increase the effective distance *z* and therefore reduce the van der Waals force. Making the gripper surface rough might compromise ultimate positioning precision though. Also, gripper coatings can reduce the van der Waals force.

The presence of water on surfaces increases the normal force between the contacting surfaces as a result of capillary effects. The source of the liquid film between a gripper and part can be either a preexisting film of liquid and/or capillary condensates of water vapor from the environment. The surface tension force can be attractive or repulsive depending upon the configuration and the materials involved. The degree of hydrophobicity/hydrophilicity affects the contact angle (θ) and thus the surface tension force. The capillary tension force between a ball and a plate, with reference to Figure 4.41, is given by the following:

$$F_{tens} = \pi R_2^2 \gamma\left(\frac{1}{R_1}+\frac{1}{R_2}\right) \qquad (4.3)$$

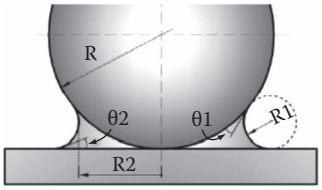

FIGURE 4.41 The capillary tension force between a ball and a plate.

where $\gamma = 72 \times 10^{-3}$ N/m is the water interfacial energy, and R_1 and R_2 are the axial and the tangential radius of the meniscus. To a good approximation, $2R_1$ corresponds to the thickness of the water film between the ball and the plane at the level of the meniscus, and both radii R_1 and R_2 can be expressed as function of ball radius R.

For small values of $2R_1$ the capillary force between the ball and the plane is given by the following equation:

$$F_{tens} = 2\pi R\gamma\left(2 + \sqrt{\frac{R_1}{R}}\right) \qquad (4.4)$$

For $R_1 << R$, the capillary force F_{tens} does not depend on the meniscus radius, and this relation simplifies to the following:

$$F_{tens} = 4\pi R\gamma = 2\pi d\gamma \qquad (4.5)$$

where R is the ball radius and d its diameter. When humidity is high, or with hydrophilic surfaces, a liquid film between a spherical object and a planar surface contributes a large capillary force. This effect can be reduced, for example, by working in a controlled environment or in a vacuum.

Surface forces make the release of objects after picking them up very difficult. To overcome these adhesion problems, some simple mechanisms for small-scale manufacture have been developed. They include electrostatic probes and vacuum probes. Also, the smallest components often are manipulated in a liquid medium (e.g., with laser trapping or dielectrophoresis). Microassembly obviously requires new handling techniques and electrostatic contact-less handling appears to be quite promising. Using a desktop factory (DTF) (see Volume II, Chapter 6), Nakao et al. used an electrostatic probe tip to assemble the microhouse shown in Figure 4.42.[113] The electrically charged tool can pick up and place

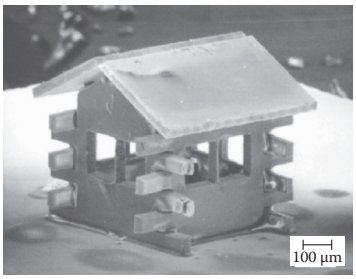

FIGURE 4.42 Scanning electron microscope of a microhouse. Using a desktop factory and an electrostatic probe tip, a microhouse was assembled.[113]

down micro-objects, and a semiconductor laser bonds both metal and nonmetal materials.

Vacuum pipettes, commonly used in microbiology for handling living cells, are another microassembly option. A vacuum gripper consists of a glass pipette and a vacuum control unit, and the actuating force is generated by the pressure difference on both sides of microcomponents. They are easy to use and are capable of picking, holding, and placing, and to overcome adhesion during placement they may use stripping off, pushing, or blowing away (see Figure 4.43).

On a large scale, vibration is used extensively in industrial part feeders that singulate, position, and orient parts before they are transferred to an assembly station. Sony's Advanced Parts Orientation System (APOS) part feeder, for example, uses an array of nests (silhouette traps) cut into a vibrating plate.[114] The traps and the vibratory motion are designed so that parts can remain in the nest only in one particular orientation. The traps in the vibrating plate are filled by tilting the plate and letting the parts flow across it. The APOS system with its controlled vibration to provide stochastic motion, combined with gravity as a motive force for nonprehensile manipulation, is a good model for microassembly. Again, scaling effects must be taken into account; vibration relies on the inertia of the parts and becomes less efficient with decreasing part size, so that higher vibration amplitudes or frequencies are required for smaller parts.

In the microscale, objects can be transported, for example, using acoustic traveling waves generated on a surface (see Chapter 8, this volume, Figure 8.28). Two types of waves are used, Lamb and Rayleigh waves. Lamb waves cause bending of the plate over its whole thickness (the substrate thickness is small

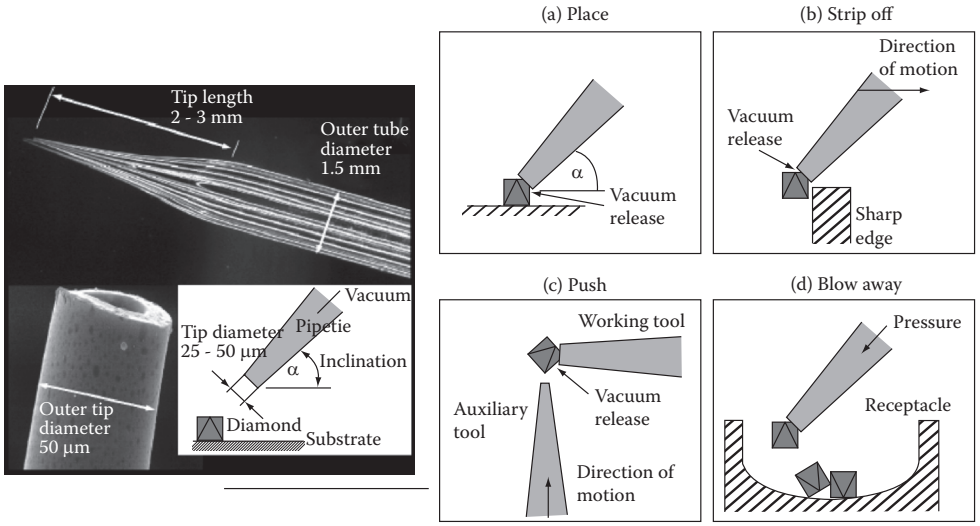

FIGURE 4.43 A glass pipette and a vacuum control unit are capable of picking, holding, and placing, and to overcome adhesion during placement they may use stripping off, pushing, or blowing away.

compared with the wavelength), while Rayleigh waves propagate only in the surface layer of the plate. Objects placed on the surface move in the opposite direction of the traveling wave (see Figure 8.28). Separation of particles may be effected by the competition between the acoustic force and the electrostatic force. The displacement of particles from pressure nodes in acoustic standing waves depends on the effective charge, radius, and stiffness of the particles. Yasuda has used lead zirconate titanate (PZT) transducers in a quartz cell to continuously concentrate, separate, and mix cells (e.g., blood cells).[115]

Another option is the use of distributed micromotion systems using arrays of tiny simple actuators that cooperate to move objects over relatively large distances and possibly in different directions and orientations. Several MEMS research groups have built such actuator arrays for micromanipulation; these arrays typically consist of a regular grid of "motion pixels" (mechanical members such as cilia).[116–123] These actuators are called *cilia* by analogy to their biological counterparts (see Chapter 8, this volume, Figure 8.11, and Chapter 5, this volume, Figure 5.13). Cilia arrays can move small objects placed on them by synchronous vibrations of the tiny hairs. To move objects in the x direction as well as the y direction, four cilia, one for each direction and sense, are grouped in motion pixels. The motion system consists of an array of these motion pixels. Appropriate control allows motion in any direction.

Table 4.4 summarizes some of the assembly issues one faces when manipulating parts in the mesoscale to the microscale and then into the nanoscale.

Serial Microassembly

In Volume II, Chapter 6, we saw how a 280-μm-high Japanese temple (Gojyunoto) on a polyimide platform was erected with the help of a microrobot manipulator. Many of the serial manipulation methods listed in Table 4.3 are used for manipulation of even smaller components, smaller than the typical MEMS device, such as biological cells, subcellular organelles, and even atoms.[125]

A small-enough object that is relatively transparent to laser light of a particular frequency refracts an incident laser beam, bending the light. As a result of this refraction, momentum is transferred from the light to the particle (see laser tweezers in Figure 2.33 this volume and in Volume I, Figure 5.34). When the geometry of light beams and particle is correct, the imparted momentum pulls the particle in the direction of the incident beam. The beam (or multiple beams) can then hold the particle in place, or by moving the beam(s), the laser operator can move the particle from place to place. In other words, light has momentum* and can be used to catch and manipulate objects in a size range from nanometers to micrometers in so-called *optical tweezers*.

* As far back as 1619, Johannes Kepler explained that the tails of comets are always directed away from the sun by the pressure of sunlight.

Table 4.4 Assembly Issues as a Function of Part Size[124]

Assembly Attribute	Assembly Scale		
	Mesoscale	Microscale	Nanoscale
Positioning	Easy	Difficult	Very difficult
Velocity	cm/s or m/s not unusual	Slow (μm/s or mm/s), vibration suppression	Very slow (nm/s or μm/s)
Force sensing and control	Easy, necessary to avoid part damage and improve manipulability	Difficult; range of forces could be as low as μN	Difficult; AFM used to measure force
Dominant forces	Gravity, friction	Surface forces (stiction, friction, electrostatic, Van der Waals)	Molecular/atomic forces
Throughput	Serial assembly provides adequate throughput	Serial assembly usually not sufficient; parallel manipulation methods preferred	Parallel manipulation methods or self-assembly necessary
Gripper	Mechanical	Micromechanical, gripper-free manipulation preferred	Other methods needed: optical, proximity forces, etc.
Fixturing	Mechanical	Micromechanical fixturing must be used	Chemical
Compliance	Gripper compliance not necessary if force measured	Gripper compliance usually necessary	Mechanical compliance not applicable
Vision	Easy	Difficult (expensive optics)	Impossible with visible wavelengths; SEM and TEM are used

The laser wavelengths in optical tweezers typically are between 0.7 and 1.06 μm, and 25 to 500 mW of power is generated in a focal spot between 0.5 and 1.0 mm in diameter. The first work with optical tweezers was performed by Ashkin et al. at AT&T Bell Laboratories. In pioneering works in 1985 and 1986, they successfully demonstrated that small particles could be trapped by focused low-power laser light (<1 W).[126,127] The first demonstration on trapping of living biological objects was also by Ashkin et al. in 1987.[104] The authors not only trapped and manipulated single cells, they demonstrated that the trap was harmless to living biological species. For example, reproduction of yeast cells was achieved in a trap capable of manipulating them at velocities of 100 m/s. Combined with other techniques (such as a laser scalpel), a number of important studies within microbiology have been carried out and many more can be visualized in the future. The difference between tweezers and scalpels is that the latter employ short pulses of high irradiance, whereas tweezers use continuous, low-irradiance beams. The laser scalpel can be used for cutting biological objects inside cells (e.g., DNA segments). Steven Chu,* a 1997 Nobelist in Physics (see Volume I, Figure 1.28) showed while at Stanford University that laser tweezers can be used to stretch molecules such as DNA: with colloidal spheres attached to the DNA strands, the spheres were trapped and the DNA was stretched by moving in fluid flows[128] (see also Chapter 2, Figure 2.33). The most common form of optical tweezers in biology is the "single-beam gradient trap," immobilizing transparent dielectric particles near the focal point of a tightly focused continuous-wave laser with a force proportional to the electric field gradient:[125,129,130]

$$F_{grad} = -n\left(\frac{1}{2}\alpha\nabla E^2\right) \tag{4.6}$$

where

n = the index of refraction of the solvent/medium

α = the polarizability of the particle

Such a beam generates forces in the piconewton range, more than sufficient for trapping cells and moving organelles inside and outside the cells. Usually, the technique cannot be used to lift objects much larger than the wavelength of the light. Links to pages related to optical tweezers can be found at http://www.phys.umu.se/exphys/OpticalTweezers.

Two different serial manipulation approaches can be used together. For example, cages for biological

* Dr. Steven Chu is currently the US Secretary of Energy.

cells have been made by combining optical trapping and dielectrophoresis.[131] Such a combination enables manipulation of two bioparticles in close proximity, which would be impossible using two laser beams or two electrical fields, as those fields would interfere. Dielectrophoresis is an AC electrokinetic effect (electro-osmosis and electrophoresis are direct current electrokinetic effects) discussed in detail in Volume I, Chapter 7. It is a powerful tool for separating particles of the size of biological cells but is more difficult to apply for particles below 1 µm.

In mechanosynthesis, an STM is used to manipulate individual atoms, as demonstrated in Volume II, Figure 2.43, where Pt atoms have been arranged on a Pt(111) surface. The Kanji character for *atom* in Figure 6.26 was also made this way. As pointed out in Chapter 1, serial manufacturing processes that use building blocks that are too small are not viable manufacturing candidates unless an army of them can work together on the same construction project.

Parallel Microassembly

The concept of self-assembly is inspired by biological processes in which complementary pairs such as antigens bind to antibodies on the basis of shape recognition. In the nonbiological world, objects can be similarly assembled on the basis of geometry. The advantage of self-assembly is that it is a batch process, in which hundreds or thousands of objects or even more are assembled at a time. When the interface is well designed, the objects are also self-aligned, and different types of objects can be assembled simultaneously by using different interfaces.

An example of deterministic parallel assembly by Cohn et al. for wafer-to-wafer transfer of MEMS and other microstructures was shown already, in Figure 4.37.[83,87] In this HEXSIL flip-chip process, the finished microstructures are suspended on breakaway tethers on the substrate. The target wafer with indium solder bumps is precisely aligned and pressed against the substrate, such that the microstructures are cold welded onto the target wafer. In another example of deterministic parallel microassembly, Keller et al. demonstrated microgrippers (see Volume II, Figure 7.88) and proposed gripper arrays for parallel transfer of palletized microparts.[94,102]

Many stochastic approaches for microassembly are under investigation. Yando, for example, employs an array of magnetic sites to assemble magnetically coated semiconductor parts in a square array. The components are vibrated at a gradually attenuated amplitude to "place" the array elements.[132] Similarly, Yeh et al.[90,91] trap semiconductor light-emitting diodes (LEDs), suspended in a liquid, in micromachined wells on a wafer by solvent-surface forces. As illustrated in Figure 4.44, carrier fluid containing the GaAs parts is dispensed over the host Si wafer with etched holes to assemble the GaAs blocks. Because of the trapezoidal design, the blocks fit preferentially into the holes in the design orientation. Random mechanical vibration of the microstructures enables large numbers of microstructures to be positioned into precise registration with the sites. More than 90% of the holes etched in Si were correctly filled by the blocks before the carrier fluid evaporated. However, during evaporation, surface tension pulls some objects out of the holes, reducing the yield to 30–70% locally. This problem can be addressed by using liquids with lower surface tension or by using supercritical drying methods.

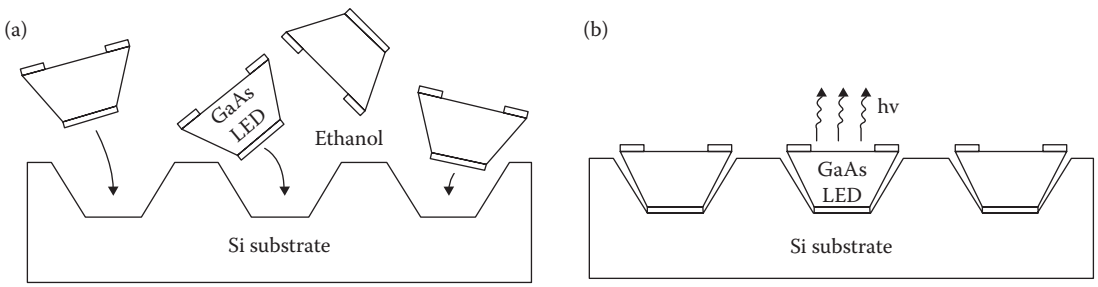

FIGURE 4.44 Fluid self-assembly of GaAs light-emitting diodes (LEDs) on Si micromachined substrate. (a) Solution containing the GaAs blocks is dispensed over the patterned silicon substrate. (b) Silicon substrate with GaAs LEDs integrated by fluidic self-assembly. [From Yeh, H.-J., and J. S. Smith. 1994. In *Proceedings of the IEEE International Workshop on Micro Electro Mechanical Systems (MEMS '94)*, 279–84. Oiso, Japan. With permission.[90]]

In 1991, Cohn et al.[96] first reported on stochastic assembly experiments that use vibration and gravitational forces to assemble periodic lattices of up to 1000 silicon chiplets.[133] Later, the same group[96] demonstrated an interesting variation on the work of Yando[132] and Yeh et al.[90,91] by using alignment capabilities over electrostatic traps. The process is illustrated in Figure 4.45. A critical problem in attempting to vibrate microstructures into specific sites from a liquid is that when structures adhere to the substrate or to each other, their progress toward optimal, precise registration is halted. This is caused by the same stiction phenomena we described for surface micromachined structures in Volume II, Chapter 7. Cohn et al. addressed this problem by levitating the microstructures a short distance above the target electrostatic trap site before letting them settle. As a result, random sticking is prevented, and critical positioning and orientation of the microstructure with respect to the trap become possible with a relatively low applied field (10 V/μm). The levitation over the trap site is accomplished by creating a short-range repulsive force between the microstructure and the target site. Microstructures with a relatively high permittivity (ε = 10) are suspended in a low-permittivity solvent (hexane), resulting in a net attraction to the charged electrodes making up the sites. However, a small amount of a more polar solvent (acetone) is added, which segregates into the high-field region between the two attracted parts. This prevents contact between the site and the suspended microstructure. Critical positioning and orientation become possible, in the manner of a compass needle resting on a low-friction bearing.[96] Once the sites are populated, the polar solvent is titrated out, gradually lowering the trapped devices to the target sites and pinning them onto the surface. A subsequent sintering step could effect permanent attachment—say, by eutectic bonding. Böhringer et al. subsequently demonstrated the ability to break surface forces using ultralow-amplitude vibration in vacuum, which holds promise as an extremely sensitive technique for positioning parts as well as discriminating part orientation, shape, and other physical properties.[97] Hosokawa et al.[134] modeled the kinetics of self-assembly and, using planar parts of various simple geometries floating on water,

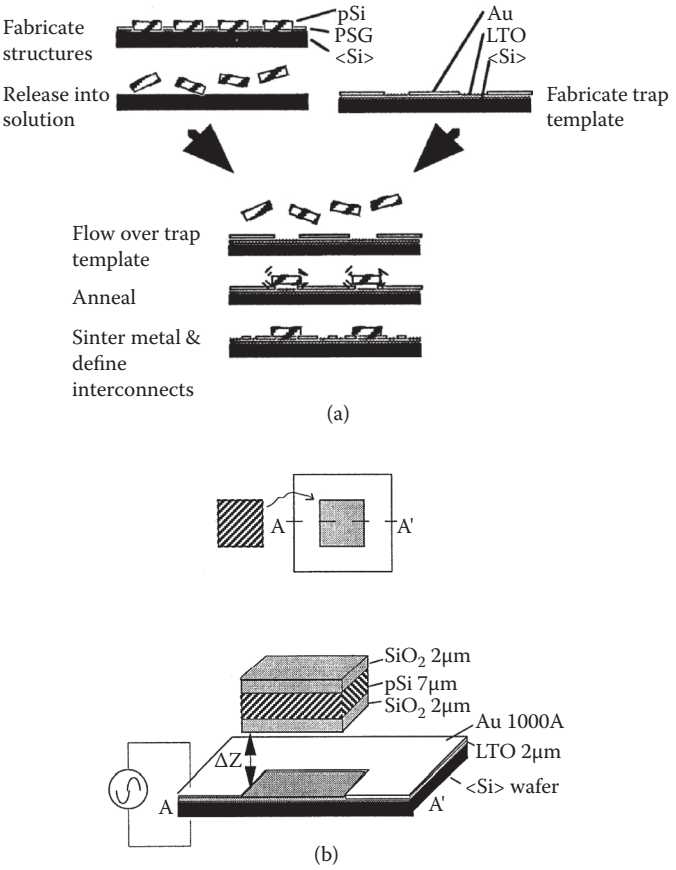

FIGURE 4.45 Self-assembly using electrostatic levitation. (a) Batch assembly of microstructures into binding sites on a substrate. Structures may include microelectromechanical system, complementary metal-oxide-silicon, optoelectronics, magnets, etc. (b) Detail of an electrostatic binding site. The section view shows position of a levitated microstructure. The levitation height (Δz) is in the range of 0–100 mm. The microstructure, a SiO_2-pSi-SiO_2 sandwich, has an average dielectric constant (ε) of 10, between that for hexane and acetone. The aperture in the gold film may range from ~2 to 100 mm in diameter, depending on the size of the microstructure to be trapped. (Courtesy of Dr. M. Cohen, University of California, Berkeley.)

demonstrated two-dimensional (2D) self-assembly. The units, consisting of a polyimide layer on a polysilicon layer (assembly units were 400 μm in size), selectively bonded to each other because of surface tension (a dominant force in the microscale; see above). The floating parts that were at equal height attracted each other. Sharp corners induced yet larger selective attractive forces, and parts located at different heights were mutually repulsed. To disturb the self-assembly system, magnetic or fluid forces were used. The floating units tended to align, with their sharpest features pointing toward each other.

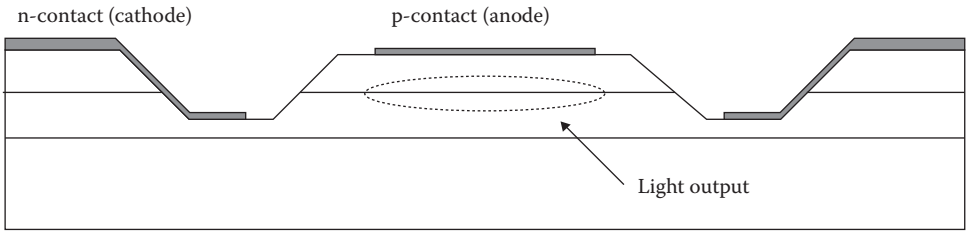

FIGURE 4.46 Schematic InGaAs microlight-emitting diodes have contacts on one side of the device as shown in the cross-section. (Courtesy of Dr. M. Heller, Nanogen.)

At Nanogen, Inc., electric fields are used to transport and control the placement of proteins, RNA, and DNA, as well as semiconductor components on a substrate equipped with an array of electrodes in a low-conductivity solution.[99,135] The electrophoretic nano assembly of DNA on the Nanogen platform is reviewed in Volume II, Chapter 8, Example 8.2. Here we illustrate the use of electric fields for precision placement of microlight-emitting diodes (microLEDs) (20 μm in diameter) onto a Si substrate using electro-osmosis (for details on electrophoresis and electro-osmosis, see Volume I, Chapter 7). The InGaAs microLEDs used all have contacts on one side of the device, as shown in the cross-section schematic in Figure 4.46. The corresponding substrate site has two sets of electrodes designed for the mounting process. As seen in Figure 4.47, a first pair of larger horseshoe electrodes brackets an inner set of electrodes. The inner set of electrodes is designed to mate with and bond to an LED and is made of standard tin/lead, electroplated to a height 50 nm above the surrounding surface. The linear structures seen in the pictures connect the exposed electrodes and are insulated to avoid shunting through the overlaying aqueous solution. Activation of the outer electrodes with respect to a counterelectrode (not shown in the figure) causes an electro-osmotic flow (see Volume I, Chapter 6) along the surface of the chip and moves the LED placed in the solution. Once the LED is on the electrode, the electro-osmotic flow is briefly reversed, and the reversal of the fluid flow drives the LED onto the awaiting bonding points

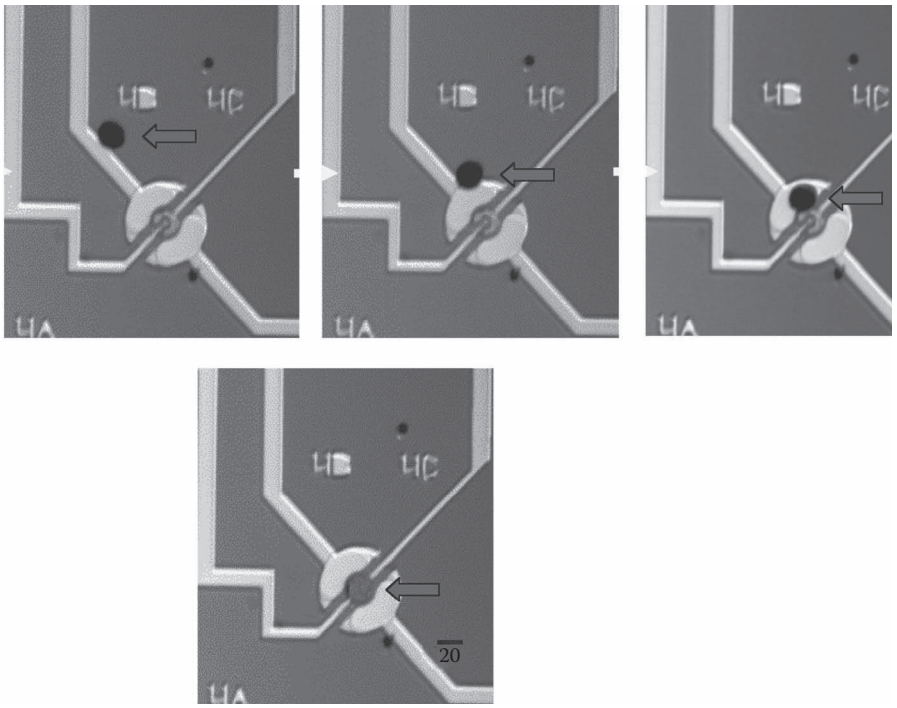

FIGURE 4.47 Electric field directed placement of light-emitting diodes (LEDs). The arrow points toward the moving LED. (Courtesy of Dr. M. Heller, Nanogen.)

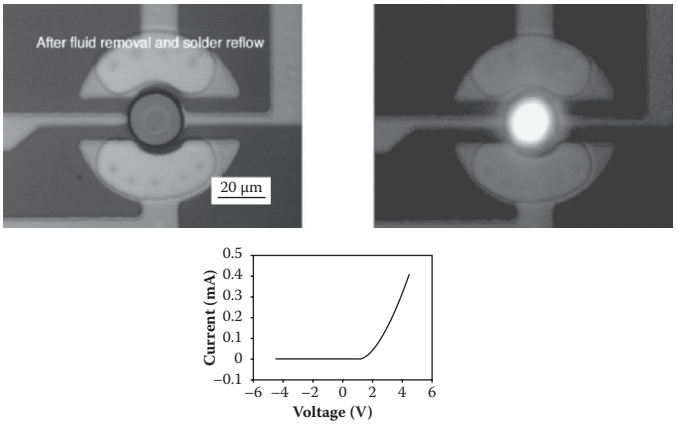

FIGURE 4.48 Circuit integrity and light-emitting diode (LED) activation demonstrated by forward biasing the LED. (Courtesy of Dr. M. Heller, Nanogen.)

with microscale precision. After the fluid is removed, the solder is reflowed under forming gas at 250°C. Circuit integrity and LED activation are demonstrated by forward-biasing the LED using the silicon circuit's contacts, as demonstrated in Figure 4.48.

The Nanogen authors point out that the same process could be used to assemble a large variety of components simultaneously and selectively on a circuit by the parallel activation of sets of electrodes while maintaining a number of components present in the low-conductivity solution. They speculate that the process might be aided by the use of a self-sorting mechanism by attaching short sections of complementary DNA on components and target sites on the circuit (see next section).[135]

Self-Assembly Examples

DNA-Mediated Assembly

While work continues on self-assembly of MEMS components with top-down methods, many researchers have recognized that the exquisite molecular recognition of various complementary biological molecules may be used to assist in the assembly of micro- or nanocomponents into complex networks. In this approach, DNA nanostructures and DNA mediated assembly of nano- and microstructures have received most attention in the literature. In the DNA nanostructures approach, pioneered by N. C. Seeman, the 2-nm-wide DNA molecules themselves are used to form 2D and 3D structures.[139–143] As shown in Figure 4.49a, DNA four-armed branched junctions are made by properly choosing the sequence of complementary strands. These DNA scaffolds can be linked together to make periodic crystals as shown in Figure 4.49b.

To use DNA for assembling nano- or microparts, one first needs to attach DNA molecules to these parts. The most widely used method is the covalent bond between sulfur and gold, that is, a metal thiolate (~44 kcal/mol). DNA molecules can be functionalized with thiol (S-H) or disulfide (S-S) groups, and upon immersion of microparts with clean gold surfaces in solutions of such thiol or disulfide derivatized oligonucleotides, the sulfur adsorbs on the gold surfaces, forming a single layer of molecules. Using this methodology, Mirkin et al. described a method of assembling colloidal gold

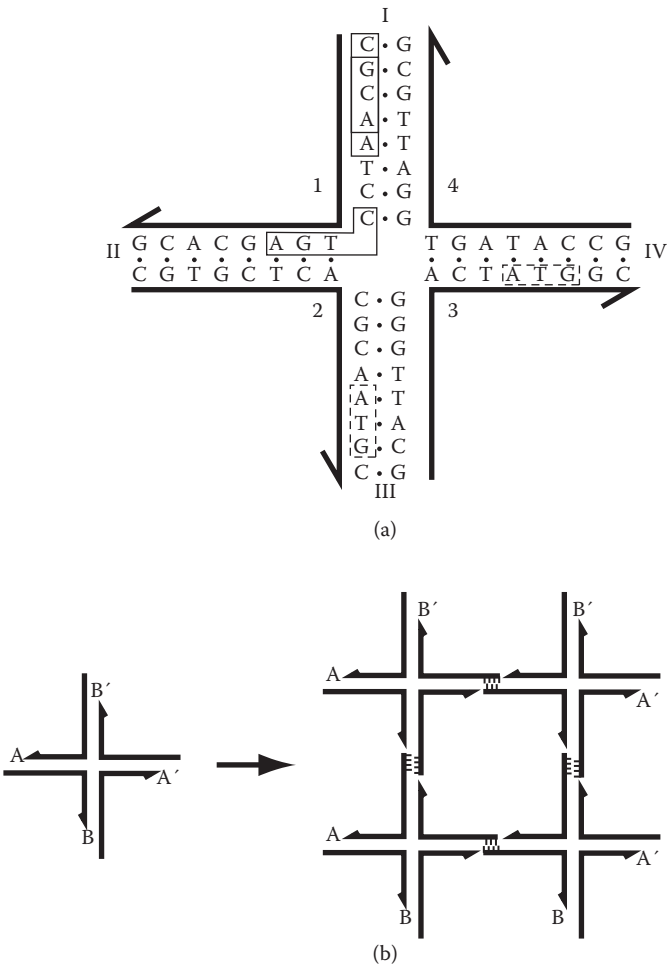

FIGURE 4.49 (a) Four-armed stable branched junction made from DNA molecules. (b) Use of branched junctions to form periodic crystals. (Based on Seeman, N. C. 1991. *Nanotechnology* 149.[140])

nanoparticles into macroscopic aggregates using DNA as linking element.[144] Noncomplementary DNA oligonucleotides were attached to the surfaces of two batches of 13-nm gold particles. An oligonucleotide duplex with ends complementary to the grafted sequences was then introduced into the particle mixture, and the nanoparticles self-assembled into aggregates. The process is illustrated in Figure 4.50. It can be reversed by increasing the temperature, which melts the double-stranded DNA linkers. Closely packed assemblies of aggregates with uniform particle spacings of about 60 Å were demonstrated this way.

The concept of DNA-mediated self-assembly has been extended to metallic nanowires/rods.[145] The idea behind this is to fabricate gold and/or platinum wires, functionalize them with single-stranded DNA (ssDNA), and assemble a wiring network on a substrate that has the complementary ssDNA molecules attached at specific sites. Thus, self-assembly of interconnects and wires is rendered possible. DNA has also been used as a template for the fabrication

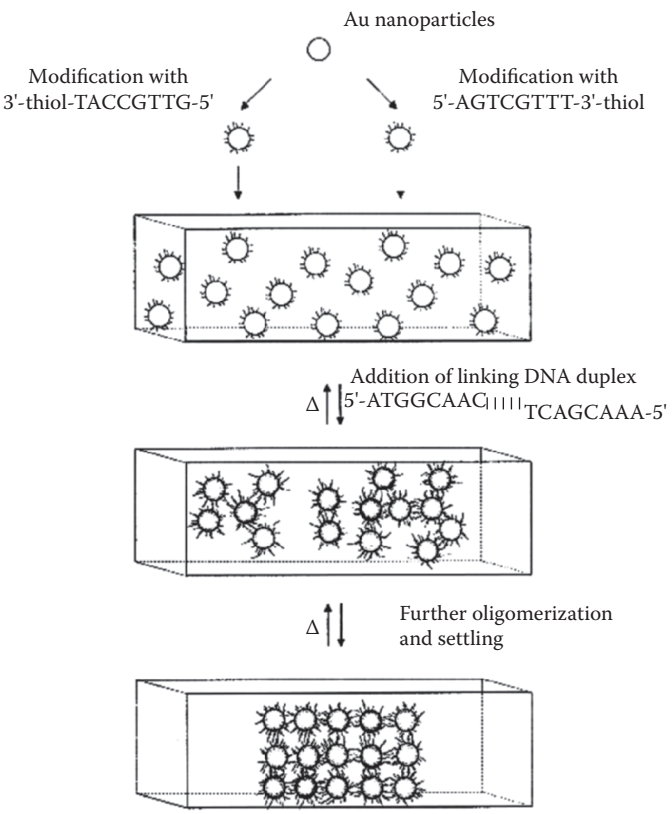

FIGURE 4.50 Fabrication process for the aggregated assembly of DNA conjugated gold nanoparticles. (Based on Mirkin, C. A., R. L. Letsinger, R. C. Mucic, and J. J. Storhoff. 1996. *Nature* 382:607.[144])

of nanowires. Braun et al.[136] formed a DNA bridge between two gold electrodes, again using thiol attachment. Once a DNA bridge is formed between the 12–16-μm spacing of the electrodes, a chemical deposition process is used to deposit silver ions along the DNA through Ag^+/Na^+ ion exchange and reduction of the silver complexes with hydroquinone. The result is a silver nanowire that is formed using DNA as a template or skeleton. The most ambitious goal is the DNA-assisted assembly (molecular "Velcro") of semiconductor active devices, such as transistors, laser diodes, etc., proposed by Edman et al. at Nanogen.[135] For a review of this area, check out Bashir[137] and Lee et al.[138]

Micro-Origami

Often MEMS includes hinged parts that must be set in place before operation. This can lead to challenging and time consuming manual manipulation of components at small length scales. Researchers from the ATR Adaptive Communications Research Laboratories in Japan (http://www.atr.co.jp) have developed a technique they call micro-origami to fabricate MEMS devices that automatically move parts into position.[146] Micro-origami makes use of the energy stored as strain between lattice-mismatched semiconductor epitaxial layers to create self-positioning, three-dimensional structures with simple and robust hinges. The key to the micro-origami technique is to manufacture hinges out of a pair of material layers with slightly different atomic spacings. The lattice mismatch causes a stress that in turn bends a hinge, as shown generically in Figure 4.51. In the case shown, a distributed Bragg reflector* (DBR) or micromirror is moved out of the plane of the substrate. Micro-origami structures are manufactured by using epitaxial growth techniques to construct multilayered films designed with folding hinges etched into their surfaces in the manner of

* A distributed Bragg reflector is a structure formed from multiple layers of alternating materials with various refractive indexes. Each layer boundary causes a partial reflection of an optical wave. For waves whose wavelength is close to four times the optical thickness of the layers, the many reflections combine with constructive interference, and the layers act as a high-quality reflector. The range of wavelengths that are reflected is called the *photonic stopband*. Within this range of wavelengths, light is "forbidden" to propagate in the structure.

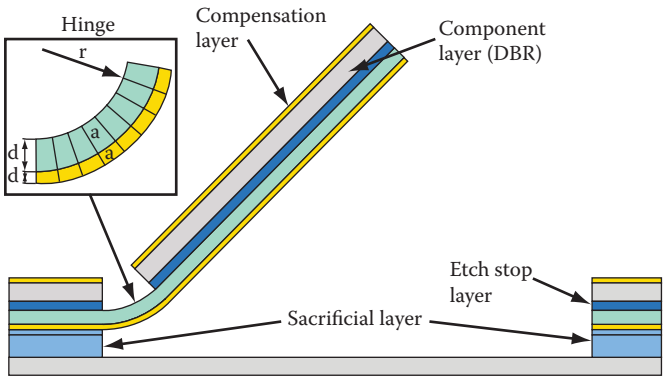

FIGURE 4.51 Schematic of the origami process. (From http://microfanatic.com/origami.html.)

the creased folds of paper. Adjusting the thickness and the length of the hinge that connects the plates to each other controls the angle between different plates. When the film is removed from its substrate by etching away a sacrificial layer, the microstructure takes on its designed shape because of the released stress in the hinge areas. In this way, this fabrication method reflects the design principles of origami, the traditional Japanese art of sculpting objects from folded paper. Because it is possible to fabricate three-dimensional structures on a semiconductor substrate, these structures can be integrated with lasers and photodetectors.

This fabrication method of simple and robust hinges for movable parts can be applied to any pair of lattice-mismatched epitaxial layers in semiconductors or metals. The first work by the ATR team involved a multilayer structure, including AlGaAs/GaAs component layers and an InGaAs strained layer, which was grown by molecular beam epitaxy on a GaAs substrate. After definition of the hinge and mirror's shape by photolithography, the micromirrors were released from the substrate by selective etching. They moved to their final position powered by the strain release in the InGaAs layer. The curvature radius of the hinges is determined by the thickness ratio of the bilayer and the indium composition in the strained layer. Depending on the growth structure, the hinge can fold up or down, making the fabrication of complex 3D semiconductor structures possible. For example, in Figure 4.52, we show GaAs corner plates assembled by the strain in two hinge regions, and in Figure 4.53 we illustrate a microstage fabricated on a GaAs substrate using

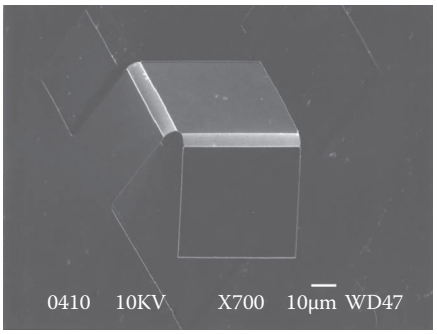

FIGURE 4.52 GaAs corner plates assembled by the strain in two hinge regions. (From http://microfanatic.com/origami.html.)

hinges with different bending directions called *tani-ori* (valley fold) and *yama-ori* (mountain fold) in origami. In the latter case, a multilayered structure including InGaAs strained layers was grown by molecular-beam epitaxy on a GaAs substrate. After the multilayered structure from the substrate is released by the selective etching of a sacrificial layer, the microstage moved into its final position powered by the strain release in the InGaAs layers, and the stage was kept parallel to the substrate owing to the combination of the two types of hinges.[147]

The ATR team also fabricated SiGe/Si free-standing micro-objects on an SOI substrate using SiO_2 as sacrificial layer material. SiGe/Si strained films were grown by molecular beam epitaxy on silicon-on-insulator (SOI) substrates and were released from the substrate by selective etching of the SiO_2 layer. The released films rolled up because of the elastic strain in the SiGe layer. Microtubes and microspirals with a diameter of about 40 μm were obtained as shown in Figure 4.54.[148]

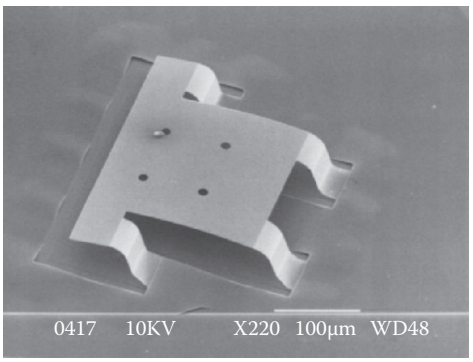

FIGURE 4.53 A self-assembled microstage fabricated using hinges with different bending directions. (From http://microfanatic.com/origami.html.)

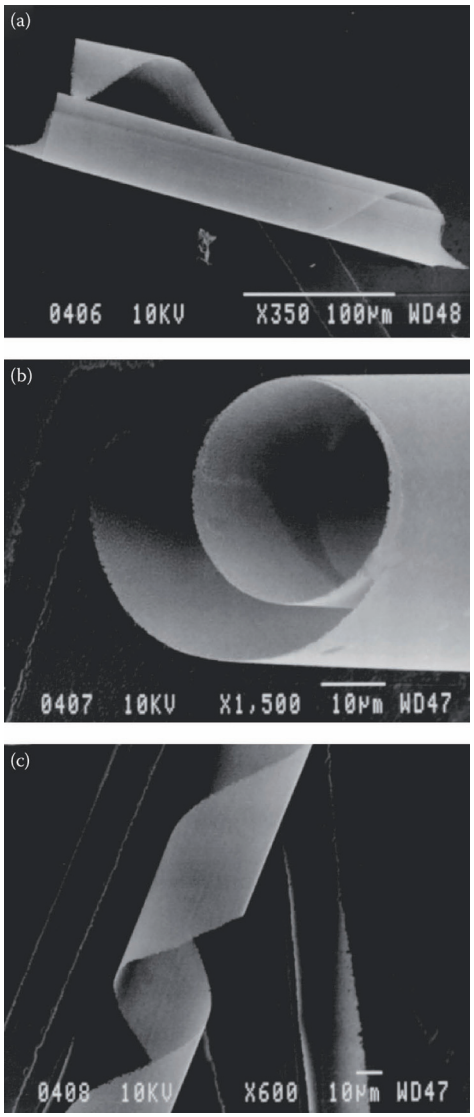

FIGURE 4.54 Free standing micro-objects on SOI substrate. (a) Top view of released SiGe/Si film scrolled in a microtube. (b) Rolled film at large magnification. (c) SiGe/Si microspiral. Curvature radius is about 20 µm.[148]

On a somewhat larger scale, researchers at the École Supérieure de Physique et de Chimie Industrielles in Paris, together with a team from the Paris Institute of Technology, have shown that water droplets can be used to make flat sheets of plastic (40–80 µm thick), a couple of millimeters across fold into 3D objects such as tiny pyramids, boxes, and spheres.[149] A drop of water, large enough to reach all corners, is placed on top of a cut-out shape. As the liquid evaporates, its surface tension tugs the membrane closer around the water's decreasing volume, until the remaining liquid is completely encapsulated inside a sphere, tetrahedron,

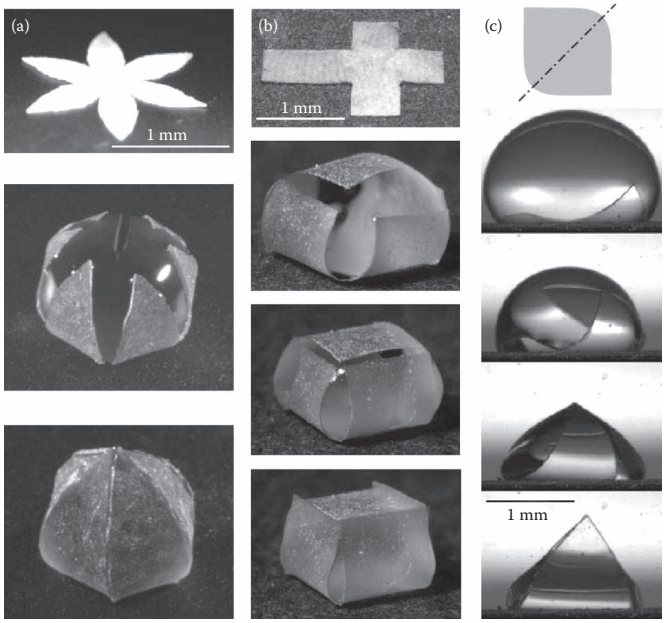

FIGURE 4.55 It is the interaction between elasticity and capillarity that is used to produce three-dimensional structures through the wrapping of a liquid droplet by a planar sheet. Tuning of the initial flat shape to obtain (a) a spherical encapsulation, (b) a cubic encapsulation, or (c) a triangular mode-2 fold.[149]

or some other shape. Tailoring the initial geometry of the thin membrane, as demonstrated with some experimental results in Figure 4.55, controls the final encapsulated 3D shape. For example, a flower-like pattern produces a sphere; a triangle becomes a tetrahedron, and a flat cross shape folds into a cube. Varying the thickness of the sheet controls how much a structure folds up, and as expected, the effect of surface tension becomes stronger as the size is decreased.

In Chapter 3, this volume, we saw several examples of DNA origami (see Figures 3.5 and 3.6).

The intersection between the subjects of origami and mathematics is rich with interesting results and applications. For details, consult http://kahuna.merrimack.edu/~thull/origamimath.html and http://www.paperfolding.com/math.

Questions

4.1: Explain front-end and back-end processes in IC or MEMS manufacturing. To which hierarchical level of manufacturing is each one related?

4.2: What are some of the advantages of a silicon-silicon bonding process over anodic bonding? Are there any disadvantages?

4.3: What is the role of packaging in ICs and in chemical and biological MEMS?

4.4: Which is easier to package, an absolute pressure sensor or an accelerometer? A pressure sensor or a pH sensor?

4.5: Describe and compare different wafer bonding techniques.

4.6: Describe the process of silicon-to-glass anodic bonding. Make a sketch of the setup and describe typical conditions required. What is the process that takes place on the molecular level?

4.7: Suggest a method for preventing an accelerometer sensor element from being subjected to undesirable mechanical stresses (from temperature changes or packing stress).

4.8: One of the modifications of anodic bonding is to deposit intermediate layers of silicon dioxide and aluminium. What are the advantages and disadvantages of this method?

4.9: Surface forces make the release of objects after picking them up in microassembly very difficult. Suggest several methods to make this process easier.

4.10: What are the three major electrical connection methods in chip-mounting?

4.11: Describe at least four techniques one could use to make a via through an Si wafer.

4.12: Describe as many methods that you know to vacuum seal a MEMS device on-chip.

4.13: Describe the difference between serial microassembly and parallel microassembly.

4.14: How do gravity, van der Waal's, electrostatic, and surface tension scale as a function of part size in microassembly, assuming a sphere (part) and a plane (gripper) interaction?

4.15: What is likely to be a major concern with DNA-assisted assembly? How could you improve the situation?

Introduction

Silicon is one of the most commonly used micromachining materials not only because of its excellent electronic and mechanical properties, the incredible degree of control one can exert over doping this semiconductor material, and the ease of insulating its surface with SiO_2 but also because it has been the dominant material in the integrated circuit (IC) industry ever since the early 1950s. However, silicon is not perfect for all applications, nor can it function on its own: the IC arsenal features a small group of additional materials, such as the metals Al, Cu, W, B, and P and the insulators SiO_2 and Si_3N_4. There are plenty of new demands that are challenging the continued dominance of silicon and will require the introduction of new materials that work in conjunction with silicon or necessitate the switch to alternative semiconductors altogether: higher speeds; better heat dissipation; merging of sensors and actuators with active electronics, optoelectronics, and quantum devices; lower power consumption; more environmentally friendly manufacturing processes, etc. In microelectromechanical systems (MEMS) and nanoelectromechanical systems (NEMS), and in some application-specific ICs, alternative semiconductor materials already are being used, including gallium arsenide (GaAs), $Al_xGa_{1-x}As$ compounds, SiGe, CdSe, SiC, TiO_2, ZnO, and carbon nanotubes. A wide variety of polymers, ceramics and metals, foreign to the standard IC process also have been adopted, especially in bio-MEMS. In this chapter, we review some selected materials and processes that have affected and will continue to affect the direction MEMS and NEMS take on next. The chapter is headed by a description of possible substrate materials for MEMS and NEMS: quartz, GaAs, diamond, SiC, ceramics (with emphasis on Al_2O_3), polyimides, silicon nitride, and amorphous and hydrogenated amorphous silicon. For exciting new MEMS/NEMS techniques, we survey carbon-based MEMS (C-MEMS), bulk metallic glasses (BMGs), fast microfluidic compact disc (CD) prototyping, and micro glass blowing. Finally, we dedicate a section to biocompatibility and the various chemistries for surface derivation of solids to make them biocompatible. Studies of in vivo MEMS devices are regaining popularity, making a deeper understanding of biocompatibility a necessity.

Selected MEMS and NEMS Materials

Introduction

Miniaturization—a mantra in electrical engineering for a long time—has become a widely accepted discipline in the other engineering branches. This has led to a wider and wider array of materials used in miniaturization science. Here we dwell upon the importance of the substrate material, i.e., the principal material on which or in which to fabricate the MEMS or NEMS. In Chapter 1, this volume, we presented a section on substrate choice, including a comparison of important substrate materials for MEMS and NEMS (see Tables 1.9 and 1.10). These tables include materials that are merely "passive" substrates (e.g., plastics or cardboard support structures) and others that are "active" and may constitute an active member of a micromachine (e.g., GaAs or quartz).[1] If the substrate to be machined must combine good electronic properties with excellent mechanical behavior, single-crystal Si is still the favored material. The electronic qualifications of Si are well known through the resounding successes scored by the IC industry in this and the previous century (see Volume I, Chapter 4). But, when comparing the yield strength, density, specific strength (i.e., ratio of yield strength to density), Knoop hardness, Young's modulus, thermal conductivity, and thermal expansion coefficient for some of the most important technological materials (Volume I, Tables 4.15 and 4.16), one realizes that Si

also is an outstanding mechanical sensor/actuator substrate. Although a large percentage of MEMS and NEMS relies on single-crystal Si, and the IC industry is almost exclusively based on it, the need for all types of miniaturized devices with a wide variety of new functions is rapidly changing this picture. This is particularly true for chemical and biological sensors, actuators, harsh environment devices, and microfluidic structures. But even for mechanical devices, Si is far from the only choice, with quartz, for example, being an excellent contender. For biomedical applications and microfluidics, glass and polymers are becoming an increasingly favored miniaturization substrate. Fast ICs, radio frequency (RF)-MEMS, optoelectronics, and NEMS are pushing GaAs, $Al_xGa_{1-x}As$ compounds, and SiGe to the foreground. For harsh environments, ceramic micromachining is emerging as a new opportunity. A check-off list to determine the optimum substrate for a given micromachining task was introduced in Chapter 1, Table 1.11. Many MEMS/NEMS substrates were covered earlier in the book; some additional details on quartz, GaAs, diamond, SiC, ceramics (with emphasis on Al_2O_3), polyimides, silicon nitride, and amorphous and hydrogenated amorphous silicon, which were not treated in sufficient detail elsewhere, follow.

Quartz

Quartz Properties and Quartz Machining

Quartz is the only material known that possesses the following combination of properties:

- Piezoelectric
- Zero-temperature expansion coefficient cuts
- Stress-compensated cut exists
- Low loss [i.e., high-quality factor (Q)]
- Easy to process: low solubility in everything, under "normal" conditions, except fluoride and hot alkali etchants
- Hard but not brittle
- Abundant in nature; easy to grow in large quantities, at low cost, and with relatively high purity and perfection

Some quartz properties are summarized in Table 5.1, and in Figure 5.1, a quartz angular rate sensor (tuning fork-based), developed by Jan Söderkvist (Colibri Pro Development AB, Sweden) for automotive and other applications, is shown. The tines of the tuning fork sensor element shown are 2.5 mm long. The sensor is well suited, for example, to space applications because of its small size and ability to withstand harsh conditions.

The properties of quartz vary greatly with crystallographic direction: when a quartz sphere is etched deeply in an HF bath, the sphere takes on a triangular shape when viewed along the z-axis and a lens shape when viewed along the y-axis. The etching rate is more than 100 times faster along the fastest etching rate direction (the z-direction) than along the slowest direction (the slow-x-direction). Quartz, in some respects, presents us with an even more ideal sensor material than Si because of its nearly temperature-independent thermal expansion

TABLE 5.1 Some Important Physical Properties of Quartz

Property	Value ∥ Z	Value ⊥ Z	Temperature Dependence
Thermal conductivity [cal/(cm/s/°C)]	29×10^{-3}	16×10^{-3}	Decreases with T
Dielectric constant	4.63 (ε_1)	4.52 (ε_3)	Decreases with T
Thermal expansion coefficient (1/°C)	7.1×10^{-6}	13.2×10^{-6}	Increases with T
Electrical resistivity (Ω·cm)	0.1×10^{15} (ionic)	20×10^{15} (electronic)	Decreases with T
Piezoelectric constant, d (pC/N)	2.31 (d_{11})		
	0.73 (d_{14})		
Young's modulus (N/m^2)	9.7×10^{10}	7.6×10^{10}	Decreases with T
Density (kg/m^3)	2.66×10^3		
Maximum coupling coefficient, k	0.1		
Curie temperature (°C)	573		
Young's modulus E(GPa)	107		

∥ Z, parallel with Z; ⊥ Z, perpendicular to Z. T, temperature. See also Chapter 8, this volume, Table 8.7.

The sensor is well suited to space applications because of its small size and ability to withstand harsh conditions. The tines of the tuning fork sensor element shown are 2.5 mm long.

coefficient. The thermal expansion coefficient of quartz is 7.8×10^{-6}/°C along the *z*-direction and 14.3×10^{-6}/°C perpendicular to the *z*-direction; the temperature coefficient of density therefore is -36.4×10^{-6}/°C. The temperature coefficients of the elastic constants range from -3300×10^{-6}/°C (for C_{12}) to $+164 \times 10^{-6}$/°C (for C_{66}). For the proper angles of cut, the sum of the different temperature coefficients may cancel, i.e., temperature-compensated cuts exist in quartz. Micromachined quartz is chemically and mechanically robust and may be used in high-temperature, high-shock applications where Si would fail. A variety of quartz micromachined piezoelectric devices also are on the market, such as electronic filters, resonators, and wristwatch tuning forks. Quartz exhibits very good temperature and long-term stability and therefore is ideal for high-precision oscillators. The frequency-accuracy, including all the environmental effects, after one year of aging, is of the order of few parts per million to tens of parts per million.

Prior to about 1956, the material used for quartz resonators was natural quartz, i.e., mined quartz. Natural quartz has been replaced by quartz grown in large single crystals in factories: "cultured quartz." Wafers up to 3 in. in diameter are commercially available as starting material. Although this quartz often is referred to as "synthetic quartz," nobody has yet found a way to synthesize single-crystal quartz directly from silicon and oxygen. Large quartz bars (typically ~15 cm long) of uniform size and shape are grown from small, irregularly shaped pieces of quartz. So, strictly speaking, the quartz is cultured quartz. Quartz is a common material in the earth's crust (e.g., sand is mostly quartz); however, the high-purity crystals needed for quartz growing are not as common. Most of the nutrient materials used by quartz growers are mined in Brazil and the United States.

Machining methods for quartz include mechanical machining, such as diamond saw cutting, grinding, lapping, polishing, and, relatively more recently, ultrasonic machining and wet and dry chemical etching. Lapping and polishing can be used for fashioning quartz plates as thin as 100 μm. These techniques do not lend themselves to making small, complex shapes, though. For the latter applications, ultrasonic machining has been applied to make, for example, high-precision bulk wave oscillators and complex-shaped piezoelectric resonator sensors in the millimeter size range, but the technique is not suitable for mass production. Wet chemical etching of quartz using HF/NH_4F on *z*-cut quartz can be used for submillimeter fashioning of complex quartz shapes and currently is used for mass production of wristwatch tuning fork resonators.[2] Etching rates depend strongly on the crystallographic orientation, with the *z*-cut exhibiting the highest etching rates: 1 mm/min at 50°C, with typical etch ratios in the range of 50:1 to 500:1 with respect to *x*-cut and *y*-cut plates.[3,4] Conventional photolithography is used to pattern shapes on quartz with chromium/gold for masking layers. High repeatability and automatic batch processing yield lower cost devices. Similar technologies are used for the fabrication of force sensors[5] and accelerometers. The tolerances of these quartz devices for mechanical sensing applications are, as expected from the temperature-independent thermal expansion coefficient, better than those of Si devices. Quartz also allows a greater number of different geometrical shapes than Si, and there is no need for deposition of an insulator between conductor and substrates. Dufour et al.[6] presented a balanced comparison between micromachined pressure sensors using quartz versus silicon vibrating beams and concluded that both materials are strong candidates for mass-produced micromachines. Companies such as Systron Donner[7] that have been selling traditional precision

Table 5.2 Accuracies of Various Oscillators

Oscillator Type[a]	Accuracy[b]	Typical Applications
Crystal oscillator (XO)	10^{-5} to 10^{-4}	Computer timing
Temperature-compensated crystal oscillator (TXCO)	10^{-6}	Frequency control in tactical radios
Microcomputer-compensated crystal oscillator (MCXO)	10^{-8} to 10^{-7}	Spread spectrum system clock
Oven-controlled crystal oscillator (OCXO)	10^{-8} (with 10^{-10} per g option)	Navigation system clock and frequency standard, MTI
Small atomic frequency standard (Rb, RbXO)	10^{-9}	C^3 satellite terminals, bistatic, and multistatic radar
High-peformance atomic standard (Cs)	10^{-12} to 10^{-11}	Strategic C^3, EW

[a] Sizes range from <5 cm^3 for clock oscillators to >30 L for cesium standards. Costs range from <$5 for clock oscillators to >$50,000 for cesium standards.
[b] Including environmental effects (e.g., –40°C to +75°C) and one year of aging.
MTI, moving-target indicator radar; C^3, command, control, and communications radar; EW, early-warning radar.

quartz products such as high-temperature, high-shock-resistance accelerometers are appreciating the potential competition from a Si technology and are developing silicon technology in parallel.

Hjort et al.[8] developed a most interesting, novel anisotropic dry/wet etching scheme for single-crystalline quartz. By bombarding quartz with fast heavy ions [e.g., ^{197}Au at 11.6 MeV/a and ^{129}Xe at 11.4 MeV/a specific energy (where a is the atomic mass unit)], deep nanosized amorphous cylindrical latent tracks (±10 mm wide) are formed. The bombarded wafers are then Au-Cr masked and etched in 20 M KOH at 143°C. By masking parts of the wafer prior to etching, microstructures can be generated along the ion track direction. The masked zone remains latent, and the tracks can be eliminated in an annealing step. When the ion tracks are etched in the mask windows, the latent pores are opened, and they widen until they overlap, creating the desired microfeatures. By irradiating the sample off its normal, slanted microstructures can be generated. The aspect ratio of the cylindrical nanotracks reaches a whopping 10^4, and after etching, aspect ratios larger than 100 result. Features as large as 80 µm were demonstrated in this fascinating new micromachining approach.

As mentioned earlier, quartz resonators constitute important quartz micromachining applications. From Table 5.2, accuracies of various oscillators range from 10^{-4} to 10^{-11}, and quartz can deliver even the highest accuracies required. Moreover, quartz comes with an excellent Q (see Chapter 8, this volume, Equation 8.28). Q is proportional to the decay time and is inversely proportional to the line width of the resonance peak. The higher the Q, the higher the frequency stability and accuracy capability of a resonator; i.e., high Q is a necessary but not a sufficient condition for high accuracy.*

Silicon MEMS (Si-MEMS) startup companies Discera, Silicon Clocks, and SiTime are currently targeting the quartz oscillator market. They are building packaged Si-MEMS oscillators, consisting of a MEMS resonator and the electrical circuits for the oscillator function and frequency and temperature compensation. The micromechanical resonator is a Si micromachined structure that vibrates at a specific frequency because of an external excitation (e.g., electrostatic). Today, the main technologies for oscillator clock products are quartz, ceramic and complementary metal-oxide-silicon (CMOS) silicon clocks. Si-MEMS is just barely emerging as a potential competitor. The market is still mostly served by quartz (70–80% of the value), with Japanese companies such as Kyocera, Rakon, and Epson Toyocom in control of this market. Silicon timing or CMOS clocks (i.e. non-MEMS, simply electronic) are available from, for example, Maxim or Linear Technologies and gradually are replacing

* If, e.g., $Q = 10^6$, then 10^{-10} accuracy requires the ability to determine the center of the resonance curve to 0.01% of the line width, and stability (for some averaging time) of 10^{-12} requires the ability to stay near the peak of the resonance curve to 10^{-6} of line width.

ceramic devices in applications with more relaxed specifications. Somewhere between CMOS clocks and quartz oscillators, Si-MEMS clocks now are looking for their piece of this multibillion-dollar pie (see Chapter 10, this volume).

The ~5-MHz resonant frequency resonator from SiTime is illustrated in Figure 5.2 and is made of single-crystal silicon. The resonator is ~200 µm on a side by ~10 µm thick. The trench gap is 0.4 µm and the Q is ~75 k at room temperature. The resonator is integrated into standard silicon CMOS chips, which makes the oscillator inexpensive to produce. All oscillator frequencies are derived from the same 5-MHz resonator. The oscillator is compensated by measuring the temperature with a bandgap thermometer on the same CMOS die. The temperature resolution is ~0.05°C, giving a frequency resolution of ~1.5 ppm.

An analysis of the competition between silicon and quartz for MEMS oscillators constitutes a good exercise to acquire a better insight into all of the arguments that need consideration in such a comparison (it is also another opportunity to test the decision tree presented in Chapter 1, "Decision Tree for the Optimized Micromanufacturing Option"). Si-MEMS oscillators are not new; the first publications mentioning MEMS resonators for oscillator applications appeared in the 1980s. Until recently, however, the poor temperature stability of silicon and the need for expensive ceramic or metal vacuum packaging prevented Si-MEMS oscillators from becoming a serious alternative to quartz. But, progress in processes, packaging and integration of the circuitry over the last five years has gone quite a way to address those issues.

Si-MEMS technology, in theory, offers major advantages over quartz in terms of size (especially for mobile applications), power consumption, integration cost, and ability to provide multiple operation frequencies. Let us look at each of these criteria in somewhat more detail, starting with the size argument (http://www.memsinvestorjournal.com/2006/10/mems_oscillator.html).

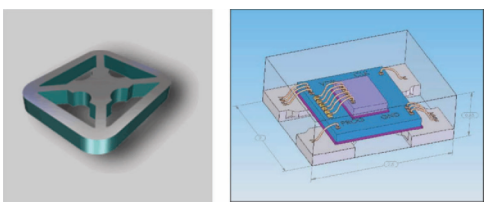

FIGURE 5.2 The ~5 MHz resonant frequency resonator from SiTime is made of single-crystal silicon.

Size Argument

Si-MEMS resonator elements have traditionally been much smaller than their quartz MEMS counterparts. This used to be the key selling argument in the mobile communication industry. A tiny MEMS oscillator often is pictured on top of a quartz oscillator that is 100 times its size to seal this argument. However, as is clear from the above discussed quartz micromachining efforts, the latest quartz MEMS products are very small as well. A new generation of quartz MEMS is emerging, with dimensions similar to those of the first Si-MEMS oscillators (e.g., $2 \times 2.5 \times 0.8$ mm for a quartz device from NDK compared with $2 \times 2.5 \times 0.85$ mm for the Si-MEMS structure from SiTime). The first generation Si-MEMS oscillators are pin-to-pin compatible with quartz products, allowing an easy one-on-one replacement. Since the size of the package will be the same, the main advantage of Si-MEMS oscillators in the "small oscillator segment" will not be size but price. The manufacturing and encapsulating of small quartz devices is expensive compared with Si-MEMS (see next). Printed circuit board (PCB) space also can be saved with Si-MEMS oscillators, which do not require additional bypass capacitors and resistors.

Low Cost Argument

Si-MEMS resonators can be manufactured at a lower cost than quartz MEMS oscillators since Si-MEMS leverages IC batch manufacturing techniques much better. The first commercial Si-MEMS oscillators are hybrid parts, though; e.g., SiTime's Si-MEMS resonators are wire bonded to an ASIC. SiTime uses an innovative wafer-scale packaging solution that is licensed from Bosch and is compatible with CMOS processing. It involves placing resonators on top of an SOI wafer and encapsulating them with an epitaxial layer of silicon, facilitating sealing at high temperatures and creating a barrier to moisture (see Chapter 4, this volume, on packaging, assembly, and self-assembly). The Si resonator is inexpensive

in volume and is estimated to be less than $0.10. The typical price of a Si-MEMS oscillator will start at $0.50 and may reach a few dollars in some instances.

Multifrequency Argument

Several RF-MEMS resonators with different frequencies can be manufactured on the same die, allowing for multifrequency devices while retaining small size and low cost. Crystals, on the other hand, are single-frequency devices. If multiple frequencies are needed such as in a cell phone, e.g., a 32 kHz oscillator for the real-time clock and several MHz oscillators for transmission, reception, and processing functions, several discrete-packaged crystals must be used.

High Q Argument

Si-MEMS devices exhibit a higher *Q* than CMOS clocks. However, Si-MEMS has not yet reached the quality factor of quartz (100,000–200,000 for quartz compared with 75,000 for Si-MEMS). The related phase noise of MEMS also is an issue that must be overcome to reach the performance required for temperature-compensated crystal oscillators (TCXOs).

Integration Argument

Contrary to the case with quartz, Si-based RF-MEMS oscillators are manufactured with CMOS-compatible processes. This could pave the way to true single-chip solution with built-in frequency references. Advantages in terms of power consumption (lower parasitics from the wires) and size are obvious. However, as stated above, the first commercially available Si-MEMS oscillators are actually hybrid parts.

Low Power Argument

The low power consumption of MEMS resonators is a key advantage in portable applications. However, MEMS solutions only reduce power consumption when monolithically integrated, because all of the parasitics associated with an off-chip component (i.e. wire bonding quartz or discrete MEMS) are eliminated. This advantage also is diminished in a hybrid part because of wire-bond parasitics.

Summary

Of the human-grown single crystals, quartz, at ~3000 tons per year, is second only to silicon grown in quantity (three to four times as much Si was grown annually as of 1997). Despite the mechanical/thermal advantages of quartz, quartz micromachining lags considerably behind that of Si. This is mainly due to the lack of plasma processes to structure quartz with the versatility achieved in the case of Si. Another reason that quartz is not competing better with Si as a mechanical MEMS substrate is the lack of large quartz substrates and its cost: a quartz wafer, 76.2 mm in diameter, 0.45 mm thick, and polished on one side costs about $200, while the average selling prices for 200- and 300-mm silicon wafers are about $45 and $200, respectively.

GaAs

GaAs Properties

The first gallium arsenide (GaAs) metal semiconductor field effect transistor (MESFET) was proposed in 1966 and the first GaAs high-electron mobility transistor (HEMT) was demonstrated in 1978 at the Bell Laboratories. However, GaAs is only now rising from its position as the technology that remains the technology of the future to true technological wonder. The main economic driver for widespread use of GaAs semiconductors was the emergence of the digital cellular phone, which needs faster IC technology than Si can provide, and ever since 1994, the GaAs industry has grown at least 25% per year. As the micromachining industry largely evolves in lockstep with the IC industry, we can expect GaAs micromachines to succeed as GaAs use penetrates the IC industry further. The growing importance of quantum mechanical devices also is pushing GaAs toward becoming a more important MEMS/NEMS substrate contender. As we pointed out in Volume I, Chapter 3, an important feature of the III-V technologies in general, and of GaAs in particular, is the possibility of forming compatible ternary and quaternary compounds. Using GaAs as the substrate material, the formation of $Al_xGa_{1-x}As$ compounds is especially attractive, since their lattice constants are nearly equal to those of GaAs, and

aluminum and gallium atoms are easily substituted in the lattice without causing too much strain. Today, epitaxy techniques have matured, and both high-quality MOCVD and molecular beam epitaxy (MBE) epitaxy are commercially available. Layers deposited with these techniques have very little induced strain, which allows them to be grown almost arbitrarily thick. In Volume I, Chapter 3, we describe GaAs-based quantum wells; Volume I, Chapter 5 covers double-barrier resonant tunneling diodes and quantum cascade lasers, all based on layers of gallium aluminum arsenide sandwiched between gallium arsenide layers. With its direct bandgap, GaAs can be used to emit light efficiently, whereas silicon has an indirect bandgap and is very poor at emitting light (see Volume I, Chapter 3). Nonetheless, recent advances in nanotechnology, as we described in Volume I, Chapters 3 and 5, may make silicon light-emitting diodes and lasers possible after all. Another important application of GaAs (and III-V compounds in general) is for high-efficiency solar cells. In 1970, Zhores Alferov (see Volume I, Figure 3.60) and his team in the USSR created the first GaAs heterostructure solar cells. Today, the combination of GaAs with germanium and indium gallium phosphide is the basis of a triple-junction solar cell that holds the record for solar light conversion efficiency of over 32% and can operate also with light as concentrated as 2000 suns.* This type of solar cell powers the robots *Spirit* and *Opportunity*, which are exploring the Mars surface.

In Chapter 1, this volume, Table 1.10, we compare some of the material properties of single-crystal SiC, Si, GaAs, and diamond with relevance to electronics and MEMS/NEMS. Gallium arsenide, it emerges, is a very promising MEMS/NEMS substrate for a variety of reasons. These include well-known optoelectronic properties such as a direct bandgap transition (see above) and high-mobility electrons. The higher saturated electron velocity and higher electron mobility of GaAs compared with those of Si allow it to function at frequencies in excess of 250 GHz. GaAs HEMTs are a typical high-electron mobility application, and the same property also renders the material ideal for the measurement of magnetic fields through the Hall effect (see Volume I, Equation 3.64). Also, GaAs devices generate less noise than silicon devices when operated at those high frequencies. Because of its high switching speed, GaAs, it would seem, also is more ideal for computer applications than Si. In the 1980s it often was suggested that the IC market might switch from Si to GaAs, which it never really did (from there its unfortunate designation as "the technology that remains the technology of the future"). Cray even built a GaAs-based computer in the early 1990s, the Cray-3, but the company filed for bankruptcy in 1995. Because it has a larger bandgap than Si, GaAs is considered to be a better material for high-temperature electronics. GaAs devices can be operated at higher power levels than equivalent silicon devices because GaAs has a higher breakdown voltage. Pressure, temperature, and vibration sensors, making use of the influence of external pressure and temperature on the bandgap, have already been built.

GaAs has piezoelectric properties comparable to those of quartz, and various physical effects give higher piezoresistive values than those of silicon. The piezoelectric effect enables GaAs-based piezoelectric transducers, and one may excite any vibration mode used in quartz if the proper crystal orientation is observed. Overall, the material is less attractive for purely mechanical MEMS devices, though, since the yield load is smaller by a factor of two compared with silicon.[9] We summarize some of the most important GaAs properties in Table 5.3.

GaAs Micromachining

Besides wet[9] and dry[10] bulk micromachining of GaAs, some GaAs surface micromachining work has been reported.[11] Because of the zinc blend structure of GaAs (same as Si), the wet etching of {111} crystal planes proceeds more slowly than all others. In wet bulk micromachining of GaAs, a unique triangular prism-shaped bridge can be obtained through anisotropic etching by appropriate placement of the etch mask (see Figure 5.3). This unique profile, not possible in silicon, is formed because of the

TABLE 5.3 GaAs Properties

Property	GaAs
Atomic or molecular weight	144.63
Atoms or molecules/cm^3	4.42×10^{22}
Breakdown field, V/cm>	$\sim 4 \times 10^5$
Chemical resistance	Poor
Crystal structure	Zinc blend
De Broglie electron wavelength (Å)	240
Debye temperature	360
Density, g/cm^3	5.32
Dielectric constant (high frequency)	10.89
Dielectric constant (static)	12.9
Effective density of states: valence band N_v (cm^{-3})	7.0×10^{18}
Effective density of states: conduction band N_c (cm^{-3})	4.7×10^{17}
Effective mass: electrons	0.063 m_0
Effective mass: holes	0.051 m_0
Electron affinity (eV)	4.07
Energy gap (eV)	1.42 direct
Energy gap (eV)	1.43
Intrinsic carrier concentration, n_i (cm^3)	1.8×10^6
Intrinsic mobility: Electron, cm^2/V-s	8600
Intrinsic mobility: Hole, cm^2/V-s	400
Knoop hardness (kg/mm^2)	600
Lattice constant, nm	0.5653
Maximum operating temperature (°C)	460
Melting point (°C)	1238
Number of atoms in 1 cm^3	4.42×10^{22}
Optical phonon energy	0.035
Physical stability	Fair; sublimation of arsenic is a problem
Saturated electron drift velocity ($\times 10^7$ cm/s)	2
Symmetry group	T_d^2– F43 m
Temperature coefficient of expansion (°C^{-1})	6.8×10^{-6}
Thermal conductivity (W/cm-°C)	0.46
Yield strength (GPa)	2.0
Young's modulus (GPa)	75

crystallographic polarity in some axial directions, and the differences between the etch rates of the A{111} planes and the other low-index planes.[12]

Although slower etching planes exist, GaAs does not present real etch stop planes, as observed in silicon when using, for example, KOH-based solutions (see Volume II, Chapter 4). In the latter etchants, the {111} Si planes present etch rates of up to 400 times lower than the other planes. Surface micromachined sensor and actuator structures made of metal on a GaAs substrate have been demonstrated in schemes compatible with normal GaAs IC processing. The most frequently used sacrificial wet and dry etch systems for III-V crystals are presented in the review papers of K. Hjort[14] and S. D. Collins[15] and in the work by Karam et al.[16] It was shown that to craft surface micromachined structures in epitaxial GaAs, $Al_xGa_{1-x}As$ ($x \geq 0.5$) may act as a sacrificial

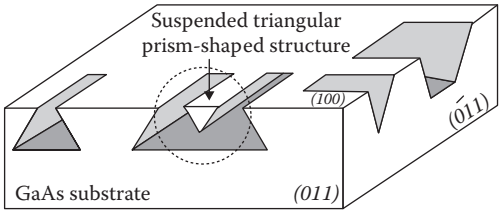

FIGURE 5.3 Free-standing triangular bridge in GaAs.[13]

layer. By using several steps of MOCVD epitaxial layer regrowth, structures of polysilicon-like complexity were built.[17,18] Note that not only different material compositions but also different dopant concentrations and damaged regions of GaAs can act as stop and sacrificial layers.

In Volume II, Chapter 3, we detail the GaAs single-crystal reactive etching and metallization process, which includes chemically assisted ion beam etching (CAIBE) and reactive ion etching (RIE) for vertical and undercut dry etches, respectively. Suspended and movable GaAs structures are produced with a 25:1 aspect ratio of vertical depth (10 μm) to lateral width (400 nm) (Volume II, Figure 3.43).

Ribas from TIMA developed a front-side bulk GaAs micromachining approach compatible with standard GaAs microelectronics technologies for the fabrication of integrated, low-cost, high-volume microsystem applications (http://cmp.imag.fr/products/mems/thesis.pdf).[13] Dr. Ribas also developed a set of computer-aided design tools for GaAs MEMS layout level design, such as cross-section and three-dimensional layout viewers, layout generators, and a bulk GaAs etching simulator within the Mentor Graphics environment. In the same context of GaAs IC compatibility, Karam et al.[16] are investigating gallium arsenide micromachining techniques using high-electron mobility transfer (HEMT) and metal Schottky field effect transistor (MESFET) foundry processes.

In an interesting example of self-assembly, two-dimensional arrays of self-positioning, free-standing GaAs structures were fabricated using a new method of surface micromachining called *micro-origami*. This technique is based on epitaxial growth of III-V multilayers on GaAs substrates followed by photolithography and wet etching, as we described in Chapter 4, this volume, on packaging, assembly, and self-assembly.

Progress in processes to deposit GaAs epitaxially on Si could benefit both IC and micromachining industries. GaAs grown epitaxially on Si substrates has great potential to lower the costs, improve the manufacturability, and improve the thermal characteristics of GaAs-based ICs. GaAs/Si wafers are larger and stronger and lighter than GaAs wafers.[19] This combination opens the possibility of monolithic integration of GaAs-based ICs with Si-based ICs. GaAs-on-Si has significant market potential, both as a substitution technology for manufacturing traditional GaAs devices and as a new technology for monolithic integration of GaAs devices and silicon integrated circuits. As a substitution technology, GaAs-on-Si holds the potential to fundamentally change the economics of manufacturing GaAs integrated circuits and GaAs optical components. As a technology for monolithic integration of GaAs devices and silicon integrated circuits, GaAs-on-Si technology is even more interesting. In fiber optics, integration of GaAs lasers and photodetectors with silicon control circuitry would become feasible. Because of these obvious advantages, many attempts have been made over the past thirty years to grow GaAs on Si substrates. The GaAs lattice constant (5.65 Å) is about 4% larger than silicon's (5.43 Å), and this difference makes it difficult to grow high-quality GaAs directly on silicon. Instead, Motorola researchers place a thin layer (about 50 Å) of strontium titanate ($SrTiO_3$) between the two semiconductors.[20] Strontium titanate's lattice constant falls roughly halfway between GaAs and Si. Moreover, an amorphous layer (10–20 Å thick) forms between Si and $SrTiO_3$. This layer, it is hypothesized, absorbs the lattice mismatch strain between the two materials, allowing the crystalline $SrTiO_3$ to form a normal lattice without distortion from the underlying Si. Because the $SrTiO_3$ layer is very thin, the amorphous interlayer also absorbs the mismatch strain between the $SrTiO_3$ and GaAs layers.

In 2001, scientists from Motorola reported on supposedly device-quality GaAs epitaxial layers with low dislocation densities, close to that of bulk GaAs crystals (~$10^4/cm^2$), grown onto Si by molecular beam epitaxy (MBE) (Figure 5.4).[21] In spite of the initial worldwide publicity, Motorola decided to stop its activity in this area in 2003.[22] The presence of a low dislocation density in the epitaxial GaAs layers has never been independently confirmed and remains controversial. So it is back to the drawing board. Another approach to integrating GaAs on a Si substrate was pursued by Yeh and Smith, who assembled GaAs laser diodes in micromachined wells in a Si substrate by trapping them as discussed in Chapter 4, this volume (see Figure 4.44).[23,24]

FIGURE 5.4 Motorola Labs created the world's first 8-in. GaAs on silicon wafer and worked with epitaxial wafer manufacturer IQE to create the world's first 12-in. GaAs on silicon wafer.

In the micromachining world, possible applications of GaAs MEMS are optical shutters or choppers, actuators in monolithic microwave integrated circuits (MMIC), sensors using piezo- or optoelectrical properties of GaAs, or applications favoring integration of micromechanical devices with electronic circuitry for fast signal processing, high operating temperature, or high radiation tolerance. GaAs micromachining might constitute a good method by which to incorporate micromirrors in resonant optical cavities for tunable lasers. Also, micromachining using gallium arsenide and group III-V compound semiconductors is a practical way to integrate RF switches, antennas, and other custom high-frequency components with ultrahigh-speed electronic devices for wireless communications (see Chapter 10, this volume).

Summary

Overall, it remains hard for GaAs to compete with Si as a semiconductor substrate, but GaAs did start making major commercial inroads for high-frequency applications with the introduction of mobile phones. Silicon presents at least three major advantages over GaAs, explaining why it is so hard for GaAs to compete. To begin, silicon is abundant and cheap to process. Silicon's greater physical strength allows working with larger wafers (maximum of ~300 mm compared with ~150 mm diameter for GaAs). Silicon is abundantly available in the Earth's crust in the form of all types of silicate minerals, and the economy of scale available to the silicon IC industry discourages a more rapid adaptation of GaAs. The second major advantage of Si over GaAs is the existence of silicon dioxide—one of the best and most stable insulators that may be created with a very low defect concentration at interface Si/SiO_2. Silicon dioxide can easily be incorporated onto silicon circuits, and such layers adhere very well to the underlying Si. GaAs does not form such a stable adherent insulating layer (its native oxides are typically leaky). The third, perhaps most important advantage of silicon over GaAs is that it possesses a much higher hole mobility. This high hole mobility allows for the fabrication of higher-speed p-channel field effect transistors required for CMOS logic. Because they lack a fast CMOS structure, GaAs logic circuits have much higher power consumption, which has made them unable to compete with silicon logic circuits.

As suggested before, the micromachining industry largely evolves with and piggybacks on the IC industry, so we can expect GaAs micromachines to succeed as GaAs use penetrates the IC industry further. The most effective approach to the cost reduction of any device is to increase the diameter of GaAs wafers. Along this line, Anadigics Inc., which manufactures RF ICs for the wireless handset and broadband communications markets, is building a 6-in. GaAs fab in China, a certain sign that GaAs has arrived (cost per 6-in. GaAs wafer is projected at $300).

The SiGe devices market has grown more rapidly than some anticipated, and III-V producers have some reason to be concerned about the transition from Si to SiGe instead of using GaAs in a number of key applications. With the talk of SiGe (see Volume I, Figure 4.59) matching performance with GaAs and beating it on cost, GaAs still edges out SiGe in terms of efficiency, so for those applications where this is less important—e.g., the shorter-range wireless networks, such as WiFi and Bluetooth—SiGe is going head to head with RF-CMOS.

Diamond

Introduction

Diamond, the hardest of all natural materials, is a wide bandgap semiconductor material with

excellent thermal, tribological, and mechanical properties. The thermal conductivity of diamond is higher than that of any other material near room temperature, making it an ideal material for heat sinking. Diamond components may be as much as 10,000 times more wear-resistant than those made from silicon and come with a much higher thermal and chemical stability. Diamond is also a biocompatible material, so that it could be used in the body as a drug-dispensing unit without initiating an allergic reaction. This is because carbon (the elemental ingredient of diamond) is chemically benign (see also below, under C-MEMS). If it could be micromachined easily, the exceptional physical and chemical properties of diamond would promise to expand the range of applications for microdevices. It is an ideal candidate for MEMS applications, particularly in harsh environments. In addition, diamond reduces stiction compared with silicon (diamond's low coefficient of friction is comparable to that of Teflon), perhaps making diamond-surface micromachined devices easier to manufacture. Diamond can be doped to change it from an insulator to a semiconductor: p-doping works fine, but it remains difficult to make an n-type diamond. We compare the properties of diamond with those of silicon, GaAs, and SiC in Table 5.4.

Diamond Deposition and Diamond Micromachining

Chemical vapor deposition (CVD) of single-crystalline diamond has been the subject of a great deal of research since the early 1980s. Very high-quality diamond thin films with negligible levels of defects and impurities (even superior to natural diamonds and high-pressure, high-temperature diamonds) are achievable when using microwave plasma chemical vapor deposition. However, high- quality homoepitaxial single-crystal CVD diamonds are still very expensive and are available only on small areas (3×3 or 4×4 cm^2) because of the need of single-crystalline diamond substrates.[25,26]

Alternatively, polycrystalline diamond film, deposited by CVD, is one potentially viable approach

Table 5.4 Properties of Diamond and Other Semiconductors at 293 K

	Diamond	Silicon	GaAs	SiC
Lattice constant (Å)	3.567	5.431	5.653	a = 3.086; c = 15.117
Hardness (kgf/mm^2)	7,000–10,000	1,000		1,875–3,980

to high-temperature, harsh-environment MEMS[27] (see also http://www.nasatech.com/Briefs/Feb99/NPO20529.html). Chemical vapor deposition of diamond on Si substrates is compatible with the integration of Si-based electronics. The most common polycrystalline diamond CVD process involves a flowing mixture of methane and hydrogen, typically at a total pressure of 45 Torr (6 kPa) and a substrate temperature of 800–950°C. Diamond heteroepitaxially deposited on Si is polycrystalline (Figure 5.5) with a large number of grain boundaries, a high intrinsic stress, and a rough surface, making it difficult to use in MEMS. The grain size of typical diamonds grown from a methane and hydrogen gas source by microwave plasma CVD on Si is around 30 nm to 10 µm.[28] Problems with polycrystalline diamond films also include difficulties in growing good-quality diamond films and making reliable ohmic contacts to the material, as well as poor reproducibility.[29] This leaves us with ultrananocrystalline diamond (2–5 nm grain size)[30] and amorphous diamond[31] as the two most suitable diamond candidates for MEMS applications.

At Argonne National Laboratories, "ultrananocrystalline" diamond films have been deposited by a novel CVD process that may overcome some of the problems mentioned above (http://www.anl.gov/techtransfer/Available_Technologies/Chemistry/uncd_flc.html). Argonne's patented CVD method was developed at first using fullerenes as the carbon source. Fullerene powder was vaporized and introduced into an argon plasma, causing the fullerenes to fragment into two-atom carbon molecules (dimers). Silicon or other substrate materials are "primed" with fine diamond powder. When the carbon dimers settle out of the plasma onto the substrate, they arrange into a film of small diamond crystals about 3–5 nm in diameter. Subsequent work showed that the same result can be achieved by introducing methane into an argon plasma as long as little or no additional hydrogen is present. The Argonne method differs in two major respects from other CVD methods for making diamond film. First, the molecular building block is different (carbon dimers rather than methyl radicals), and second, little or no hydrogen is present in the plasma (~1%), whereas in other methods the plasma contains 97–99.5% hydrogen along with methane. The ultrananocrystalline films produced by Argonne's method are completely free of intergranular flaws and nondiamond secondary phases that degrade the properties of conventionally produced diamond films, have crystals about 50–200 times smaller than those in other films, and are 10–20 times smoother than conventional high-purity CVD diamond films.

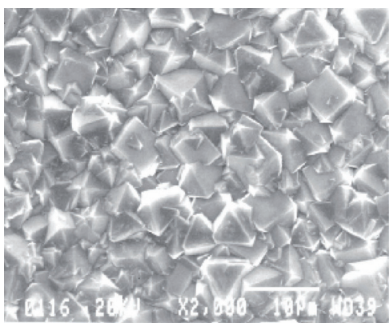

FIGURE 5.5 A typical SEM image of a CVD diamond surface on a Si substrate. (Courtesy of Dr. Chunlei Wang, Florida International University.)

For surface micromachining, a "starter" (nucleation) layer of nanocrystalline diamond powder on a silicon substrate is patterned, and the diamond film forms only in the areas where the nucleation layer remains. Flat, free-standing diamond films can also be grown on silicon dioxide. The diamond layer may be released from the substrate by etching away the silicon dioxide. The result is free-standing diamond structures as little as 300 nm thick with features as small as 100 nm and friction coefficients as low as 0.01. Argonne is also developing deposition methods that permit integrated fabrication of complete devices, such as micrometer-sized pinwheels, gears, turbines, and micromotors, without manual assembly. Also, hollow, three-dimensional (3D) structures can be fabricated in diamond surface micromachining. In this case, silicon is used as the sacrificial material (e.g., a disc or pin) for the desired diamond component. The diamond film is grown on the Si structure and conforms to its shape. The silicon is etched away, leaving a diamond cylinder or tube. It has been shown that this method is capable of making convex hollow structures (e.g., a hollow pyramid)—shapes that cannot be produced by conventional silicon lithographic methods.

Sandia researchers have explored amorphous diamond for micromachining. Amorphous diamond is the second hardest substance known, after crystalline diamond (http://www.sandia.gov/media/NewsRel/NR2000/diamond.htm). They use pulsed laser deposition, and a simple proof-of-principle device—a diamond interdigitated comb—takes about 3 h to fabricate. Subsequent annealing of the diamond film device down to zero stress (to prevent warpage) takes a few minutes. Before this work, amorphous diamond itself had been impractical because its tremendous internal stresses—hundreds of atmospheres—made it impossible for the material to stand alone or to coat thickly on any but the strongest substrates.

Diamond-based MEMS, such as cantilevers, membranes, and microturbines, can be fabricated using two strategies: lithographic patterning and selective deposition.[31,32] In the selective deposition method, diamond microstructures are fabricated by selective diamond growth on Si using a patterned SiO_2 mask. With this selective growth approach, piezoresistors and thermal resistor structures have been patterned.[32]

In lithographic diamond patterning, diamond films are synthesized on an appropriate substrate such as Si. This is followed by diamond surface micromachining processes similar to the ones used in the fabrication of poly-Si-MEMS. Diamond layers can be masked by photoresist or metals, followed by dry etching (RIE) in oxygen-containing plasmas.

Diamond films also can be directly patterned using focused ion beam (FIB) milling without the use of a mask.[33] Figure 5.6 shows CVD diamond microscale p-i-p electronic devices fabricated on homoepitaxially grown single-crystalline layers by FIB etching; the latter devices were used to investigate carrier transport properties of diamond at high electric field strengths (more than10^7 V/cm).[33]

A number of other diamond-based devices have been investigated; these include basic electronics elements, sensors, and actuators.[34–36] Although their cost, performance, and processibility are still not compatible with Si-based MEMS, diamond as a complementary MEMS material remains very promising, especially for use in extreme environments.

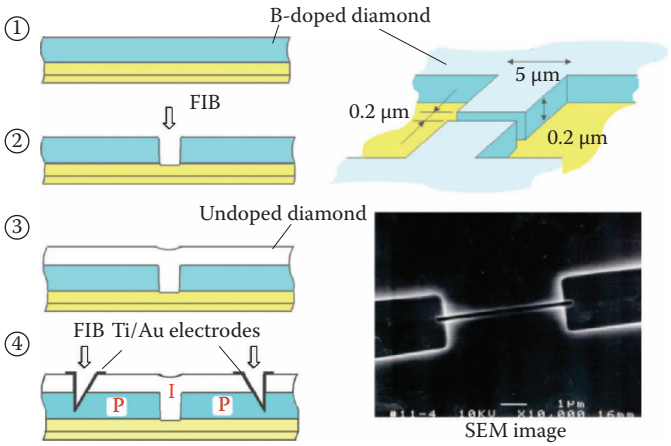

FIGURE 5.6 Schematic fabrication processes for a diamond p-i-p structure consisting of a narrow *intrinsic* (undoped) region sandwiched between two p-type (boron-doped) regions. Top view schematic drawing and a scanning electron microscope picture show narrow (0.2-μm) grooves formed in the 0.2-μm-thick p layer (at step 2). These grooves are filled with i diamond (at step 3).[33]

SiC

Like diamond, silicon carbide (SiC) is well known for its mechanical hardness, chemical inertness, high thermal conductivity, and electrical stability at temperatures well above 300°C, making it another excellent candidate for high-temperature MEMS. Both exhibit piezoresistive properties. In comparison with diamond, other SiC features are that it can be doped both p-type and n-type fairly easily and that it allows a natural oxide to be grown on its surface, which make SiC an attractive candidate for alternative semiconductor MEMS material. Because of its large bandgap and good carrier mobility, it can be employed in high-temperature and high-power applications. In addition, the fabrication technology for SiC active electronic devices is based mostly on processes established in the Si microelectronics industry. One property that makes SiC films particularly attractive for micromachining is that these films easily can be patterned by dry etching using Al masks. Patterned SiC films actually can be used as passivation layers in the micromachining of the underlying Si substrate (SiC can withstand both KOH and HF etching).[37]

SiC crystallizes in many different polytypes, which differ from one another in the stacking sequence of a repeat unit consisting of two planes

of close-packed Si and C atoms. The two most common SiC polytypes are 3C-SiC and 6H-SiC. The 3C polytype, also known as β-SiC, is the only polytype with a cubic structure. 3C-SiC crystallizes in a ZnS-type structure; hence, it can be deposited on Si. Historically, most research has focused on developing 6H-SiC as a semiconductor material for high-temperature and high-power electronics. However, the small wafer size (<2 in.) and the inability to grow epitaxial layers on substrates other than 6H-SiC have hindered the development of the 6H polytype. Over the last seven years we have witnessed a growing interest in 3C-SiC as a MEMS material. As we saw above, unlike 6H-SiC, the 3C-SiC polytype can be epitaxially grown on single-crystal silicon substrates. Large-area substrates enable low-cost batch processing, essential in making SiC MEMS devices viable for mass production applications (e.g., automotive). It was at Case Western Reserve University (CWRU) that the first successful depositions of spatially uniform, single-crystal, 3C-SiC films on 4-in. (100) silicon wafers were made. These epitaxial 3C-SiC films on Si were used to craft structures such as diaphragms and cantilever beams. Since SiC films are highly resistant to KOH and EDP etching, dry etching and Al masks are employed for patterning. Because these diamond films must be grown directly on single-crystal silicon, surface micromachining with a sacrificial layer was not possible at first. The solution was again invented at CWRU and involves growing polycrystalline cubic silicon carbide (poly-SiC) films of about 2 μm thickness by an APCVD process on 4-in. polysilicon-coated (100) silicon wafers.[38,39] Surface micromachining is achieved by using the underlying polysilicon film as the sacrificial layer. The poly-SiC deposition process is carried out at 1280°C in a cold-wall, RF-induction heated, vertical APCVD reactor. After deposition, the SiC film is polished to reduce the surface roughness (Ra) from ~400 Å in the as-grown film to <40 Å. The poly-SiC lateral resonant device shown in Figure 5.7 was made by this surface micromachining approach, and the finished device exhibits Qs as high as 215,000 at pressures below 10^{-5} Torr (see also "Quality Factor" in Chapter 8, this volume, on actuators). Resonant frequency drifts of less than 18 ppm/h have been observed, and device operation at elevated temperatures as high as 950°C

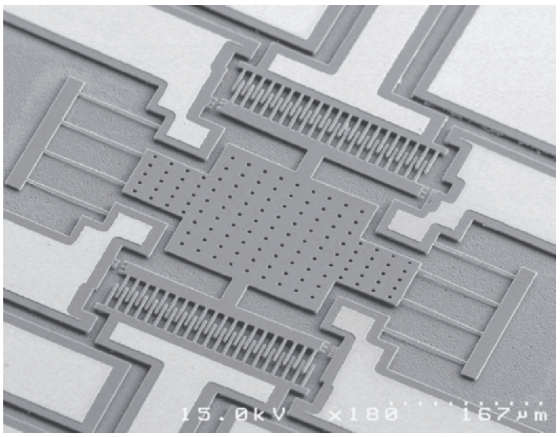

FIGURE 5.7 Scanning electron microscope (SEM) micrograph of a released poly-SiC lateral resonant device. The suspension beam length and width are nominally 100 and 2.5 μm, respectively. Exposed poly-SiC shows up as dark gray, while Ni metallization appears light gray. (Courtesy of Dr. M. Mehregany, Case Western Reserve University.)

has been achieved. The poly-SiC surface micromachining steps are outlined in Figure 5.8.

In Chapter 1, this volume, Table 1.10, we compared some of the material properties of single-crystal SiC with Si, GaAs, and diamond with relevance to electronics and MEMS/NEMS. For an update on this

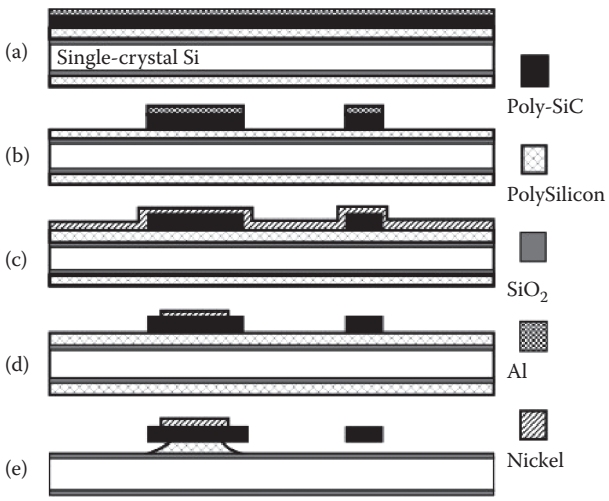

FIGURE 5.8 Schematic description of the poly-SiC resonator fabrication process showing cross-sections after a 5000-Å-thick layer of aluminum is sputter deposited over the polished poly-SiC (a); the Al layer is patterned using lithography and anisotropic CHF_3/O_2/He plasma etching to transfer the Al pattern into the poly-SiC (b); the Al layer is stripped and a 7500-Å-thick layer of Ni is deposited by sputtering (c); the Ni film is patterned for contacts using photolithography and wet etching (d); and poly-SiC is released in 40 wt% KOH at 40°C (e).

table for SiC properties, consult http://www.ioffe.rssi.ru/SVA/NSM/Semicond/SiC/index.html.

Further advances in SiC deposition and patterning techniques have led to the development of single and multilevel implementations similar to the polysilicon MUMPs (multiuser MEMS process). The multiuser silicon carbide (MUSiC) is an eight-mask, four polycrystalline SiC (poly-SiC) layer surface micromachining process.

The State of Ohio has funded high-temperature MEMS efforts both at Case Western Reserve University (http://mems.case.edu) and at NASA Glenn (http://www.grc.nasa.gov/WWW/SiC/SiC.html) and made these two centers leaders in the field.

Bulk and Surface Microstructuring of Ceramics

Ceramics encompass a vast array of materials, and a concise definition of ceramics is almost impossible. A workable definition of ceramics is that of a class of refractory, inorganic, and nonmetallic materials. This class of materials can be divided into traditional and advanced ceramics. Traditional ceramics include clay products, silicate glass, and cement, whereas advanced ceramics consist of carbides (SiC; see above), pure oxides (quartz; see above: Al_2O_3, etc.), nitrides (Si_3N_4), nonsilicate glasses, and many others. Ceramics offer many advantages compared with other materials. They are harder and stiffer than steel, more heat and corrosion resistant than metals or polymers, and less dense than most metals and their alloys, and their raw materials are both plentiful and inexpensive. Ceramic materials display a wide range of properties, which facilitates their use in many different product areas and ceramic MEMS, and NEMS represents another promising development.

The inherent chemical resistance of refractory materials makes their anisotropic micromachining very difficult and expensive.[40,41] In Volume II, Chapter 9, we promoted the use of plasma spray deposition for making oxygen-sensitive ZrO_2 membranes in batch mode (see Volume II, Figure 9.24). Another potential solution for working with these poorly machinable materials is by casting or by gas phase deposition into molds. MIT's micromachined gas turbines, for example, were made of thick (10–200 μm) SiC or silicon nitride, deposited by CVD into Si molds (http://web.mit.edu/aeroastro/faculty/index.html). Sol-gel-type solidification of ceramic liquid precursors in molds, as covered in Volume II, Chapter 8, is another available option—less expensive but yielding low- to medium-resolution microstructures only. Deep UV resists may be used as alternative, sacrificial molds. In most cases a high-temperature sintering step will significantly shrink the dimensions of the high-temperature part, reducing achievable accuracy. In Volume II, Chapter 10, on LIGA, we described how UV and LIGA techniques provide some of the highest-resolution ceramic parts. Finally, in Volume II, Chapter 7, we introduced atomic layer deposition by which precursor gases or vapors alternately are pulsed onto the substrate surface to make Al_2O_3 (see Volume II, Figures 7.47 and 7.48).

Here we introduce Al_2O_3 and TiO_2 micromachining work for high-accuracy ceramic MEMS with the potential for a plethora of novel micro- and nanomachining applications.

Micromachining of alumina ceramic appears particularly appealing and might have advantages over other high-temperature MEMS substrates, such as quartz, 3C-SiC, diamond, and GaAs (see Chapter 1, this volume, Table 1.10), in terms of cost, manufacturability, and performance.

Routkevitch et al.[42] and Li et al.[43] have made fascinating microstructures from nanoporous anodic alumina films (also known as porous anodic alumina). Anodic alumina is a self-organized material with unique pore morphology, composition, and properties. Regular porous films, from less than 100 nm thick to more than 300 μm, are formed when aluminum metal is anodized in solutions of phosphoric, oxalic, or sulfuric acid (in low concentrations—from 2 wt% to 10 wt%). Pore diameter is tunable from a few nm to several hundred nm, and pore densities vary from 10^9 to 10^{11} cm^{-2}. For typical anodization voltages (50–100 V), the pore diameter ranges from 0.15 to 0.3 μm, and by sintering above 830°C in air, the amorphous anodic alumina may be converted into crystalline material, thereby increasing its chemical and thermal

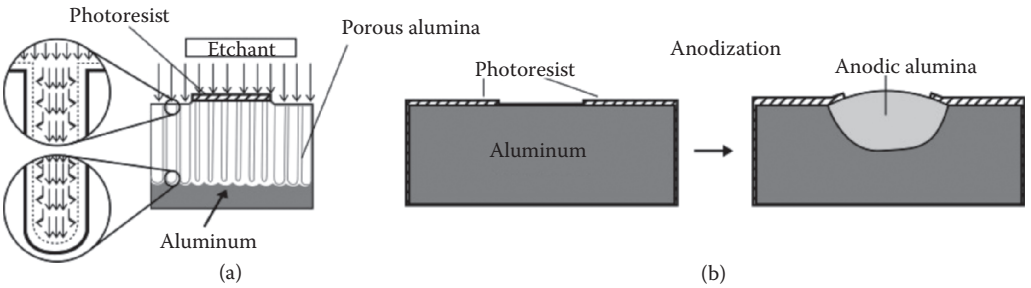

FIGURE 5.9 Schematic of two approaches for micromachining of anodic alumina. (a) High-resolution micromachining. (b) Lower-resolution microstructure prepared by localized anodization of aluminum. (Based on Routkevitch, D., A. Govyadinov, and P. Mardilovich. 2000. High aspect ratio, high resolution ceramic MEMS. *2000 International Mechanical Engineering Congress and Exposition,* 1–6.[42])

stability dramatically. The schematic in Figure 5.9 summarizes two approaches for micromachining of porous anodic alumina. In the higher-accuracy micromachining method (Figure 5.9a), the alumina film is anisotropically etched after patterning with conventional lithography. As prepared, anodic alumina dissolves readily at a pH lower than 4.2 and at a pH higher than 9.9, and the dissolution process is highly anisotropic. The walls of the porous pipes through the alumina film (see Figure 5.10) consist of an anion-contaminated outer layer and a purer inner alumina layer. The outer anion contaminated layer etches 25 times as fast as the purer inner layer. This etching rate difference and the anisotropic nature of the pores themselves, which provides access for the etchant throughout the entire thickness of the film, results in microstructures with aspect ratios as high as 50 (Tan et al.[41] projected the possibility of a 1000:1 aspect ratio) and a resolution better than 2 µm. The lateral underetching of the photoresist mask stops once the purer alumina at the wall of the first pore closed off at the top by the mask is reached by the etchant. Obviously, the smaller the pore diameter, the better the expected resolution of the technique. Routkevitch et al.[42] developed a second type of alumina micromachining process based on local anodization of aluminum metal. This process is simpler but has a somewhat poorer resolution limit (~20 µm) as pictured schematically in Figure 5.9b. In this case, the sidewalls do not remain vertical, since aluminum under the mask gets oxidized, and the alumina expands as compared with the initial volume of aluminum. Either the aluminum metal or the aluminum oxide may be etched selectively to reveal textured surfaces, with one being the exact imprint of the other. For selective etching of anodic alumina, a mixture of chromic and phosphoric acids is used, and aluminum may be selectively etched away in a solution of $CuCl_2$ in HCl. This work presents a whole new approach to microstructuring ceramic and metal surfaces.

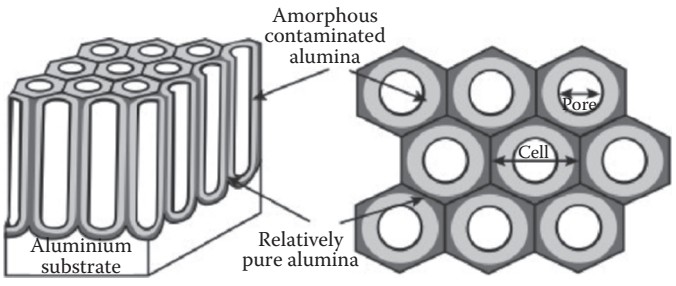

FIGURE 5.10 Schematic morphology and chemical composition of amorphous alumina. (Based on Routkevitch, D., A. Govyadinov, and P. Mardilovich. 2000. High aspect ratio, high resolution ceramic MEMS. *2000 International Mechanical Engineering Congress and Exposition,* 1–6.[42])

The nanoporous morphology of this ceramic MEMS material presents a controllable, very high surface area (up to 100 m^2/g) with numerous opportunities for applications such as a mechanical filter or as a support for catalysts and gas sensors, the latter of which require a high number of triple points (i.e., sites where gas reactants, catalyst, and support can meet). Recently, the method has been used in template-assisted nanowire growth as well.

Mechanical filters based on porous alumina are called *Anodisc™ Membrane Filters*. These aluminum oxide membrane filters are available in three nominal sizes (47, 25, and 13 mm diameter) and three pore sizes (0.2, 0.1, and 0.02 µm). Inorganic mechanical

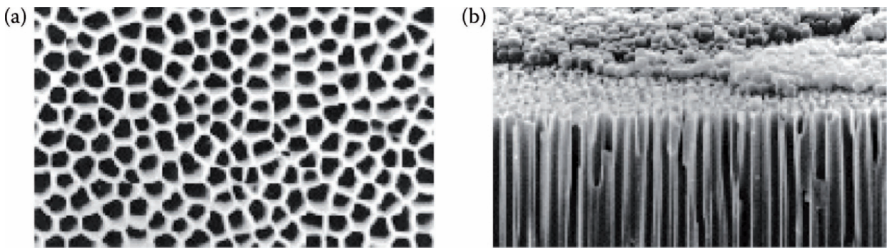

FIGURE 5.11 (a) Top view of a 0.2-μm Anopore™ inorganic membrane. (b) A cross-sectional view (below right) showing 0.23-μm latex microspheres retained on the membrane's surface. Membrane thickness is approximately 60 μm. Note the extraordinarily high pore density, which makes very high flow rates possible—unusual for membrane filters with pore sizes this small.

filters have several advantages over polymer membranes (e.g., polycarbonate sheets, about 10 μm thick, with pore sizes in the range of 15–12,000 nm), including higher flow rates, sieving of particles at the surface rather than trapping at an uncertain depth within the membrane and temperature and electron beam radiation resistant (see Figure 5.11) For more information, see http://www.2spi.com/catalog/spec_prep/filter2.shtml.

Porous alumina-based humidity sensors have been demonstrated.[44] The insulating material also makes for an excellent low-power and very-high-temperature microheater substrate with demonstrated temperatures up to 1200°C, power consumption as low as 50 μW/°C, and a very fast response.[44] The latter application represents an important alternative to Si as a microheater substrate in Taguchi sensors (see Volume II, Figures 9.11 and 9.12); Si is limited in temperature range and is a rather good heat conductor, so that it needs to be passivated for this application (it is also considerably more expensive).

The nanopores can also serve as a template for the deposition of nanostructures of a material of choice, such as metals, semiconductors, and polymers.[45] This is demonstrated in Figure 5.12 for the electrochemical deposition of nanowire thermoelectric material Bi_2Te_3. The process allows the oxide barrier layer to be removed/dissolved so that pores are in contact with the substrate. Filling rates of up to 90% have been achieved (T. Sands, HEMI group, http://www.mse.berkeley.edu/groups/Sands/HEMI/nanoTE.html).

The growth of aligned arrays of carbon nanotubes (CNTs) inside the pores of the self-organized nanoporous alumina templates is an especially intriguing application. Govyadinov et al.[46] synthesized arrays of CNTs (deposited with catalytic CVD) in alumina pores with diameters in the sub-100-nm range and densities from 10^8 to 10^{11} tips per cm^2. These prototype CNT arrays have been used as field emitters (carbon has a low work function) and shown to exhibit field emission at a low threshold of 3–5 V/μm and emission current densities up to 100 mA/cm^2 in low-vacuum conditions.

Other applications of porous alumina include microchannel plates, mesoscopic engines, filters, membranes, and nozzles and apertures.

Nanostructures similar to the ones shown in porous alumina have been produced by photoelectrochemical etching of polycrystalline n-type semiconductors, such as TiO_2, CdSe, CdS, and ZnO.[47] The most detailed work was performed on TiO_2. Results demonstrate an underlying anisotropic etching mechanism substantially different from the one

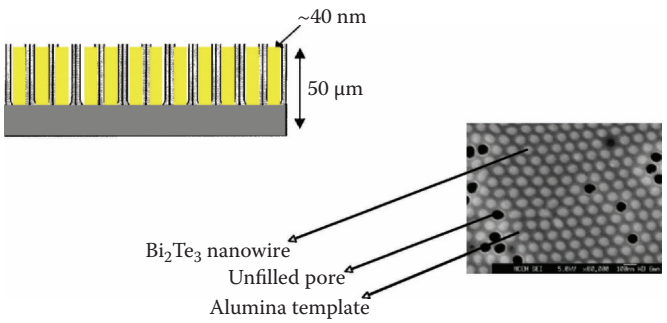

FIGURE 5.12 Nanoporous alumina works well for the electrochemical deposition of thermoelectric materials (Bi_2Te_3) and for metals. The process allows for the removal/dissolution of the oxide barrier layer so that pores are in contact with substrate. Filling rates of the pores of up to 90% have been achieved. (From T. Sands/HEMI group.)

at play in anodized alumina films.[48] Anodization of polycrystalline TiO_2 in a sulfuric acid solution under UV irradiation causes photoelectrochemical corrosion or photoetching. After a prolonged photoetching procedure, regularly ordered submicrometer porous structures (called *nanohoneycombs*) are observed at the TiO_2 surface. The quadrangle cells of the revealed nanohoneycomb are a few hundred nanometers wide and several micrometers deep. The thin walls (10–20 nm) of the pattern consist of {110} crystal faces. Etching selectively dissolves the grains, while the grain boundaries remain. The explanation for this selective etching behavior is readily understood from the fact that the holes created in the valence band of the semiconductor by the UV light readily corrode the bulk of the grains but recombine with electrons at the grain boundaries, leaving those intact. Besides their use in a dye-sensitized solar-cell and as a photocatalyst, fewer applications have been suggested for these new nanostructures than for porous alumina.

Conceptually, the alumina and TiO_2 micromachining approaches described here are somewhat similar to the quartz micromachining approach discussed earlier in which high-aspect ratio micromachining is achieved in single-crystal quartz by etching along the nuclear tracks left after bombardment with heavy ions. Obviously, alumina micromachining is a lot less complicated and costly, and so is the TiO_2 etching procedure, although the latter entails a rather difficult to control photoetching step and results in much less regular patterns than porous alumina.

Polymer MEMS-Polyimides

Introduction

Quartz and ceramic micromachining, discussed above, principally address harsh environment MEMS. Polymer materials also have some distinct advantages over more traditional engineering materials used in MEMS. Incentives for using polymers include increased fracture strength, low Young's modulus, high elongation, and reduced material costs. Furthermore, polymers are often inert and biocompatible, making them attractive for use in biological and chemical applications. As we have seen, in Volume I, Chapter 6, on fluidics, polymers are the most-used substrate for all types of fluidic platforms. We saw plenty of other examples of polymer MEMS in the section on soft lithography and dry photoresists in Volume II, Chapters 1 and 2, on lithography, in Volume II, Chapter 10, on replication and LIGA, and in Chapter 4, this volume, on packaging, assembly, and self-assembly. We conclude this section on new MEMS and NEMS substrate materials by considering the many applications of polyimides as an example of polymer MEMS.

Polyimide MEMS

Polyimides are part of a group of high-temperature polymers that have been in commercial use since the 1970s. Because of their structure, involving very strong carbon ring bonds, they do not melt and flow as most thermosets and thermoplasts do. Polyimides are synthesized from two monomers, a dianhydride and a diamine. Commercial products are supplied as soluble polyamic acid (PAA) intermediates, which undergo a thermal imidization with the evolution of water to form the insoluble polyimide. Polyimide films feature excellent thermal stability (up to ~450°C for short periods of time, $T_g > 300$°C), low dielectric properties ($\varepsilon = 3.3$) and a resistivity of ~10^{16} ohm-cm, superior chemical resistance, toughness, wear resistance, and flame retardance. Because of their flexibility they also exhibit interesting mechanical properties, and the material is easy to process. However, its tendency to absorb moisture causes the polyimide layers to swell and their dielectric constants to increase significantly. Another negative aspect of polyimides is their short shelf-life stability, which still needs to be addressed by organic chemists. Various polyimide analogs have been developed to avoid some of these inherent undesirable properties.

Current macro applications of nonphotosensitive polyimides include ball-bearing separators and mechanical seals. Polyimides in the microworld are used as passivating and interlayer dielectrics, planarizing compounds, reactive ion masks, alpha-particle barriers, humidity-sensitive materials,[49,50] liquid crystal display, color filters[51] (by incorporating dyes), and other optical elements, such as

waveguides. In planarization, polyimides smooth the undulation caused by topographic features on the wafer, so that the top-imaging layer has a much smaller thickness variation (see Volume II, Chapter 1, on photolithography). A typical polyimide, designed for MEMS applications, packaging dielectric and as substrate material is PI 2611, a low-moisture, low-stress (coefficient of thermal expansion (CTE) = 5 ppm), and high modulus of elasticity (8.5 GPa) polyimide. This polyimide can be patterned using dry etching techniques as well as TMAH etching (for example, using the developers MF 319 and AZ 300). Film thicknesses in the range 4–8 μm can be obtained in a single coat with good uniformity by varying spin speeds in the range 5000–1000 rpm. The polyimide substrate can withstand metal sputtering such as Cr, Au, and Al without substantial damage.

An organic ciliary array of thin-film polyimide bimorph microactuators exploiting combined thermal and electrostatic control was employed to implement sensorless manipulation strategies for small objects. The tasks of parts translation, rotation, orientation, and centering were demonstrated using small integrated circuit (IC) dice by Kovacs et al. (see Figure 5.13).[52,53] To induce motion on a part that is placed on an array of cilia, the cilia are actuated in a cyclic, gait-like fashion. In each cycle, the part is moved in a certain direction by the motion of the actuators that are in contact with it. The speed of the moving part depends on the (horizontal) displacement of the actuators per cycle, as well as the frequency of cycle repetition. It also depends on the surface properties and weight of the moving part.

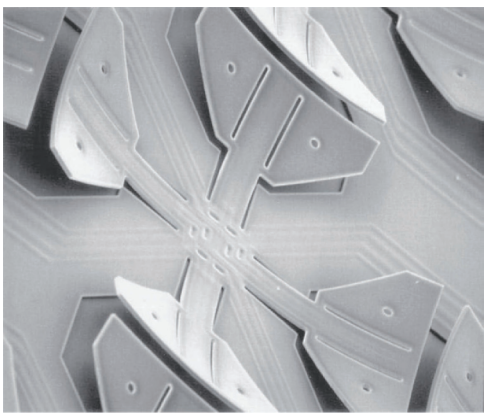

FIGURE 5.13 Polyimide cilia motion pixel (scanning electron microscope micrograph). Four actuators in a common center configuration make up a motion pixel. Each cilium is 430 μm long and bends up to 120 μm out of the plane. (Figure by John Suh.[52])

In our own work, we have used polyimide sheets as precursor material to design carbon structures in C-MEMS (see below), and in building flat panel displays at SRI International, Capp Spindt used polyimide posts to separate the glass plate from the Si field emitters (see Volume II, Figure 7.90).

Photosensitive polyimides have found many applications in both integrated circuitry and in MEMS and NEMS. Photosensitive polyimide is typically a negative tone resist and in use as photoresist, polyimide precursors, called polyamic acids (*PAAs*), are spun on the wafer; upon exposure to UV light, cross-linking results (more recently introduced positive polyimide resists are discussed in Volume II, Chapter 1, on photolithography; see Volume II, Figure 1.28). During development, the unexposed regions are dissolved, and final curing by further heat treatment leads to a chemical transformation (known as *imidization*) of the remaining cross-linked material, which yields polyimide. At a temperature of 275°C, more than 99% of the polyimide precursor is converted to polyimide. As with other negative resists, an oxygen effect is noted in the exposure. The actinic sensitivity of the resist usually is confined to 365 nm.

Polyimide photoresists often are used as permanent photoresists; that is, as resists that after exposure and curing can be left behind as a structural and/or functional component. For example, they have been used as a dielectric, especially when the uniquely low dielectric constant of the polyimide gives devices a decreased capacitance, resulting in increased speed for electronic applications.[54] In multiple spin-coats, thick polyimide films can be deposited (>100 μm). Since the films are so transparent, UV lithography permits the fabrication of high aspect ratio features (see LIGA-like processes in Volume II, Chapters 1 and 10). An important commercial application of both photosensitive and nonphotosensitive polyimides is in multiple chip modules.[55] As we explained in Volume II, Chapter 1 on lithography in the multiple chip module application, the use of photosensitive polyimides dramatically simplifies the manufacturing procedure as compared with non-photosensitive option, as illustrated in Figure 1.28.[55]

In a finished device, up to five layers of metallization are insulated by 15–20-μm-thick polyimide films on a ceramic wiring board.

Photosensitive polyimides also come as dry-film photoresists. Dry photoresists were introduced by DuPont as far back as 1968. These dry films come in rolls and consist of a photopolymerizable layer sandwiched between a polyester support film and a separator sheet (see Volume II, Figure 1.33). They do not need to be spin coated on, as they can, after removal of the separator sheet, be laminated onto a substrate. Also, the polyester cover sheet protects the resist film from oxygen diffusion, which would inhibit the cross-linking reaction. Both chlorinated and aqueous-base-developable dry film resist systems are available. The current resolution capabilities of dry film resists are less than 75 μm. The fact that the laminated dry film can bridge or "tent" over holes and cavities not only benefits the manufacture of printed wiring boards (PWBs) but can be exploited in the manufacture of biosensors as well, as we illustrate in Chapter 1, this volume, Example 1.1. For other photosensitive dry resist systems, see Table 1.12.

Exploration of IC and MEMS applications of modified polyimides also has started. A common approach to reducing the dielectric constant of polyimides is the inclusion of organofluorine components, in the form of pendant perfluoroalkyl groups. The polyamic acid precursor for fluorinated polyimides is commonly based on hexafluorodianhydrideoxydianiline. The inclusion of fluorinated monomers in the polyimide backbone has been found to reduce their moisture absorption and dielectric constant. Unfortunately, these polyimides generally show an increased susceptibility to chemical attack, making their use in multilayer fabrication questionable. Recently, however, newer formulations have improved the chemical resistance of the polyimide and have demonstrated a unique wet etch capability for vias with aspect ratios approaching 1.2:1.

Special perfluorinated polyimides were synthesized at the NTT laboratories in Japan. These remarkable materials are resistant to soldering temperatures (260°C) and are highly transparent at the wavelengths of optical communications (1.0–1.77 mm). In addition, their low dielectric constants and refractive indices match the conventional fluorinated polyimides, whereas their birefringence is lower.[56] As we saw in Volume II, Example 3.4, dry plasma etching of these modified polyimides results in very high aspect ratio microstructures with interesting optical properties.

Silicon Nitride

Introduction

Silicon nitride (Si_xN_y) is a commonly used material in microcircuit and microsensor fabrication because of its many superior chemical, electrical, optical, and mechanical properties. The material provides an efficient passivation barrier to the diffusion of water and to mobile ions, particularly Na^+. It also oxidizes slowly (about 30 times less than silicon) and has highly selective etch rates over SiO_2 and Si in many etchants. Some applications of silicon nitride are optical waveguides (nitride/oxide), encapsulant (diffusion barrier to water and ions), insulator (10^{16} Ω-cm, high dielectric strength, field breakdown limit of 10^7 V/cm), mechanical protection layer, etch mask, oxidation barrier, and ion implant mask (density is 1.4 times that of SiO_2). Silicon nitride also is hard, with a Young's modulus higher than that of Si, and can be used, for example, as a bearing material in micromotors.[57]

Silicon nitride can be deposited by a wide variety of the CVD techniques reviewed in Volume II, Chapter 7—APCVD, low-pressure chemical vapor deposition (LPCVD), and plasma-enhanced chemical vapor deposition (PECVD)—and its intrinsic stresses can be controlled by the specifics of the deposition process. Silicon nitride and silicon oxide deposited with these techniques usually exhibit too much residual stress, which hampers their use as mechanical components. However, CVD of mixed silicon oxynitride can produce substantially stress-free components.

Nitride often is deposited from SiH_4 or other Si containing gases and NH_3 in a reaction such as the following.

$$3SiCl_2 + 4NH_3 \rightarrow Si_3N_4 + 6HCl + 6H_2$$

Reaction 5.1

In this CVD process, the stoichiometry of the resulting nitride can be moved toward a silicon-rich composition by providing excess silane or dichlorosilane compared with ammonia.

PECVD Nitride

Plasma-deposited silicon nitride, also plasma nitride or SiN, is used as the encapsulating material for the final passivation of devices. The plasma-deposited nitride provides excellent scratch protection, serves as a moisture barrier, and prevents sodium diffusion. Because of the low deposition temperature, 300–350°C, the nitride can be deposited over the final device metallization. Plasma-deposited nitride and oxide both act as insulators between metallization levels, which is particularly useful when the bottom metal level is aluminum or gold. The silicon nitride that results from PECVD in the gas mixture of Reaction 5.1 has two shortcomings: high hydrogen content (in the range of 20–30 atomic percent) and high stress. The high compressive stress (up to 5×10^9 dyn/cm^2) can cause wafer warping and voiding and cracking of underlying aluminum lines.[58] The hydrogen in the nitride also leads to degraded MOSFET lifetimes. To avoid hydrogen incorporation, source gases containing little or no hydrogen, such as nitrogen, may be employed instead of ammonia as the nitrogen source. Also, a reduced flow of SiH_4 results in less Si-H in the film. The hydrogen content and the amount of stress in the film are closely linked. Compressive stress, for example, changes to tensile stress upon annealing to 490°C in proportion to the Si-H bond concentration. By adding N_2O to the nitride deposition chemistry an oxynitride forms with lower stress characteristics; however, oxynitrides are somewhat less effective as moisture and ion barriers than nitrides.

One key advantage of PECVD nitride, besides the low temperature aspect, is the ability to control stress during deposition. Silicon nitride deposited at the typical 13.56 MHz plasma excitation frequency exhibits tensile stress of about 400 MPa. When depositing the film at 50 kHz, a compressive stress of 200 MPa is typical. We discussed the effect of RF frequency on nitride stress, hydrogen content, density, and the wet etch rate in more detail in Volume II, Chapter 7. We concluded that low frequency (high energy bombardment) results in films with low compressive stress, lower etch rates, and higher density. Therefore, the effect of ion bombardment is more pronounced at lower pressures, and better quality CVD films ensue, characterized as films with a low wet etch rate (high film density) and low compressive stress. Experimental results show that as the reactor pressure is lowered, film stress goes from tensile to compressive (Volume II, Figure 7.59) and wet etch rates decrease. Often, stress dynamically changes when the film is exposed to the atmosphere and subsequent heating; the higher the ion bombardment during PECVD, the higher the stress. Stress also is affected by moisture exposure and temperature cycling (for a good review, see Wu and Rosler[59]).

We compare properties of silicon nitride formed by LPCVD and PECVD in Table 5.5, and Table 5.6 highlights typical PECVD process parameters. The refractive index of the deposited silicon nitride films is a measure of impurity content and overall quality. Its value ranges from 1.8 to 2.5 for PECVD films as compared with 2.01 for stoichiometric LPCVD (see below). The higher numbers indicate excess silicon, and lower numbers represent excess oxygen.

LPCVD Nitride

In the IC industry, stoichiometric silicon nitride (Si_3N_4) is LPCVD deposited at 700–900°C and at 200–500 mTorr, and it functions as an oxidation mask and as a gate dielectric in combination with thermally grown SiO_2. In micromachining, LPCVD nitride serves as an important mechanical membrane material and isolation/buffer layer. The standard source gases are SiH_2Cl_2 and ammonia, and at the above specified temperatures and pressures, this leads to a deposition rate of about 30 Å/min. The deposition of the amorphous silicon nitride is reaction-limited, so it deposits on both sides of the wafers with equal thickness. Dichlorosilane is used instead of silane because it results in more uniform film thickness, and the wafers can be spaced closer together for larger loads. For stoichiometric silicon nitride, typical gas flows are in a 10:1 ratio of ammonia to dichlorosilane. Stoichiometric silicon nitride has a large residual tensile stress of about 10^{10} dynes/cm^2, and as a consequence, film thickness

Table 5.5 Properties of Silicon Nitride

Deposition	LPCVD	Plasma-Enhanced CVD
Temperature (°C)	700–800	250–350
Density (g/cm^3)	2.9–3.2	2.4–2.8
Pinholes	No	Yes
Throughput	High	Low
Step coverage	Conformable	Poor
Particles	Few	Many
Film quality	Excellent	Poor
Dielectric constant	6–7	6–9
Resistivity (ohm-cm)	10^{16}	10^6–10^{15}
Refractive index	2.01	1.8–2.5
Atom % H	4–8	20–25
Energy gap	5 eV	4–5 eV
Dielectric strength (10^6 V/cm)	10	5
Etch rate in conc. HF	200 Å/min	
Etch rate in BHF	5–10 Å/min	
Residual stress (10^9 dyne/cm^2)	1 T	2 C–5 T
Poisson ratio	0.27	
Young's modulus	270 GPa	
TCE	1.6×10^{-6}/°C

often is limited to a few thousands angstroms. By increasing the Si content in silicon nitride, the tensile film stress reduces (even to compressive), the film turns more transparent, and the HF etch rate lowers. Such films result by increasing the dichlorosilane to ammonia ratio.[63] At an ammonia to dichlorosilane ratio of approximately 1 to 6, the films are nearly stress free, for deposition temperatures of 850°C and pressures of 500 mTorr.[64] Figure 5.14 illustrates the effect of gas flow ratio and deposition temperature on stress and the corresponding refractive index and HF etch rate.[63]

Silicon-rich or low-stress nitride has emerged as an important micromechanical material. Low residual stress means that relatively thick films can be deposited and patterned without fracture. Low etch rate in HF means that films of silicon-rich nitride survive release etches better than stoichiometric silicon nitride. The etch characteristics of LPCVD Si_xN_y are summarized in Table 5.7. The properties of a LPCVD Si_xN_y film, deposited by the reaction of $SiCl_2H_2$ and NH_3 (5:1 by volume) at 850°C, were already summarized in Table 5.5.

Amorphous Silicon and Hydrogenated Amorphous Silicon

Amorphous silicon behaves quite different from the coarse- and the fine-grained polysilicon discussed in Volume II, Chapter 7. Amorphous Si can be stress annealed at temperatures as low as 400°C.[65] This low-temperature anneal makes the material

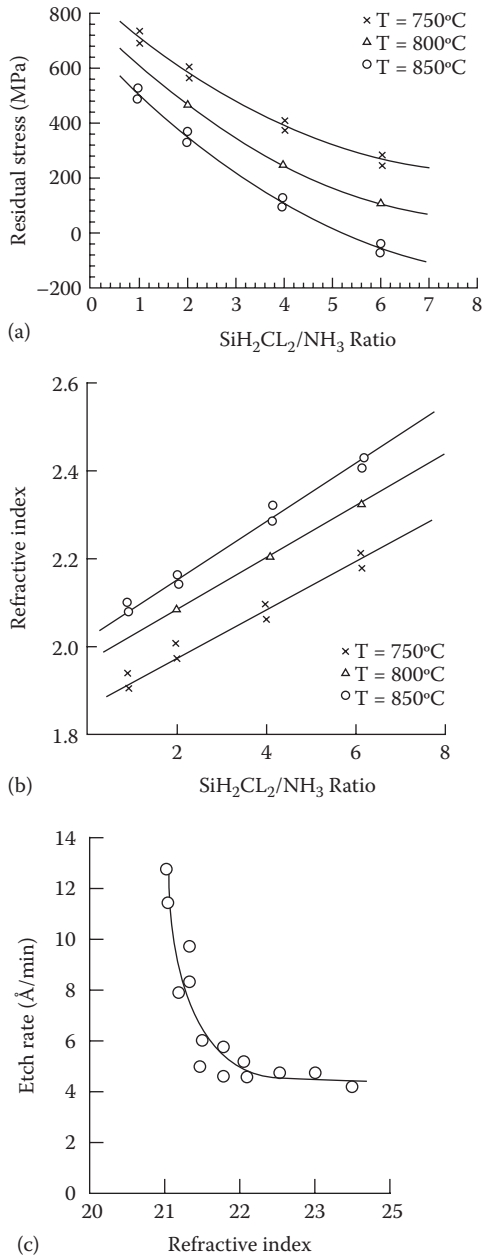

FIGURE 5.14 Silicon nitride low-pressure chemical vapor deposition parameters. (a) Effect of gas-flow ratio and deposition temperature on stress in nitride films. (b) The corresponding index of refraction. (c) The corresponding HF etch rate. (From Sakimoto, M., H. Yoshihara, and T. Ohkubo. 1982. compatible with almost any active electronic component. Unfortunately, little is known about the mechanical properties of amorphous Si.

Hydrogenated amorphous Si (α-Si:H), with its interesting electronic properties, is even less well understood in terms of its mechanical properties. If the mechanical properties of hydrogenated amorphous Si were found to be as good as those of polysilicon, the material might make a better choice than polysilicon as a MEMS material, given its better electronic characteristics.

TABLE 5.7 Etching Behavior of Low-Pressure Chemical Vapor-Deposited Si_3N_4

Etchant	Temperature (°C)	Etch Rate (Å/min)	Selectivity of Si_3N_4:SiO_2:Si
H_3PO_4	180	100	10:1:0.3
CF_4–4% O_2 plasma		250	3:2.5:17
BHF	25	5–10	1:200:±0
HF (40%)	25	200	1:>100:0.1

The amorphous polysilicon material produces a high breakdown strength (7–9 MV/cm) oxide with low leakage currents (vs. a low breakdown voltage and large leakage currents for polycrystalline Si oxides). Amorphous polysilicon also attains a broad maximum in its dielectric function without the characteristic sharp structures near 295 and 365 nm (4.2 and 3.4 eV) of crystalline polysilicon. Approximate refractive index values at a wavelength of 600 nm are 4.1 for crystalline polysilicon and 4.5 for amorphous material.[60] As deposited, the material is under compression, but an anneal at temperatures as low as 400°C reduces the stress significantly, even leading to tensile behavior.[65]

Like polysilicon, amorphous silicon exhibits a strong piezoresistive effect. The gauge factor is about five times smaller than that of single-crystal Si, but the temperature coefficient of the resistance (TCR) is lower than that of Si.

Hydrogenated amorphous silicon enables the fabrication of active semiconductor devices on foreign substrates at temperatures between 200°C and 300°C. The technology, first primarily applied to the manufacturing of photovoltaic panels, now quickly is expanding into the field of large-area microelectronics, such as active matrix liquid crystal displays (AMLCD). It is somehow surprising that micromachinists have not taken more advantage of this material to either power surface micromachines or implement electronics cheaply on nonsilicon substrates. In Figure 5.15 we compare polycrystalline-based solar cells with ultrathin amorphous Si on glass and ultrathin amorphous Si on flexible substrates.

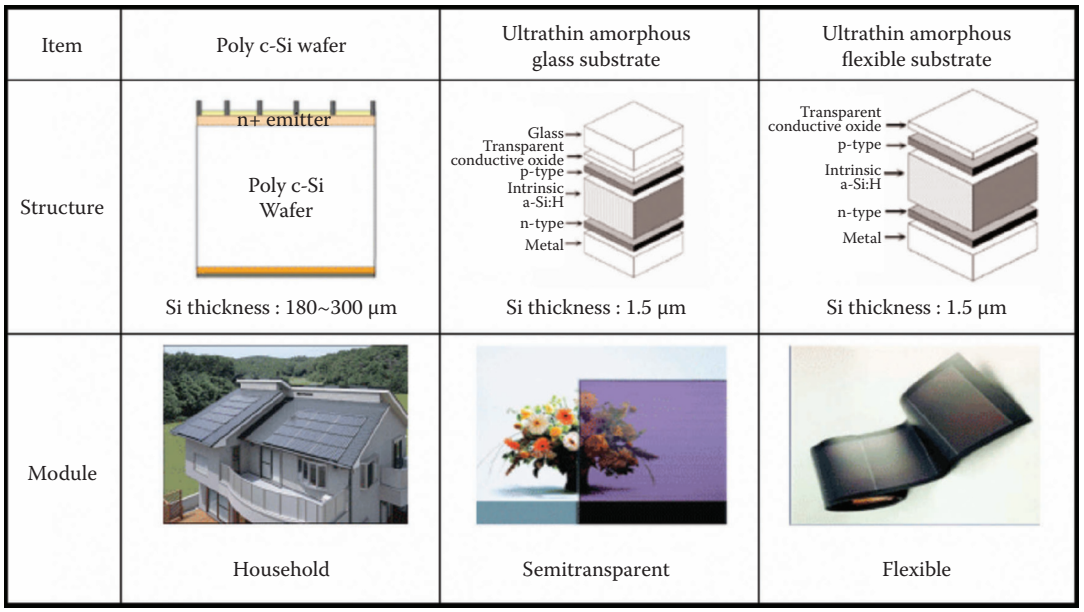

FIGURE 5.15 Comparison of polycrystalline-based solar cells with ultrathin amorphous Si on glass and ultrathin amorphous Si on flexible substrates. (From http://www.displaybank.com.)

Spear and Le Comber[66] showed that, in contrast to α-Si, α-Si:H could be doped both n- and p-type. Singly bonded hydrogen, incorporated at the silicon dangling bonds, reduces the electronic defect density from ~10^{19}/cm^3 to ~10^{16}/cm^3 (typical H concentrations are 5–10 atomic percent—several orders of magnitude higher than needed to passivate all the Si dangling bonds). The lower defect density results in a Fermi level that is free to move, unlike in ordinary amorphous Si, where it is pinned. Other interesting electronic properties are associated with α-Si:H—exposure of α-Si:H to light increases photoconductivity by four to six orders of magnitude, and its relatively high-electron mobility (~1 cm^2/V s^{-1}) enables fabrication of useful thin-film transistors. Lee et al.[67] noted that hydrogenated amorphous silicon solar cells are an attractive means to realize an onboard power supply for integrated micromechanical systems. They point out that the absorption coefficient of α-Si:H is more than an order of magnitude larger than that of single-crystal Si near the maximum solar photon energy region of 500 nm. Accordingly, the optimum thickness of the active layer in an α-Si:H solar cell can measure 1 μm, much smaller than that of single-crystal Si solar cells. By interconnecting 100 individual solar cells in series, the measured open circuit potential reaches as high as 150 V under AM 1.5 conditions, a voltage high enough to drive onboard electrostatic actuators.

Hydrogenated amorphous silicon is manufactured by plasma-enhanced chemical vapor deposition (PECVD) from silane. Usually, planar RF-driven diode sources using SiH_4 or SiH_4/H_2 mixtures are used. Typical pressures of 75 mTorr and temperatures between 200°C and 300°C allow silane decomposition with Si deposition as the dominant reaction. Decomposition occurs by electron impact ionization, producing many different neutral and ionic species.[68] Deposition rates for usable device quality α-Si:H generally do not exceed ~2–5 Å/s, due to the effects of temperature, pressure, and discharge power. Table 5.8 gives state-of-the-art parameters for α-Si:H prepared by PECVD. Although its semiconducting properties are inferior to those of single-crystal Si, the material is finding more and more applications. Some examples are thin film transistor (TFT) switches for picture elements in AMLCDs,[69] page-wide TFT-addressed document scanners, and high-voltage TFTs capable of switching up to 500 V.[70] An excellent source for further information on amorphous silicon is the book *Plasma Deposition of Amorphous Silicon-Based Materials*.[71]

Table 5.8 Typical Optoelectronic Parameters Obtained for Plasma-Enhanced Chemical Vapor Deposition α-Si:H

	Symbol	Parameter
Undoped		
Hydrogen content		~10%
Dark conductivity at 300 K	σ_D	~10^{-10} $(\Omega\text{-cm})^{-1}$
Activation energy	E_σ	0.8–0.9 eV
Pre-exponent conductivity factor	σ_0	>10^3 $(\Omega\text{-cm})^{-1}$
Optical bandgap at 300 K	E_g	1.7–1.8 eV
Temperature variation of bandgap	$E_g(T)$	2–4 × 10^{-4} eV/K
Density of states at the minimum	g_{min}	>10^{15}–10^{17} cm^3/eV
Density of states at the conduction band edge		~10^{15}/cm^3
ESR spin density	N_s	~10^{21}/cm^3-eV
Infrared spectra		2000/640 cm^{-1}
Photoluminescence peak at 77 K		~1.25 eV
Extended state mobility		
Electrons	μ_n or μ_e	>10 cm^2/V-s
Holes	μ_p or μ_h	~1 cm^2/V-s
Drift mobility		
Electrons	μ_n or μ_e	~1 cm^2/V-s
Holes	μ_p or μ_h	~10^{-2} cm^2/V-s
Conduction band tail slope		25 meV
Valence band tail slope		40 meV
Hole diffusion length		~1 μm
Doped amorphous		
n-type[a]	σ_D	10^{-2} $(\Omega\text{-cm})^{-1}$
	E_g	~0.2 eV
p-type[b]	σ_D	10^{-3} $(\Omega\text{-cm})^{-1}$
	E_g	~0.3 eV
Doped microcrystalline		
n-type[c]	σ_D	≥1 $(\Omega\text{-cm})^{-1}$
	E_g	≤0.05 eV
p-type[d]	σ_D	≥1 $(\Omega\text{-cm})^{-1}$
	E_g	≤0.05 eV

Selected MEMS and NEMS Processes

Introduction

In this section we review selected MEMS/NEMS processes that might affect the direction that MEMS/NEMS takes next. Many relatively new and important processes, such as soft lithography (see Volume II, Chapter 1) and atomic layer deposition (see Volume II, Chapter 7), are covered elsewhere in this work. The following additional selection is rather arbitrary and complements the new materials/processes covered elsewhere. For exciting new MEMS/NEMS techniques, we survey carbon-based MEMS (C-MEMS), bulk metallic glasses (BMG), fast microfluidic CD prototyping, and micro glass blowing.

C-MEMS

Introduction

In nature, carbon occupies a very special place as the essential building block of life. In human enterprise, too, carbon in its various forms has acquired an enviable position. To just name a few, diamonds are made of carbon, and graphite, coke, diamond-like carbon, and glassy carbon are all forms of carbon. So are the more recently discovered buckyballs, carbon fibers, and carbon nanotubes (CNTs).[72,73] Carboneous materials have been used in various application fields because their widely different crystalline structures and morphologies enable different physical, chemical, mechanical, thermal, and electrical uses. For example, glassy carbon electrodes often are used because of their wide electrochemical stability window, low background currents and low cost. Graphite and hard carbons are well known for their utility in Li ion battery applications because of their Li intercalation/deintercalation capacity. Other properties, such as biocompatibility, chemically inertness, and ease of functionality have made carbon very attractive for biosensor and implantable device applications. Moreover, CNTs are of tremendous current interest in both fundamental research and for nanoelectronics applications, including flat panel displays, chemical sensors, and the next generation of transistors (see Volume I, Figure 1.30). Recently, new microfabrication methods for carboneous materials have received a lot of attention, especially with regard to their use as microelectrodes in electrochemical sensors and miniaturized energy storage/energy conversion devices. Some key advantages of carbon compared with Si are summarized in Table 5.9. Although silicon, human's foremost technological material, is abundant in silicate minerals, carbon is the key to life. It can rightfully be argued that carbon is becoming a more and more important material in human technology. Besides the common use of carbons in sensors and batteries, carbon nanotubes might form the basis for a future carbon-electronics industry. We speculate that C-MEMS, described here, might be the material to use to contact those carbon-nanotube-based devices.

Additional important C-MEMS properties are included in Table 5.9: the material has a very wide

TABLE 5.9 Carbon: The Next Si?

• Polymerizes better than Si (see inset 1 below)
• Takes all types of forms: amorphous, graphite, nanotubes, etc. (see inset 2 below)
• Has a wide electrochemical stability window
• Exhibits biocompatibility
• Has a low cost
• Is chemically inert
• Is easy to derivatize
• Is well known for its battery and sensor application
• Carbon nanotubes connect via carbon-based microelectromechanical system
• Is nature's building block for living things

Inset 2

electrochemical stability window, exhibits excellent biocompatibility, and is low cost, and the surface of this very chemically inert material is easy to functionalize. The material has particular importance in bio-MEMS applications, including electronic DNA arrays (replacing the platinum shown in Nanogen's DNA array; see Figure 8.51 this Volume), glucose sensors, and microbatteries (see below).

Microfabrication of Carbon: C-MEMS Process

For microfabrication of carbon structures, IC processing technologies, such as focused ion beam (FIB) and reactive ion etching (RIE), are time consuming and expensive because of the need of high-vacuum systems. Low feature resolution and poor repeatability of the carbon composition, as well as the widely varying properties of the resulting devices, limit the application of screen printing with commercial carbon inks for carbon microfabrication.[73] Recently, more nontraditional carbon microfabrication methods were reported. Whitesides and co-workers described the use of soft lithography (see Volume II, Chapter 2) to fabricate glassy carbon microstructures.[74] In this approach, micromolding of a resin such as poly(furfuryl alcohol) in an elastomeric mold yields polymeric microstructures, the microstructures are converted to free-standing carbon by heat treatment (500–1100 °C) in an inert atmosphere (see Volume II, Figure 2.55).

The carbon microfabrication technique introduced by this author is based on the pyrolysis of shaped/patterned polymers (e.g., resists patterned with photolithography) at different temperatures and different ambient atmospheres.[75,76] Carbon, because it is brittle and hard, is a difficult material to machine. Polymers, on the other hand, can be machined easily in a wide variety of machine tools. The underlying principle of C-MEMS is to choose an easy to work with polymer precursor, machine, or pattern this precursor material and then convert it to carbon by pyrolysis.

In one embodiment of the C-MEMS process, a photoresist is patterned by photolithography and is subsequently pyrolyzed at high temperatures in an oxygen-free environment. By changing the lithography conditions, soft and hard baking times and temperatures, additives to the resist, pyrolysis time, temperature, and environment, C-MEMS permits a wide variety of interesting new MEMS and NEMS applications that employ structures having a wide variety of shapes, resistivities, and mechanical properties. The process is detailed in Figure 5.16.[73]

The photolithography to make C-MEMS structures, illustrated in Figure 5.16, includes the usual spin coating, soft bake (not shown), near-UV exposure, postbake (not shown), and development. A typical patterning process for a 200-μm-thick SU-8 photoresist film involves photoresist spinning at approximately 500 rpm for 12 s and then at 1400 rpm for 30 s, followed by a 10-min soft-bake at 65°C and finally a soft-bake for 80 min at 95°C. Exposure is performed in a Karl Suss MJB3 contact aligner for about 100 s. The postbake is carried out for 2 min at 65°C and for 30 min at 95°C. Development is

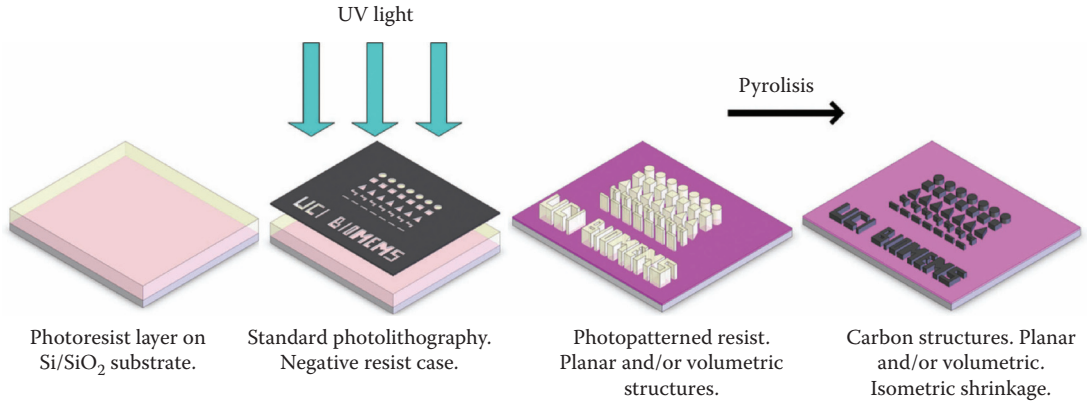

FIGURE 5.16 An illustration of one type of carbon-based microelectromechanical system: photolithography patterning of a polymer precursor and pyrolysis (see text for details).

carried out using a SU-8 developer from MicroChem (NANO™ SU-8 developer).

Photoresist-derived C-MEMS architectures are obtained in a two-step pyrolysis process in an open-ended quartz-tube furnace, in which samples are postbaked in an N_2 atmosphere at 300°C for about 40 min first and then heated in a N_2 atmosphere (2000 sccm) up to 900°C. At this point, the N_2 gas is shut off and forming gas [H_2 (5%)/N_2] is introduced (2000 sccm) for 1 h, and then the heater is turned off and the samples are cooled down again in an N_2 atmosphere to room temperature. The heating rate is about 10°C/min, and the total cooling time is about 10 h.

The resulting carbon material was found to be amorphous and glass carbon-like in electrochemical behavior.[77] The average height of the SU-8 posts shown in two typical scanning electron microscope (SEM) pictures (Figure 5.17a and 5.17b), is around 300 µm.

As shown in Figure 5.17c and 5.17d, after pyrolysis, the overall shape of the cylindrical posts largely is retained, and a typical aspect ratio of the carbon post achieved is around 10:1. It was found that the C-MEMS posts shrink much less during the pyrolysis process near the base of the structures than at the midsection because of the good adhesion of SU-8 to the substrate.

The processes described above easily can be extended to two-level or multilevel C-MEMS structures. This feature was used for making Li-ion-based C-MEMS batteries.[78] In the C-MEMS battery depicted in Figure 5.18, one layer of carbon constitutes the current collector for the rows of anode and cathode posts made in a second C-MEMS layer.[78]

In Figure 5.18, the current collector is 20 µm thick and the posts are 250 µm high. C-MEMS Li ion batteries, as shown here, hold the promise of changing the battery world in three significant ways (see also Chapter 9, this volume, on power and brains in miniature devices): 1) Smarter batteries: C-MEMS batteries contain a multitude of anodes and cathodes (we call them *baxels*, by analogy to *pixels*) that can be interconnected to provide the optimal current or voltage depending on the application need. In other words, we can perform in-battery smart load

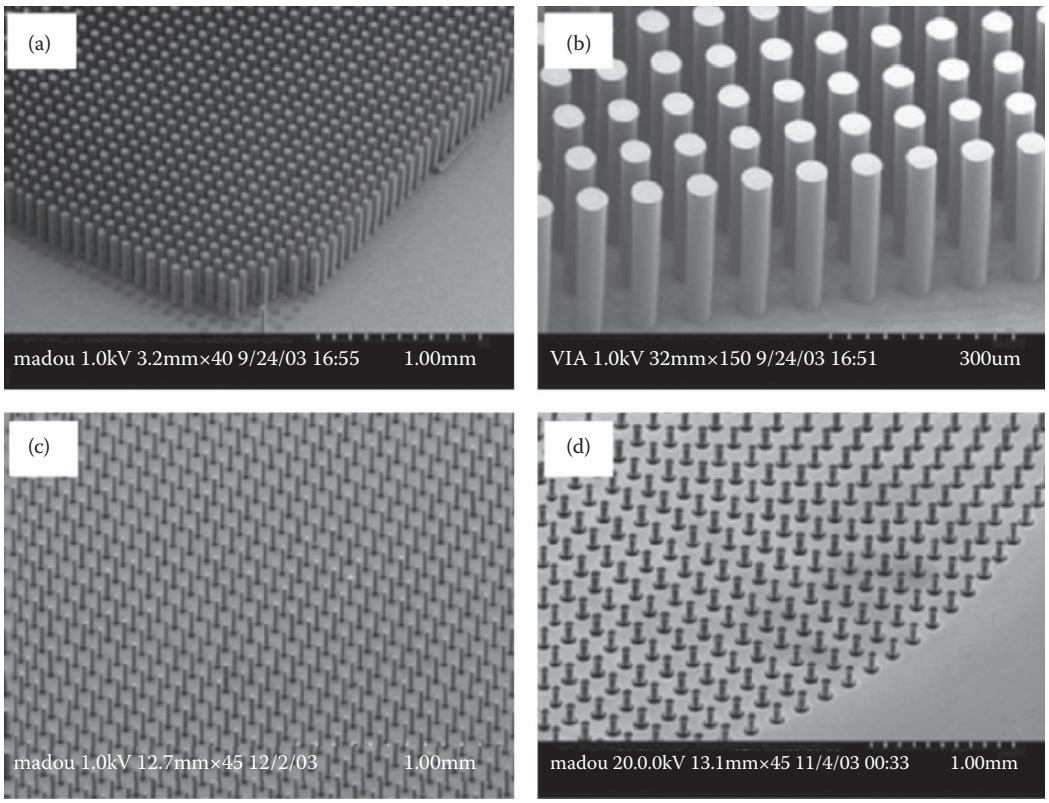

FIGURE 5.17 Typical scanning electron microscope photos. (a) and (b) SU-8 post arrays before pyrolysis. (c) and (d) Carbon post arrays after pyrolysis.

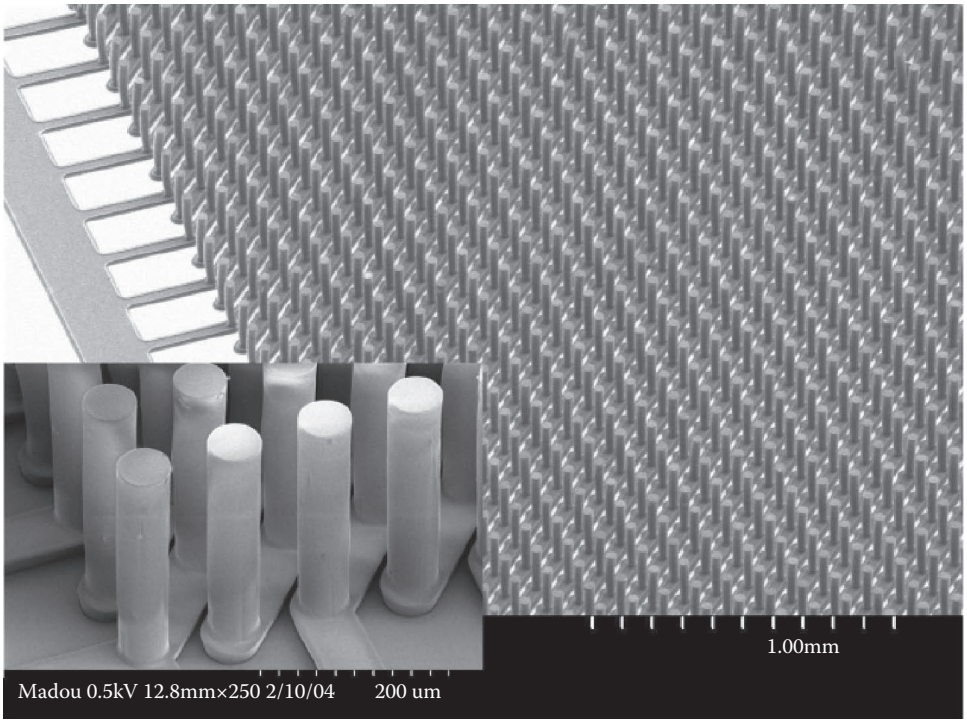

FIGURE 5.18 Typical two-level carbon-based microelectromechanical system electrodes with carbon contacts underneath. The inset image shows enlarged SU-8 two-level structure.[78]

leveling; 2) Faster charging batteries: in charging the C-MEMS battery, Li ions only need to intercalate into the thin individual carbon posts rather than intercalating into one big chunk of carbon; 3) Theoretically, the capacity of the C-MEMS batteries, depending on the aspect ratio of the posts and the thickness of the electrolyte, can be significantly higher than that of current Li ion batteries.[79]

In order to build yet higher aspect ratio C-MEMS structures (up to 40:1), we developed a three-level C-MEMS process. In a multilayer C-MEMS process, each layer of SU-8 photoresist is exposed and baked separately, but the whole assembly is developed all at the same time in the last step. Typical SEM photos of three-level C-MEMS devices are shown in Figure 5.19, with a three-level C-MEMS structure in which the first two are in good alignment but the third is out of alignment.

By carefully controlling the lithography processing parameters, a variety of complex 3D C-MEMS structures, such as suspended carbon wires, bridges, plates, and self-organized posts (carbon flowers) and ribbons (networks), were also microfabricated by Madou and coworkers.[72] These intricate 3D structures are fabricated using nontraditional process recipes, such as overexposure, underdevelopment, photoresist additives, directed flow of the developer, and exploitation of surface tension in the developing photoresist patterns. Suspended carbon fibers are shown in Figure 5.20, and a C-MEMS table was shown in the inset in the heading of this chapter. The diameter of the suspended carbon fibers in Figure 5.20 is submicrometer. The wire resistance between two posts was measured at room temperature and in air using two point probes, and a typical resistivity

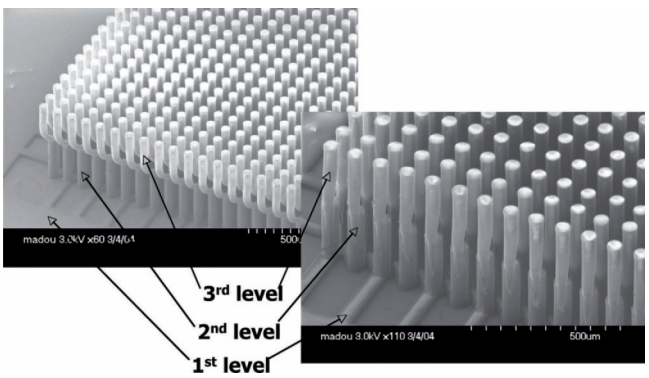

FIGURE 5.19 Typical scanning electron microscope photos of three-level carbon-based microelectromechanical system (C-MEMS) devices: a three-level C-MEMS structure with two levels in good alignment but with a third level out of alignment.

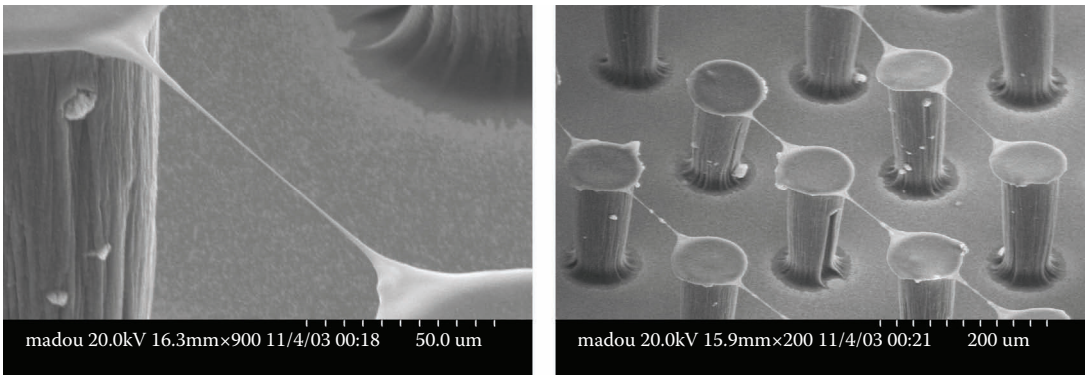

FIGURE 5.20 Carbon-based microelectromechanical system suspended carbon wires. Washcloth lines.

of 1.8×10^{-2} Ωcm was obtained. The Madou team is currently working on measuring the influence of chemical reactions on the suspended wire's resistivity. The aim is to turn these amorphous carbon "washcloth lines" into "washcloth line sensors" by derivatizing the C-MEMS surface with a monolayer of a sensor molecules (e.g., proteins, DNA). It is anticipated that the fact that these nanowires are removed from the supporting substrate and are thus suspended in air or liquid will lead to significant advantages over other nanowire-based sensors typically embedded on a solid substrate. This arrangement exposes the sensor to its sensing environment in all directions and avoids deleterious substrate influences, such as contamination and charge shunting.

In Figure 5.21, we illustrate self-organized groups of carbon posts (bunched posts)—a feature most readily observed when starting with high-aspect ratio SU-8 arrays with posts higher than 300 µm. It should be noted that when bunching of the SU-8 posts occurs, the bowed posts in each bunch remain structurally intact when converted to carbon. This means that the aggregation/bunching takes place after UV exposure, i.e., during postbake, development, or the drying after development. Bunching could in principle occur at the postbake temperature, as that temperature (65°C) is above the glass transition temperature of unexposed SU-8 (50–55°C); at those temperatures, the unexposed areas reflow, which could enable the posts to move toward each other. From SEM observations, after the postbake, the mask patterns are transferred with high fidelity. Clearly no aggregation or bunching is happening during postbake. The opportunity to control and optimize self-organized two-dimensional textures obviously presents itself only during the development process itself. We speculate at this point that the dominant cause for the bunching of resist posts is surface tension. When the developer solution is removed, it gently pulls posts that are tall and close enough together into symmetric patterns.

The electrochemical characteristics of carbon produced by pyrolysis of photoresists have been extensively studied.[76,77] It is found that electrochemical reactions on pyrolyzed photoresist exhibit reaction kinetics very similar to those on glassy carbon. We also found that C-MEMS electrodes can

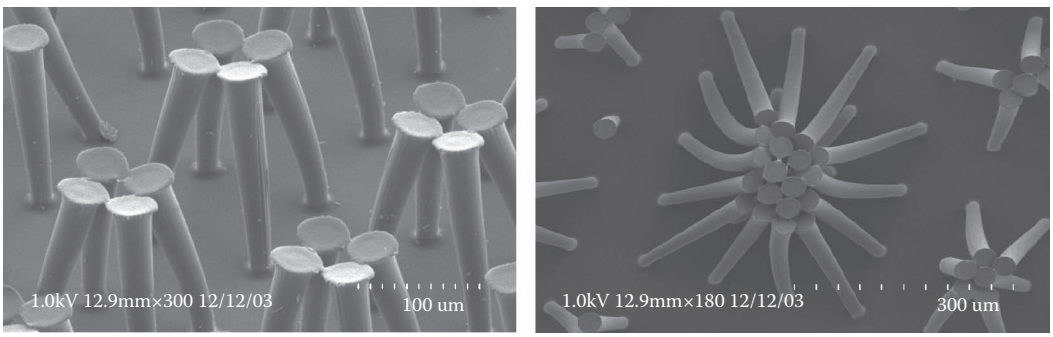

FIGURE 5.21 Carbon flowers. Self-assembly of polymer structures converted into carbon.

be reversibly charged and discharged with Li ions,[78] which led to the construction of C-MEMS Li ion batteries, as shown in Figure 5.18. The advantage of using photoresists as the starting material for the microfabrication of various carbon structures is that the photoresists can be very finely patterned by lithography techniques, and hence, a wide variety of repeatable shapes are possible. Moreover, different temperature treatments result in different resistivities and mechanical properties. Molecular rectification and conductance switching in pyrolyzed carbon-based molecular junctions were studied by McCreery et al.[80] They found that the current/voltage behavior showed strong and reproducible rectification and strong dependence on temperature and scan rate. Pyrolyzed photoresist carbon films were demonstrated to be useful in electroanalytical and microfluidic applications; for example, pyrolyzed carbon has been used in conjunction with a microchip capillary electrophoretic device.[81]

Madou and co-workers, as explained in Chapter 9, this volume, have presented theoretical arguments demonstrating that making fractal-like carbon electrodes will lead to better sensors and more energy efficient batteries and fuel cells.[82] In ongoing work, our team is attempting to make what we call a fractal garden. An artistic rendition of this concept is shown in Figure 5.22. In this fractal garden, each element in the array of fractal electrodes can be addressed individually. These electrodes maximize surface area while minimizing internal resistance and can be implemented gainfully for the sensors, batteries, and fuel cells of the future.

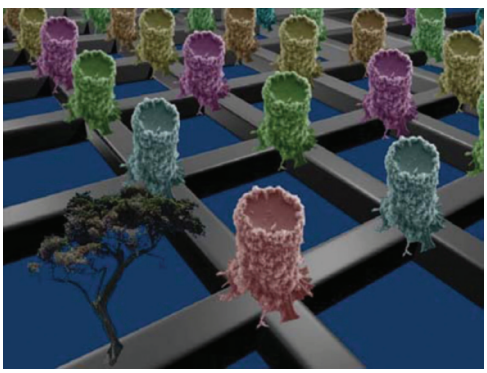

FIGURE 5.22 An artistic rendition of a carbon-based microelectromechanical system fractal garden (see also Chapter 9, this volume).

In Volume I, Chapter 6, on fluidics, we introduced 3D C-MEMS dielectrophoresis (see Volume I, Example 6.2). The main concept behind using 3D carbon electrodes here was to reduce the mean distance of any targeted particle contained in a channel or chamber to the closest electrode surface.[83]

The author believes that C-MEMS/NEMS technology can find applications in several MEMS fields as a substitute for silicon-based devices. This technology can be revolutionary not only in energy applications, such as biofuel cells, microbatteries, and supercapacitors, but also in biological and chemical sensing applications. The C-MEMS/NEMS approach gives the development engineers unprecedented freedom in designing and manufacturing high-surface area conductive structures through the use of new MEMS materials and innovative fabrication techniques. The development of novel biofuel cells based on high-aspect ratio 3D carbon structures from millimeter to nanometer size, integrating "top-down" and "bottom-up" processing approaches and combining soft biological components with hard MEMS/NEMS structures, could have the effect of making the bio-MEMS world less Si-centric and start a trend of lithographically patterning materials other than Si. Beyond the impact on the MEMS/NEMS/bio-MEMS community, one expects a broader anticipated impact on industry and on the technology end user.

Bulk Metallic Glasses

Bulk metallic glasses (BMGs) are multicomponent alloys for which crystallization is avoided during cooling. Sluggish crystallization kinetics and a corresponding ease of solidification into the amorphous state have been observed for a wide range of alloys, including compositions based on Zr, Cu, Ni, Ti, Fe, Mg, Pd, Pt, and Au.[84–94] Because of their random amorphous structure and lack of dislocation formation during deformation, these materials exhibit very high strength and elasticity, outstanding resilience, good corrosion resistance, and a near-perfect elastic behavior. For example, a typical BMG based on zirconium yields at 2000 MPa after it has elastically deformed by 2%.[95] Crystallization of a BMG must be avoided during any kind of processing, since it degrades the properties of the alloy. One

consequence of the sluggish crystallization kinetics in BMG forming alloys is the presence of a supercooled liquid region (SCLR). In this temperature region, the amorphous BMG first relaxes into a viscous liquid before it eventually crystallizes. This behavior results in a large window of material processing opportunities, where the BMG, in its supercooled liquid state, can be processed under pressures and temperatures similar to those used for plastics,[96] with several minutes of processing time allowed before crystallization sets in and starts degrading the alloy properties. Thus, thermoplastic forming (TPF) is carried out by reheating the BMG into its supercooled liquid region, and a relatively small forming pressure is sufficient to fill even the smallest and most complicated features while avoiding crystallization.[97] In other words, we can process the metal as if it were a polymer, as demonstrated in Figure 5.23.

Thermoplastic forming with BMGs has a strong potential as a technology for MEMS and NEMS fabrication.[99–100] The amorphous structure of a BMG makes it an ideal material for small geometries, since it lacks an intrinsic limitation like the grain size in crystalline materials or the large molecular weight of polymers. The BMG is homogeneous and isotropic down to the atomic scale. The absence of crystallization during solidification and the low processing temperature during TPF dramatically reduce solidification shrinkage to levels below 0.2% for most BMGs of technical relevance.[97] This low shrinkage, together with the fact that fast cooling is not required after TPF, allows one to precisely replicate mold features.

The supercooled liquid state of the BMG can be utilized for other processes, one of which is hot separation.[98] Thermoplastic forming into a mold cavity results in precise replication of micro features, which, however, are connected to a typically large reservoir of amorphous material. For MEMS fabrication and also for three-dimensional microparts, this reservoir must be separated from the part. Hot separation, where a scraper separates reservoir from part as shown in Figure 5.23, is carried out in the SCLR. This leaves a plain surface on which further fabrication steps can be carried out or a three-dimensional part after the mold is etched. The low-viscosity supercooled liquid state of the BMG can also be used to erase features in the BMG,[101] as shown in Figure 5.24. This is accomplished through surface tension forces alone. Such a process has potential for use as a rewrite mechanism for data storage, as well as to smooth the surface of microparts (where the finish is limited by the surface roughness of the mold).

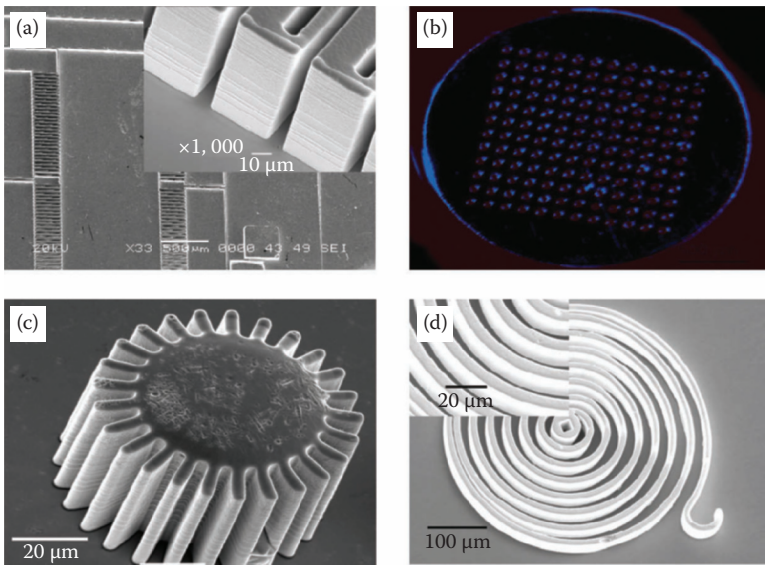

FIGURE 5.23 Examples of structures created by thermoplastic forming of bulk metallic glass (BMG). The top images depict precise replication of typical microelectromechanical system features with zirconium-based BMG (a) and a microporous membrane (b). Separation of the microparts from the BMG reservoir using a hot-separation technique results in three-dimensional microparts (c and d).[98] (Courtesy of Dr. Jan Schroers, Yale University.)

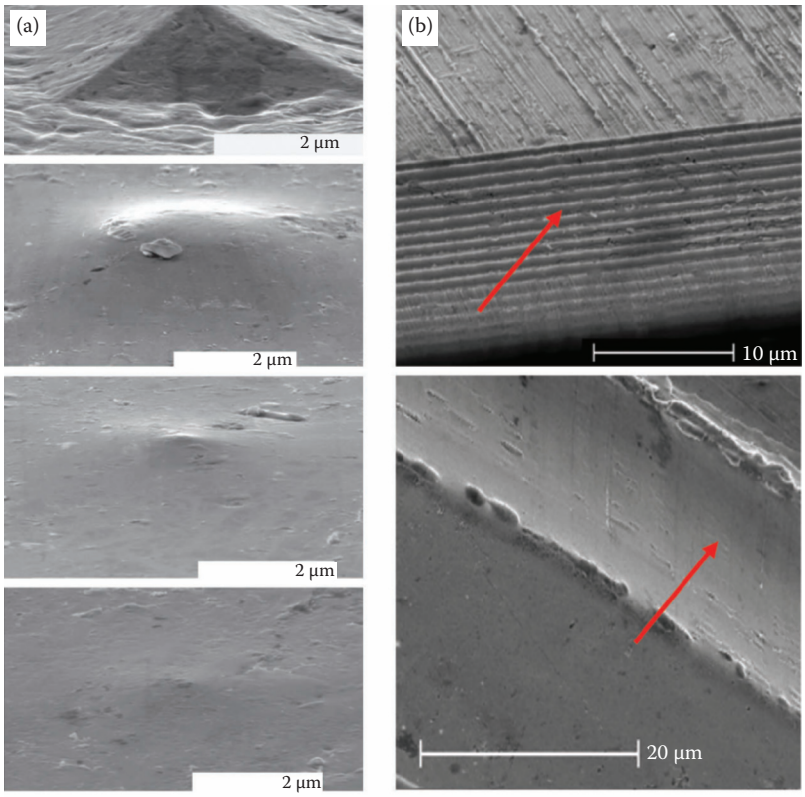

FIGURE 5.24 Forces exerted by surface tension alone can be used to erase features (a) or smoothing of the surface (b) in bulk metallic glass while processing it in the supercooled liquid region.[101]

Because of favorable chemical selectivity in BMGs, sacrificial etching and patterning can be performed without damaging the amorphous material.[98] For example, Zr- and Pt-based BMGs are resistant to most acids and bases, making them good candidates for postprocessing (selective wet-etching) of silicon after the TPF process.

Not only can BMGs be used to replicate a mold, but they can also be used as the mold material itself from which various materials are replicated. Even other BMGs can be replicated on a BMG mold, as long as they soften at lower temperatures than the mold material. BMGs typically lose their strength gradually with increasing temperature, but once the glass transition temperature is reached, where the glassy BMG relaxes into a metastable liquid, the strength significantly drops. Consequently, clever use of BMGs with decreasing T_g values allows the processing sequence depicted in Figure 5.25, where a BMG is used to replicate a conventional mold, and when processed at a lower temperature, as a mold itself.[98]

MEMS and microstructure applications are dictated by the BMG properties, processability, and process compatibility. Mechanical properties and processing temperature ranges for a few selected BMGs are summarized in Table 5.10. Their very high yield strength values, which by far exceed those of any other metal used for MEMS, are beneficial for almost every application. In particular, medical probes, skin-based drug delivery patches, sensors and actuators in high-shock environments, and microthrusters can all benefit from high strength. The high yield strength also implies a high hardness. This leads to less wear and is particularly interesting for MEMS relays and RF dielectric switches, which require robust performance after 10+ million contact cycles. The absence of dislocations also results in a very large elastic strain limit. Within the elastic region the material approaches perfect elastic behavior, reflected in low losses upon cyclic loading, which is particularly useful for resonators. Together, the high yield strength and large elastic strain limit suggest an outstanding resilience. For example, the 17-MPa resilience of a Zr-based BMG is about 1000 times higher than the resilience of nickel. Even the best conventional metallic spring material, high-carbon

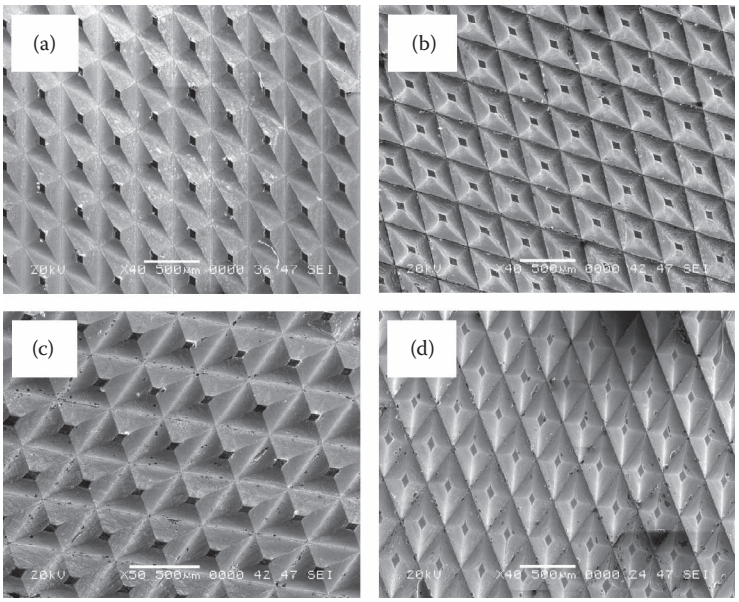

FIGURE 5.25 Sequential use of various bulk metallic glasses (BMGs) with different softening behavior as mold and molded material. The nickel master (a) is replicated at 450°C with a Zr-based BMG (b). This structure is then used as a mold for a Pt-based BMG formed at 280°C (c). A Au-based BMG with an even lower glass transition temperature of 130°C (softening behavior) is used to replicate the Pt-based BMG structure. The Au-based BMG is processed at 160°C, and perfect replication of the Pt-based BMG mold can be achieved (d).[102]

spring steel, possesses a resilience below 2 MPa. Obviously, their outstanding resilience makes BMGs excellent materials for any spring application involving energy storage and harvest, as well as for valve applications.

BMGs are available in a wide range of densities. The high density of $Pt_{57.5}Cu_{14.7}Ni_{5.3}P_{22.5}$, 15.3 g/cm^3, makes it an attractive candidate for improving the sensitivity of accelerometers.

The ability to use BMGs as a material to replicate parts on a mold and as a mold material itself suggests an alternative to the LIGA process (see Volume II, Chapter 10) for the mass production of microparts. BMG molds could supplant disposable molds.

Summarizing, BMGs are an entirely new class of material best described as an ultrahigh-strength material that can be processed like a plastic. There are many reasons why this class of materials might become an important MEMS/NEMS material:

- No intrinsic size limitation (like grain boundaries in crystalline materials)
- Perfectly isotropic
- Very large strength and strain
- Perfectly elastic (high Q factor)
- Some are very inert in most environments
- Very low processing temperature (60–400°C for various BMGs)

TABLE 5.10 Selected Properties and Processing Temperatures for BMGs with Potential for Microelectromechanical System and Microstructural Applications

BMG Material	Density (g/cm^3)	Yield Strength (MPa)	ε_{el} (%)	Y (GPa)	G (GPa)	B (GPa)	E_{el} (MPa)	ν	Thermoplastic Forming Temperature (°C)
$Au_{49}Ag_{5.5}Pd_{2.3}Cu_{26.9}Si_{16.3}$	11	1200	1.5	66.38	23.43	132.3	7.5	0.41	150–190

Fast Microfluidic CD Prototyping

In Volume I, Chapter 6, we analyzed CD-based microfluidics.[103] Here we detail some simple methods to implement fast prototyping of microfluidic CDs in a research laboratory setting.

Many microfluidic applications utilize relatively large volumes (on the order of 20 µL to several milliliters) that are not always compatible with typical microfabrication techniques. This holds especially true for biological applications, including sample preparation and nucleic acid analysis (see also Chapter 10, this volume, under sample preparation). Centrifugal platforms in which microfluidic CDs are used for biological analysis require these larger volumes and may feature small conduits and DNA analysis chambers, which means that a combination of macro- and microfabrication techniques must be used to create these devices.

Computer numerical control (CNC) machining can be used to create most macro features (>100 µm) on a microfluidic CD. Inexpensive plastics, such as polycarbonate (PC) or ABS, are used as substrates in which channels down to ~1 mm in width can be machined using standard endmill and drill bits (Figure 5.26, CNC machine, Quick Circuit 5000). The polymer substrate thicknesses can be as small as 200 µm. Using a layering approach, different sheets of thin machined plastic CDs can be laminated together using pressure-sensitive adhesive (PSA) layers (PSA-FLEX mount DFM 200 clear V-95). The PSA layers may be as thin as 100 µm and are cut using a CNC cutter-plotter (Figure 5.27, CNC plotter, Graphtec CE-2000-60). The use of PSA layers allows for channels as narrow as 250 µm. When sandwiched between two plastic sheets, these channels in the PSA connect the larger CNC machined reservoirs in the PC discs.

Even the simplest standard microfluidic CD consists of no fewer than five layers, as illustrated in Figure 5.28. Usually the fluidic compact discs made in our lab are composed of three optically clear polycarbonate disks held together by two pressure-

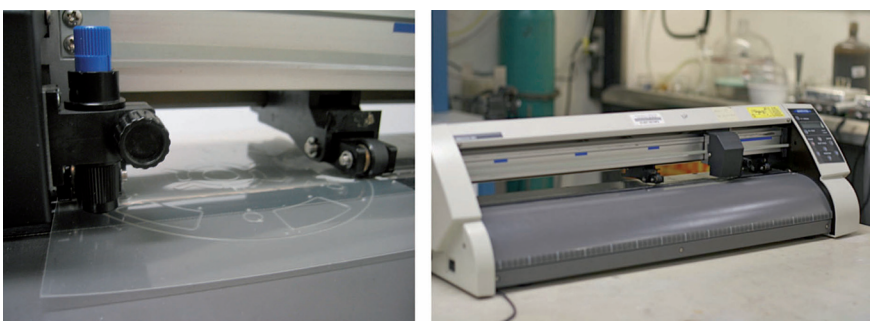

FIGURE 5.27 A roll-feed cutter plotter cuts out the pressure-sensitive adhesive layer designs. Graphtec CE-2000–60.

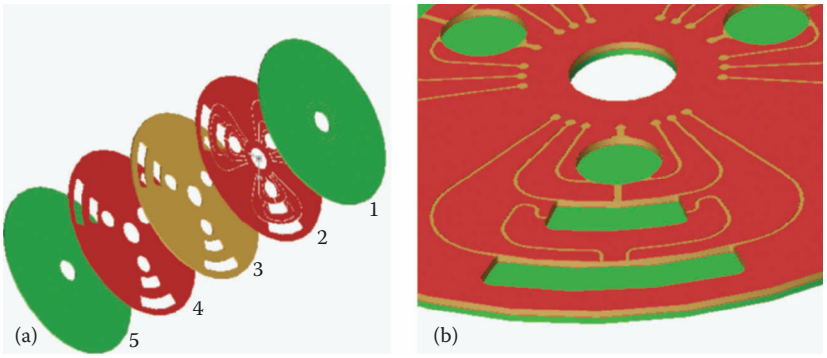

FIGURE 5.28 Computer numerical control (CNC) machined compact disc (CD) assembly. (a) Illustration showing five layers fabricated by a CNC machine and vinyl cutter: 1, top plate (1.2 mm); 2, pressure-sensitive adhesive layer (100 μm); 3, middle plate (1.2 mm); 4, pressure-sensitive adhesive layer (100 μm); 5, bottom disc (1.2 mm). (b) Schematic illustration of assembled CD structure.

sensitive adhesive layers. The top plate (including venting holes), the middle plate (containing all fluidic chambers), and the bottom plate contain the alignment holes at the same positions. Specifically, the five layers shown in Figure 5.28 are as follows: 1) top polycarbonate CD with CNC-machined sample loading, sample removal, and air venting holes; 2) pressure-sensitive adhesive with channel features cut using a plotter; 3) middle polycarbonate CD with machined channel features; 4) pressure-sensitive adhesive with channel features cut using a plotter; 5) solid bottom polycarbonate CD to seal off the channels. Microfluidic CD platforms can involve more layers to accommodate more complex fluidics. Moreover, different devices and substances can be placed inside the CD during fabrication, such as beads, lyophilized reagents, or filters. The CDs also can be exposed to O_2 plasma treatment or functionalized with bovine serum albumin to create hydrophilic and hydrophobic surfaces, respectively. Once the appropriate pieces have been designed and machined, they are aligned centrally and radially and laminated together using the PSA layers. The fabrication process ends with running the CDs through an industrial press to ensure excellent adhesion and sealing between all CD layers. After the assembled layers are pressed together, they are fed through a laminator to press the layers together tightly and ensure a good seal (Figure 5.29).

While the majority of CD platforms developed in our laboratory utilize standard macromachining processes as described above, microfabrication is easily integrated onto the CD platform. Integration usually takes the form of creating microfluidic polydimethylsiloxane (PDMS) molds on 6-in. Si wafers using multilevel, thick-resist lithography (Figure 5.30). Briefly, thick photoresist is spun on a Si wafer, prebaked to remove solvents, exposed to ultraviolet (UV) to catalyze cross-linking, postbaked to finish cross-linking, and developed to remove unexposed

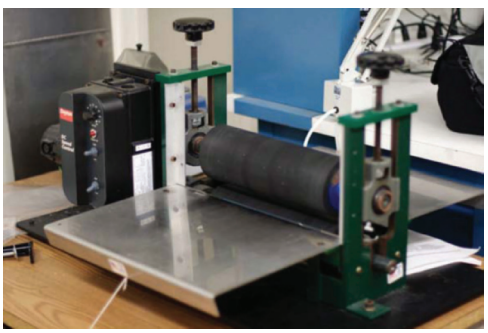

FIGURE 5.29 A laminator is used to press CNC machined discs together with pressure-sensitive adhesive layers.

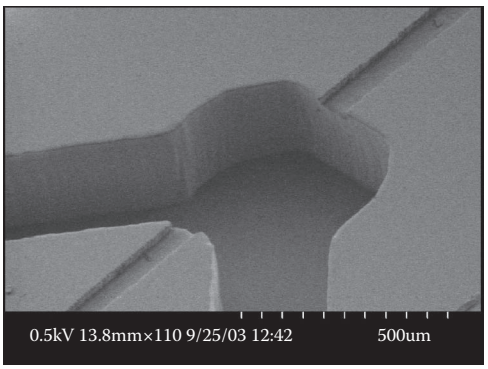

FIGURE 5.30 A scanning electron microscope image of a typical two-level polydimethylsiloxane flow cell structure. The microchannel is 25 μm deep, and the chamber is 250 μm deep.

photoresist. This creates the master mold (a negative of the desired channel features), upon which PDMS (a biocompatible elastomer) can be poured and cured. This process, termed soft lithography (see Volume II, Chapter 2), can be used to make many PDMS parts from a single Si mold.

Sample loading and venting holes can then be punched using small-gauge syringes, and the soft lithography PDMS parts (either 6-in. round entire PDMS CDs or individual microfluidic units) can be placed onto a polycarbonate CD, or in some cases bound to glass slides and secured with a specially designed slide holder CD. Most often, the passive binding properties of PDMS on glass/plastic are enough to prevent leakage during use. However, an O_2 plasma treatment process can be used to create a permanent bond with PDMS. Almost all processes and materials used to create the microfluidic CD platforms are relatively inexpensive, with the exception of the initial Si mold needed when incorporating microfabrication.

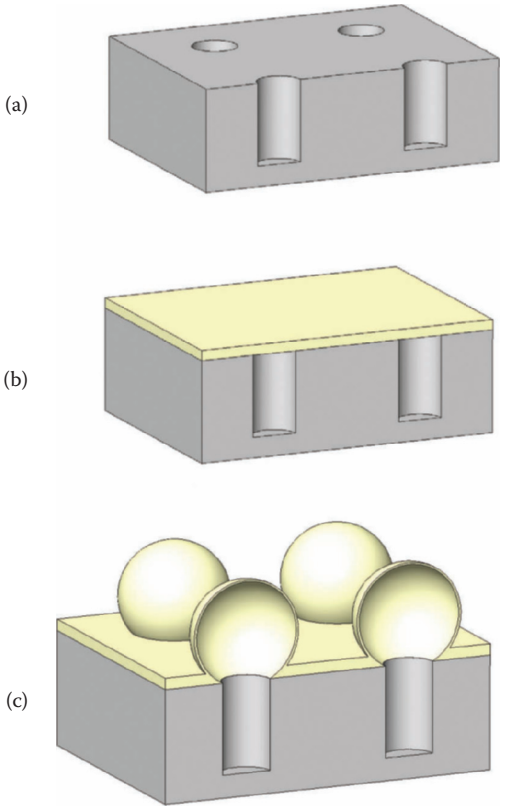

FIGURE 5.31 Micro glass blowing process sequence. (a) Step 1: etching of deep cavities in a silicon wafer. (b) Step 2: anodic bonding of glass wafer to the silicon wafer. (c) Step 3: blowing of glass spheres by heating sample inside furnace.

Micro Glass Blowing

Eklund and Shkel developed a wafer-level glass blowing process for the formation of three-dimensional glass microstructures.[104] In contrast to conventional glass blowing, where relatively large glass structures are shaped one at a time, the micro glass blowing process allows for parallel fabrication of thousands of microscopic glass parts.

The micro glass blowing fabrication process is illustrated in Figure 5.31. In a first step (Figure 5.31a), deep cylindrical cavities are dry etched in a silicon wafer. The etch mask (not shown) is removed, and a borosilicate glass wafer is anodically bonded to the silicon wafer (Figure 5.31b). Next, the parts are rapidly heated inside a furnace to a temperature above the softening point of the glass. This elevated temperature causes the pressure of the gas trapped inside the sealed cavities to increase. The glass deforms into spherical shapes because of the combination of the increased gas pressure and the low viscosity of the heated glass (Figure 5.31c).

The size of the blown glass spheres depends on the dimensions of the etched cavity, the furnace temperature, and the pressure and temperature at which the cavities are sealed. The total volume of the etched cavity and the blown glass sphere is proportional to the volume of the etched cavity, with the proportionality constant being the ratio between the final and initial temperatures. For example, if a cavity is sealed in atmospheric pressure and at room temperature and the furnace temperature is 900°C, the final volume is approximately four times as great as the volume of the etched cavity (1173 K vs. 295 K). The volume enclosed by only the glass sphere is therefore three times as great as the volume of the etched cavity.

In Figure 5.32 we show fabricated glass spheres, all with a diameter of approximately 900 µm. A layer of AZ P4620 photoresist was used as the etch mask during the deep reactive ion etching of the cylindrical cavities. For the sample shown in Figure 5.32a, a silicon wafer with a thickness of 450 µm was used, and the etched cavities were 350 µm deep and 750 µm in diameter. For the parts in Figure 5.32b and 5.32c, cavities with a depth of 750 µm and a

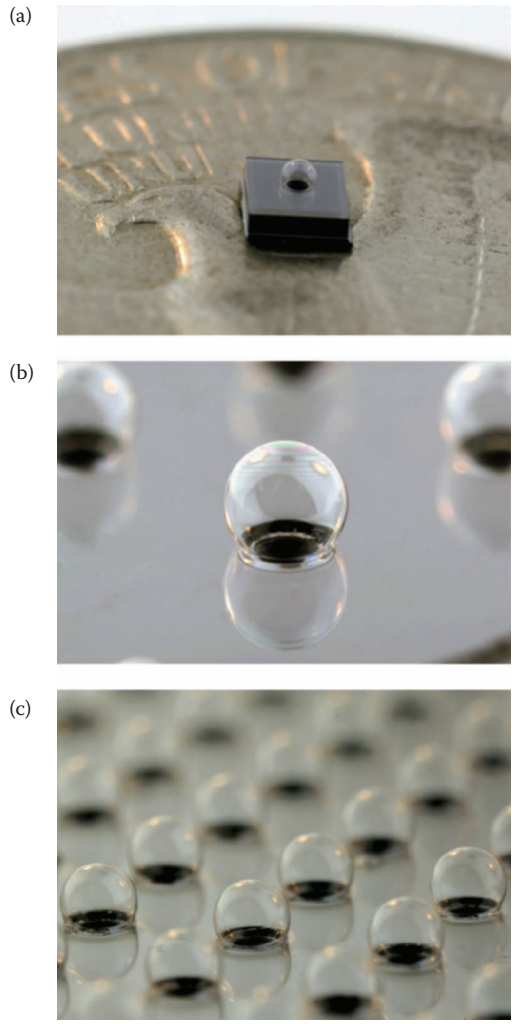

FIGURE 5.32 Fabricated glass structures. (a) Diced chip on US quarter coin. (b) Close-up of fabricated glass sphere. (c) Array of fabricated glass spheres.

diameter of 500 µm were etched in silicon wafers with a thickness of 1 mm. Pyrex 7740 glass wafers with an initial thickness of 100 µm were used for the anodic bonding of all samples, and the spheres were formed inside a furnace set to 850°C. This technology may be utilized for several different types of MEMS devices, including microfabricated glass lenses, three-dimensional microfluidic networks, and spherical gas confinement chambers for atomic MEMS.[105]

Biocompatibility and Surface Modification

Definition

Before new materials or devices can be used in conjunction with a biological system, whether cells or organisms, their effect on that system must be tested. In the simplest terms, a substance or device that has no effect on the time scale tested is said to be *biocompatible*. This can be verified at first by observing whether the material or device under study forms a suitable substrate for the growth of cultured cells. Such preliminary screening eliminates materials that have direct, harmful effects. To fully test the biocompatibility of a new material or device, one needs to test it on a wide range of different types of cells; for applications in humans, it also has to be tested on animals for any less direct effects. Biocompatibility is obviously a complex phenomenon. Some materials and devices are immediately toxic to all cells or organisms; some are toxic only to specific animals; others are harmful in the long term (e.g., carcinogens); others, while not toxic, may cause marked changes in the normal behavior of the system.[106] The definition of biocompatibility of a material or device also varies depending on how the material or device is to be used. If a device is to be implanted into a tissue, one may want the cells of the tissue to treat it as part of the tissue to stick to it and grow on it (not an advisable strategy for a chemical-type sensor where membranes might become blocked). But if a device is injected into the bloodstream, it is vital that the blood cells not stick to it, as this results in a clot, which could be fatal to the biological system. In the case of a medical nanorobot (perhaps a future version of a pharmacy-on-a-chip shown in Volume II, Figure 4.100) floating or swimming in the circulation, cell and tissue adhesion is again undesirable. The term *biocompatibility* evolved over time, and today an accepted working definition is the ability of a material or device to perform with an appropriate host response in a specific application.

History

Biocompatibility work has a long history. Two thousand years ago, gold was already used in dental applications; glass eyes and wooden teeth were introduced next, and plastics were developed in the early 1900s. After World War II, parachute cloth was used as vascular prosthesis. Finally, over the last two decades, active implants (implants providing more than a mechanical support function), such as

biosensors and drug delivery systems, have further challenged our understanding of biocompatibility issues. Indeed, in many of these active devices an efficient transport of chemicals to and from the device is essential, something that was not an issue for more traditional implants. Clogging of the pores or membranes in such active devices will render the device useless, though the device may remain perfectly harmless to the functioning of the biological system itself. Over the last fifteen years, considerable work has been directed to create nano- and microtextured surfaces that are cell-friendly and promote controlled cell growth. This promises to become another important application area for MEMS. One envisions substrates for cell culturing, the growth of nerves for neural implants, textures that encourage neural regeneration and the acceptance of prostheses, and microsubstrates for bioartificial organs and as a medium for the regeneration of tissues such as bone and tendon. Typical materials used or proposed, with or without nano- or microtexturing, include titanium, niobium, carbon, some ceramics, polyimide, some polyurethanes, Teflon, Parylene, Makrolon, polystyrene, PMMA, PEEK, polycarbonate, polypropylene, and silicone. Often, there are conflicting views (remember the breast implant controversy), and in vivo sensor applications remain so elusive that many companies have abandoned implantable devices all together and are focusing on ex vivo systems instead.[107] The field where perhaps the most progress has been made in terms of biocompatible materials evaluation is in the area of biomedical materials for drug delivery systems (see, e.g., Chapter 8, this volume, Table 8.20).[108–110] The biocompatibility of silicon was discussed in Volume I, Chapter 4.

Mechanism

A foreign material implanted in a host tissue causes a cascade of events to occur at the tissue/material interface. It starts with a noncovalent adsorption of plasma protein from blood onto the surface. This protein adsorption is quite a bit faster than the transport of host cells to the foreign surface. By the late 1960s, several researchers already knew that within 10 s of exposure to blood or plasma, a uniform ~6-nm layer of fibrinogen forms on surfaces such as Si, Pt, Ge, and Ta. Fibrinogen is a 340-kilodalton soluble plasma glycoprotein about 47.5 nm in length. It is the major surface protein. The protein-coated surface, in turn, mediates the types of cells that may adhere to the surface, which ultimately determines the type of tissue that forms in the vicinity of the implant. The type and state of adsorbed proteins, including their conformational changes, initiate coagulation via platelet adhesion, and subsequent collagen deposition leads to the encapsulation of the microdevice by fibrous tissue. Excessive fibrosis may cause tissue necrosis, granulomas, or tumor genesis.[111] The adsorption and denaturation of adsorbed fibrinogen molecules actually is commonly used as a biocompatibility indicator; the amounts of denatured fibrinogen accumulated on a surface correlates closely to the extent of biomaterial-mediated inflammation. Adsorbed amounts of denatured fibrinogen on surgical implants that are regarded "biocompatible" (such as titanium and stainless steel) are about ~2.1 mg/m^2 (the same as for CVD diamond).

There are two important viewpoints from which to approach biocompatibility:

1. The implant perspective: the protection of implanted devices against the corrosive effects of body fluids and tissue, their sterilizability, and continued operation.
2. The biological system perspective: the avoidance of blood clotting and long-term cytotoxicity, and the continued health of the host.

The former has been named *sensocompatibility*.[107] An important aspect of senscompatibility is biofouling, the adhesion of proteins and other organic matter on the sensor surface. As pointed out above, biofouling is a special concern for active implants such as biosensors (see, e.g., Volume II, Figure 4.92 for an in vivo pH, CO_2, and O_2 sensor), where an efficient transport of chemicals to and from the device is essential. Immune rejection during organ transplants may be prevented by pharmacologically depressing the immune system by the administration of cyclosporine. Such a strategy is, of course, not applicable for the long-term biocompatibility of implants, whether they are biosensors

or cell-transplant-based therapeutics—for example, Langerhans or pancreatic islets for type I diabetes,[112] cochlear implants, or heart pacemakers. Perhaps a pharmacy-on-the-chip, as shown in Volume II, Figure 4.100, could also monitor for biofouling and release anti-clotting chemicals such as heparin or herudin as required to maintain the function of the sensor. It should be kept in mind that biofouling occurs both for invasive and noninvasive sensors, but obviously intervention is easier with the latter. In Figure 5.33, we show a schematic of an amperometric invasive glucose sensor, perhaps the most widely studied and most "successful" implantable sensor to date.[107] It is assumed that the needle-type glucose sensor is embedded in tissue and in contact with blood (for details on the operation of amperometric glucose sensors, see Chapter 1, this volume).[113] Failure modes (many packaging related) include the following:

- Lead detachment (could be avoided with a telemetric device)
- Electrical short
- Membrane delamination
- Membrane biofouling
- Electrode passivation
- Enzyme degradation
- Membrane biodegradation
- Fibrous encapsulation
- Electrode fouling

Surface Modifications

Surface Modifications for Biocompatibility

Most success today for control of protein and cell adhesion on surfaces has been achieved by surface immobilization of polyethylene oxide or polyethylene glycol (PEG; one refers to a "pegylated surface") forming a water-soluble, nontoxic, and nonimmunogenic polymer film.[114,115] Zhang et al. modified silicon surfaces by covalent attachment of a self-assembled PEG film and demonstrated an effective suppression of both plasma protein adsorption and cell attachment to such modified silicon surfaces.[116] A pegylated surface may cut the amount of protein adsorbed down by a factor of ten. Glow-discharge plasma-deposited tetraethylene glycol dimethyl ether can reduce the fibrinogen adsorption to ~0.2 mg/m^2 (~350 molecules/μm^2) on many different types of substrates. A specific strategy to fabricate biocompatible ion-selective electrodes of the type shown in Volume I, Figure 7.45, implemented by Brooks et al.,[117] involves covalent attachment of heparin to the surface of derivatized cellulose triacetate membranes, which are subsequently impregnated with the potassium-selective ionophore valinomycin. The resulting ion-selective electrodes respond to potassium and have selectivity coefficients on the same order of magnitude as those of conventional poly(vinyl chloride)-based electrodes.

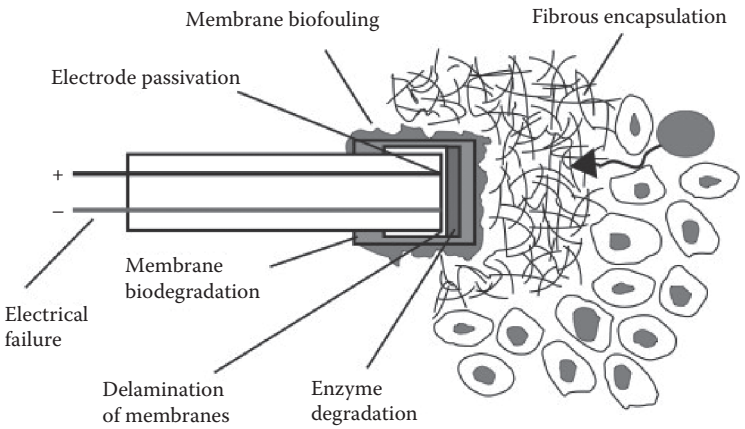

FIGURE 5.33 Schematic illustration of a blood-borne analyte exiting capillary and traversing to a needle-type glucose biosensor embedded in tissue. In addition to normal component failure—electrical failure, enzyme degradation, and membrane delamination—the sensor can fail for several physiologically related reasons, such as membrane biodegradation, electrode passivation, and reduction of analyte access due to fibrous encapsulation and membrane biofouling. (Based on Wisniewski, N., F. Moussy, and W. M. Reichert. 2000. Characterization of implantable biosensor membrane biofouling. *Fresenius J Anal Chem* 366:611–21.[107])

It was found that the heparin layer does not alter significantly the response characteristics of the electrodes. The biological activity of the immobilized heparin was measured in terms of its inactivation of blood coagulation factor Xa; the covalently anchored heparin was able to inactivate factor Xa.

Other approaches that have worked well to avoid protein adsorption are based on biomimetics. This involves the development of membranes that mimic the surface of biological membranes, that is, the design of "stealth" materials. The external region of a cell membrane, the glycocalyx, is studded with glycosylated molecules, which direct specific interactions such as cell-cell recognition and contribute to the steric repulsion that prevents undesirable nonspecific binding of other molecules or cells. By modifying a pyrolitic graphite surface with oligosaccharide surfactant polymers, which, like glycocalyx, provide a dense and confluent layer that mimics the nonadhesive properties of a cell layer, spontaneous adsorption on diverse hydrophobic surfaces is suppressed by at least ~90%.[118] The highly hydrated dextran in these layers protrudes into the aqueous phase and suppresses nonspecific adsorption of plasma proteins. Coating surfaces with phosphorylcholine groups to mimic red blood cell surfaces also leads to diminished protein adsorption. One such material is poly(methacryloyloxyethyl phosphorylcholine-co-*n*-butylmethacrylate) (see Figure 5.34). This polymer, which behaves as a hydrogel, shows very low protein and cell adsorption. Studies have revealed that sensors coated with this hydrogel demonstrate excellent sensor response characteristics, while scanning electron microscopy (SEM) of the surface of the sensors indicates no platelet adhesion. The antifouling characteristics are again believed to be due to the extreme hydrophilic nature of the surface layer; proteins have difficulty adsorbing on the surface because of the layer of bound water.[119] For a further review of in vivo biosensors, consult Frasier;[120] for surface modification strategies, see Wisniewski and Reichert.[121]

Questions

Questions by Dr. Marc Madou assisted by Mr. Omid Rohani, UC Irvine

5.1: What properties make silicon a good mechanical sensor/actuator substrate?

5.2: What has prevented Si-MEMS oscillators from becoming a serious alternative to quartz so far?

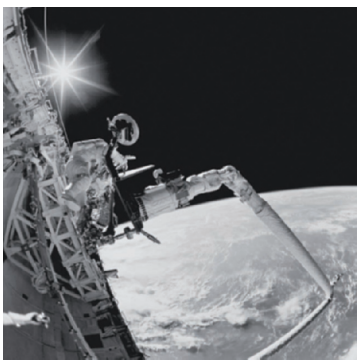
5.3: What are the possible applications of GaAs in general and GaAs MEMS in particular?

5.4: What are the two most suitable diamond variations for MEMS application? Explain briefly.

5.5: What method would you suggest for patterning convex hollow structures?

5.6: What are the main advantages of ceramics MEMS compared to other materials?

5.7: NASA's space shuttle has a long manipulator robot arm, also known as the Shuttle Remote Manipulator System or SRMS (see figure below), that permits astronauts to launch and retrieve satellites. It is also used to view and monitor the outside of the space shuttle using a mounted video camera. Select a suitable material for the arm.



5.8: List some of the applications of nonphotosensitive and photosensitive polyimides in microtechnology.

5.9: How does an increase in Si content in silicon nitride change the following parameters?
(a) Tensile film stress
(b) Film transparency
(c) HF etch rate

5.10: In the micro glass blowing method, what are the parameters on which the sizes of blown glass spheres depend?

5.11: Describe the merits and problems associated with micromachining in GaAs, Si, diamond, and 3C-SiC.

5.12: (a) Detail the C-MEMS process.
(b) What advantages might a C-MEMS world have compared to a Si-world?

5.13: What are bulk metallic glasses (BMGs)? What are their properties? How would you use them in MEMS and NEMS?

5.14: Present a definition of biocompatibility of a MEMS structure.

5.15: A thermistor is a device used to measure temperature by taking advantage of the change in electrical conductivity when the temperature changes. Select a material that might serve as a thermistor in the 500 to 1000°C temperature range.

5.16: Describe the ionic bonding between magnesium and chlorine. What are the consequences for the projected strength of the compound that forms and the electronic/ionic conductivity of such a compound?

5.17: Silica (SiO_2) is often given as an example of a covalently bonded material. In reality, silica exhibits both ionic and covalent bonding. What fraction of the bonding is covalent? Give some example applications in which silica is used. To answer this question first find a figure that plots electronegativity vs. atom type.

5.18: Silica is used for making long lengths of optical fibers (see figure below). Being a covalently and ionically bonded material, the strength of the Si-O bonds is expected to be high. Other factors such as susceptibility of silica surfaces to react with water vapor in atmosphere have a deleterious effect on the strength of silica fibers. Given this, what design strategies can you think of such that silica fibers could still be bent to a considerable degree without breaking?

5.19: Define each of the following terms: stress, strain, elastic modulus, Young's modulus of typical materials (ceramics, glasses, semiconductors, metals, and polymers), Poisson's ratio, and yield strength.

5.20: Why are p-type piezoresistors most commonly used in Si pressure sensors?

5.21: In the context of using piezoresistivity to sense strain, what are the advantages/disadvantages of using silicon versus silicon nitride for pressure sensor diaphragms? How does residual stress affect the sensitivity?

In a new field such as nanotechnology it is often the consultants and conference organizers making the only money. Another group often cashing in early are measuring instrument or metrology developers. Edwards compared this to the hardware stores and whorehouses making more money in the gold rush of 1849 than the actual gold miners. (Steven A. Edwards, in *The Nanotech Pioneers,* 2006.)

Steven A. Edwards

Introduction

This chapter is divided into two parts; one deals with metrology of microelectromechanical systems (MEMS) and nanoelectromechanical systems (NEMS), the other with their modeling. Metrology is the science that deals with measurements. Tools for MEMS and NEMS metrology are either analytical techniques derived from analytical chemistry or size measuring techniques borrowed from the semiconductor industry. We start the metrology section by exploring techniques to visualize MEMS and NEMS devices and to measure sizes such as film thickness and critical dimensions (CDs), i.e., dimensional metrology. Dimensional metrology tools we cover are light microscopes (including dark-field, bright-field, phase contrast, and fluorescence), scanning confocal and two-photon microscopes, white light interferometers, ellipsometers, scanning electron

microscopes (SEMs), and a set of scanning proximal probe microscopes (SPMs) including scanning near-field optical microscopes (NSOMs or SNOMs), scanning tunneling microscopes (STMs), and atomic force microscopes (AFMs).

In the category of material property measuring equipment, we start with a review of specialized SPMs for material property determination. SPMs are used not only to visualize structures (see SNOM, STM, and AFM, above) but also to analyze a wide variety of material properties such as magnetic, thermal, and mechanical behavior. We then consider tools used to measure conductivity and carrier type of a material. MEMS devices often are mechanically dynamic by nature, hence the need to measure dynamic motion of MEMS devices. We study mechanical properties using interferometry with a stroboscopic light-emitting diode (LED) to freeze device motion and laser Doppler vibrometry to measure contactless velocity and displacement of vibrating structures.

Next are examples of metrology techniques to analyze structure of samples (e.g., crystallinity, defects, and surface roughness) and finally analytical techniques for chemical composition. In the structural metrology category, we review stylus profilometry, which can be used for surface roughness and transmission electron microscopy (TEM) with utility for crystallinity determination. As examples of elemental analysis of surfaces, we discuss energy dispersive analysis of x-rays (EDAX), a standard procedure for identifying and quantifying elemental composition of specimen surfaces to shallow depths, and scanning Auger microscopy (SAM), which can identify every atom from lithium on up.

We close off the metrology section by looking at MEMS approaches to metrology. This includes on-chip MEMS devices to measure physical properties such as stress, Young's modulus, Poisson ratio, natural frequency, etc.

Modeling is the use of mathematical equations to simulate and predict real events and processes. In the modeling section, we introduce finite element analysis and review software packages helpful in the design phase of miniaturized devices, that is, software for computer-aided design (CAD) in MEMS. The emphasis in this modeling section is on MEMS modeling. NEMS and BIONEMS require molecular and quantum effect modeling. These techniques are used to construct, display, manipulate, simulate, and analyze molecular structures and to calculate their properties. The topic is beyond the scope of the current work, and only some useful software packages will be referred to.

Metrology

Introduction

The history of the last two industrial revolutions—first the machine revolution (1800–1920) and second the semiconductor revolution (1950–2010)—reveals that a nanotechnology revolution might not happen until the considerable lag of new nanometrology technologies has been remedied. During the machine revolution, the milli-inch (1 mil = 25 μm) was the measuring stick, and it could be gauged by vernier calipers. The semiconductor industry today has as a dominant measure 50 nm, accessible through electron imaging and SPMs. The nanometer revolution is centered at the 1 nm length-scale, for which we do not yet have the appropriate high-throughput tools. Today, high-throughput imaging or measuring sub-30-nm features, using a conventional SEM or SPMs (say, an AFM or an STM), results in fuzzy, noisy images. Fast, sharp, low-noise images at the nanoscale will take Herculean efforts. This does not bode well for the swift arrival of so-called *nanomanufacturing*, where rapid, accurate, high-resolution measurements are essential for profitability. On the positive side, in research settings, measurements, images, and motion can be controlled to within 10 picometers (10^{-11} m).

MEMS and NEMS metrology includes CD measurements of metal lines on an accelerometer, establishing surface roughness of a pressure sensitive membrane, determining compositional profiles of a pn-junction, and measuring magnetic, mechanical, electrical, and optical properties (see Figure 6.1). Accordingly, metrology equipment is divided into dimensional metrology (I), material property studies (electrical, optical, magnetic, mechanical, etc.) (II), structure identification (surface roughness, defects, crystallinity) (III), and chemical composition

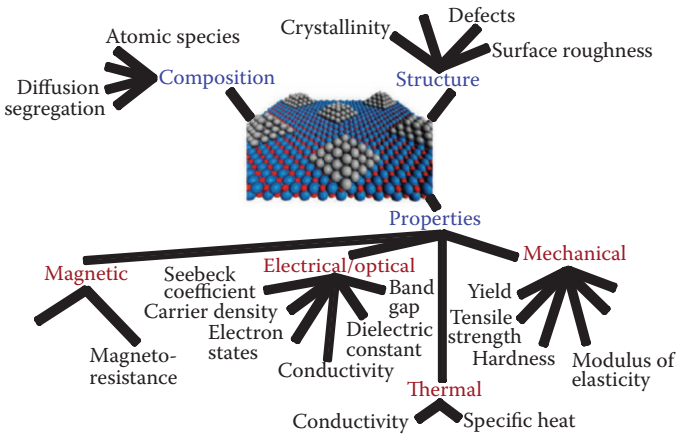

FIGURE 6.1 Characterizing integrated circuits, microelectromechanical systems, and nanoelectromechanical systems.

analysis (IV). In Table 6.1, we group metrology techniques in these four categories and list examples of typical tools.

Several metrology tools are used for different types of metrology. For example, scanning electron microscopy (SEM) can be used for dimensional metrology [e.g., to measure the CD of an integrated circuit (IC)] as well as in structural metrology (e.g., to measure defects in an IC). If the SEM comes equipped with EDAX, which it often does, chemical composition information can be collected as well. Similarly, SPMs may image MEMS, measure their size, or establish important material properties.

The measurement tools in Table 6.1, when used in IC, MEMS, or NEMS manufacturing, are further described as being stand-alone or integrated with the manufacturing line.[1] A stand-alone tool is a separate piece of equipment that is either off-line, at-line, or in-line. Off-line is an instrument that is available only outside the fab (usually involves destructive or contaminating testing). An at-line piece of equipment is one that is available in the fab itself, and in-line tools are used during production to measure, for example, processed Si wafers. An integrated tool is one that is combined with a manufacturing line and is either on-line or in situ. An on-line tool is available at the process workstation to measure patterned wafers but is not able to measure during wafer processing. In the sections below, we select some of these techniques for further scrutiny. In Table 6.2 additional characteristics of the most important metrology techniques from Table 6.1 are listed, and in Figure 6.2 we compare this most important set of analytical tools in terms of detection limit, sampling depth, and spot size.

Tools to See and Size: Dimensional Metrology

Introduction

An important category in metrology equipment comprises seeing and sizing tools, for example, to image an etched profile in a MEMS structure, to measure film thickness, or to determine a critical dimension (CD) on an IC. From Table 6.1, seeing tools range from optical microscopy (OM), to scanning electron microscopy (SEM) and scanning proximal probe microscopes (SPMs), including scanning tunneling microscopy (STM), atomic force microscopy (AFM), and scanning near-field optical microscopy (NSOM or SNOM). Film thickness is accessible, for example, through ellipsometry, photoacoustic measurements, x-ray fluorescence (XRF), reflection spectroscopy, and interferometry. CD in ICs and MEMS and NEMS are typically measured using a scanning electron microscope (CD-SEM) or an atomic force microscope (CD-AFM) with subnanometer resolution and accuracy. In the sub-100-nm IC generations, CDs are becoming harder and harder to control. With 65-nm features, for example, one typically has an error budget of only ±5 nm and current CD-SEM metrology techniques offer about ±2 nm precision. An AFM, in theory, should provide better resolution, but unfortunately AFM scanning is slow and suffers from probe tip wear. Another entry in CD measurements is the use of scatterometry that involves measurements on IC wafers by diffraction from grating test patterns. Scatterometry is a faster and more economic way to characterize periodic patterns on a wafer to relieve/bypass the heavy workload of CD-SEM and CD-AFM in a typical fab. Scatterometry involves flood exposure of a field, the measurement of changes in the polarization state of the reflected light, and calculation of IC-structure characteristics via real-time or library-based regression software algorithms. With visible light, scatterometry affords a resolution, R, of about 0.15 nm and can deliver multiple measurements, including

Table 6.1 Metrology Equipment for Integrated Circuits, Microelectromechanical Systems, and Nanoelectromechanical Systems

	Examples	Abbreviation
Dimensional metrology (e.g., film thickness, CD) (I)		
	High-resolution microscopy (R = diffraction limit, ~150 nm)	HM

R, resolution.

CDs, feature shapes (i.e., CD profiles), overlay, and film thickness on patterned structures, including stacked films. Because scatterometry tools are diffraction based, the target must be a periodic structure that consists of a single feature repeated with a well-defined pitch. The technique cannot measure isolated single lines or more complex three-dimensional (3D) shapes.

There is a need not only for sizing metrology with faster throughput but also for more equipment that provides 3D information, not only in ICs but particularly for the newer areas of MEMS and NEMS, which add a more prominent *z*-dimension to parts. These three-dimensional parts require metrology tools that can measure in three dimensions. Most available tools are two-dimensional (2D) in nature, and measurements are made on the top or bottom of the microcomponent and use an algorithm to provide a pseudo-3D image (2.5D in reality), as often no sidewall information is available.

We cannot detail all tools that are available for dimensional metrology and limit ourselves to a review of light microscopes (including dark-field, light-field, phase contrast, and fluorescence), scanning confocal and two-photon microscopy, white light interferometry, scanning electron microscopy (SEM), NSOM, STMs, AFMs, and ellipsometry.

Light Microscopy

Since the resolution of the human eye is limited to about 100 micrometers, microscopes have always been the engines for new discoveries. Optical microscopy (OM) is usually what one thinks of when studying microscopy; this is also where we are starting our discussion. It was in 1590 that the Dutch spectacle-makers Hans Janssen and his son Zacharias Janssen invented a compound microscope with a magnification of ×3 to ×9. Robert Hooke, in 1665, published *Micrographia*, a collection of biological micrographs and he coined the word *cell* for the structures he observed in cork bark. In 1674 Anton van Leeuwenhoek improved on a simple microscope for viewing biological specimens and discovered bacteria (from tooth scrapings), protozoans (from pond water—he called them *animalcules*), sperm (his own, we presume), and blood cells (magnification of ×270). In Table 6.3, a brief history of microscopy is provided. The table includes light microscopy as well as electron microscopy, proximal probe microscopy, and near field superlenses.

Table 6.2 Metrology for Integrated Circuits (ICs), Microelectromechanical Systems (MEMS), and Nanoelectromechanical Systems (NEMS)

	Spot Size or Probe Area	Resolution/ Magnification	Thickness Range	Applications	Remarks (n = Refractive Index)
Reflection spectroscopy (visible: 400–900 nm)	3.5–50 μm		40 Å to 5 μm	Nonabsorbing films.	Limit measures below 100 Å, n measures only above 700 Å. Fast.
Reflection spectroscopy (UV: 200–400 nm)	10 μm		25 Å to 2 μm	Transparent very thin films on metals.	Limit measures below 50 Å, n measures only above 100 Å.
Ellipsometry (632.8 nm standard), 790, 830, 1,300, and 1,500 nm (optional)	12–100 μm	1–2 μm	10–1,000 Å	Nonabsorbing films.	Automated, highest accuracy. Thickness and n measurements.
Optical microscopes		Magnification 10–1,000	0.3–0 5 μm	Universal tool for all dimensions > 0.29 μm.	Poor depth of field.
Scanning electron microscope (SEM)	Spots down to 10–30 Å	Lateral: –35 Å (standard SEM); –9 Å (field-emission SEM); –150 Å (low-voltage SEM); magnification is 20–150,000		SEM pictures, CD measures below 0.8 μm.	Good for surface topography. Large depth of focus. Needs vacuum. Can be destructive.
Transmission electron microscope (TEM)	10 Å	1–2 Å (resolving power 10^4 times better than optical microscope). Magnification is 500–500,000	10 Å to 1 μm	Atomic structure defect analysis nanoprobe.	Requires thin sample preparation.
Scanning acoustic microscopy	1.3 mm (50 MH_z)	Lateral: 10 nm to 2 mm Depth: 10 nm to 5 mm	Signal pene trates 1λ	Inspection inside a ceramic packaged IC. Interface inspection, wide range of samples.	Nondestructive. Subsurface information. Needs liquid medium.
Stylus profilometer	Tip size limits bandwidth	Resolution of better than 1 Å and lateral resolution of ~0.03 mm		Measures sharp steps from a few angstroms to several micrometers. Materials and process R&D, low volume QC.	Measures surface profile using a contact stylus. May damage soft samples.
Nomarski microscope (differential interference contrast)	0.3 μm			Separation of images of different layers. Sample roughness inspection.	Pseudo-three-dimensional image.
Confocal laser scanning microscope (CLSM)	0.3 μm	0.3 μm	<1 μm	Cross-sectioning. Independent layer imaging.	Nondestructive. No vacuum. Diffraction limit resolution.
Atomic force microscope (AFM)	Radius of curvature of probe tip: 50–100 Å	Atomic imaging (one atom)	<1 Å	Surface roughness. Tribology.	Slow scan. Probe tip wear. Non-destructive.

TABLE 6.2 Metrology for Integrated Circuits (ICs), Microelectromechanical Systems (MEMS), and Nanoelectromechanical Systems (NEMS) (*Continued*)

	Spot Size or Probe Area	Resolution/ Magnification	Thickness Range	Applications	Remarks (n = Refractive Index)
Total integrated scattering		With visible light 0.15 μm is possible		Lithography control, etch structure monitoring and metal grain size determination.	Nondestructive, rapid quantitative process monitor.
Scanning tunneling microscope	50–100 Å	Lateral: 0.1–1 nm Depth: 0.1 nm		Atomic resolution. measurement of chemical properties.	Sample must be conduct. Slow scan. Probe wear. Cannot measure surfaces larger than a few μm^2.
Optical interference microscope		Lateral: 0.2–2 μm Depth: 400 μm to 2 cm		Cross-sectioning.	Lateral resolution limited by diffraction.
Near-field scanning optical microscope	0.02–4 μm Depth: 10 nm	Lateral: 1–200 nm		General imaging. Lithography.	No vacuum.

Table 6.3 Seeing Better and Better

Year	Researcher	Discovery/Instrument
1590	Hans and Zacharias Janssen	First compound microscope, magnification × 3 and × 9
1590–1609	Galileo	One of the earliest microscopists; came up with the term *microscope*
1660	Marcello Malpighi	Father of embryology and early histology-observed blood capillaries
1665	Robert Hooke	Publishes the book *Micrographia* with the study of thin slices of cork
1674	Anton van Leeuwenhook	Microscope with ×275 magnification 1827	Robert Brown	While examining pollen grains and the spores of mosses suspended in water under a microscope, Brown observed minute particles within vacuoles in the pollen grains executing a continuous jittery motion.
1860s	Ernst Abbe (1840-1905)	The Abbe sine condition: intrinsic diffraction limit
1926	Jean Baptiste Perrin	After Albert Einstein published his theoretical explanation of Brownian motion in terms of atoms (1905), Perrin did the experimental work to test Einstein's predictions, thereby settling the century-long dispute about John Dalton's atomic theory.
1931	Ernst Ruska and Max Knoll	The first electron microscope [a transmission electron microscope (TEM)]
1935	Frits Zernike	The phase contrast microscope
1936	Erwin Müller	The field emission microscope (FEM)
1951	Erwin Müller	The field ion microscope (FIM). Müller published his historic first FIM paper describing the significant improvement in contrast and resolution brought about by imaging with positive (hydrogen) ions compared with imaging by FEM and presenting the first evidence that atomic resolution was achieved.

Table 6.3 Seeing Better and Better (*Continued*)

Year	Researcher	Discovery/Instrument
1957	Marvin Minsky	Confocal microscope
1967	Erwin Müller (the same Müller)	The first atom probe, also known as the *atom probe field ion microscope,* incorporates FIM capability to give an atomic map of the specimen surface, by means of which the user selects atoms for chemical identification by time-of-flight mass spectrometry.
1981	G. Binnig, H. Rohrer	The scanning tunneling microscope (STM)
1984	Pohl	Near-field optical microscope
1986	Binnig, Quate, Gerber	The atomic force microscope (AFM)
1988	A. Cerezo, T. Godfrey, G. Smith	Added a position-sensitive detector to the atom probe → 3D
1988	Kingo Itaya	The electrochemical scanning tunneling microscope
1991	M. Nonnenmacher, M. P. O'Boyle, and H. K. Wickramasinghe	Kelvin probe force microscope is the Kelvin mode of scanning probe microscopy; it measures contact potential difference between the probe and the sample.
2003	Zhang	Silver near-field superlens

The first lenses were made in about 1000 AD, and spectacles came about around 1200 AD. From Table 6.3, it is obvious that optical microscopes have come a long way since van Leeuwenhoek's animalcules (1674), Brown's observation of moving pollen grains (Brownian motion) (1827), and Jean Perrin's demonstration of Einstein's proof that atoms really do exist (1926 Nobel Prize for Physics) by observing the distribution of particles undergoing Brownian motion. Ernst Ruska and Max Knoll invented the electron microscope in 1931, interestingly; at first they were working with the electron as a particle concept. But as de Broglie showed, the wavelength of an electron is 100,000 times smaller than the smallest wavelength of light, small enough to allow for 2.2-Å resolution. That type of resolution was only achieved forty years after Ruska and Knoll's breakthrough, and by the 1970s, researchers were able to visualize individual proteins and DNA molecules.

Microscopy helps to describe the size and structure of samples. This information is often critical for understanding the mechanisms of forming the sample or of the observed performance of the material. A very important question to ask regarding a microscope is about its ultimate resolution: what is the smallest feature size that it can resolve? Resolution is usually different when comparing lateral resolution (resolution in the plane of the sample) and vertical resolution. One also needs to know the dynamic range of the instrument. Techniques that have a high resolution often are not able to image large objects or feature sizes that vary over several orders of magnitude (they have a small field of view).

Roughly speaking, the lateral resolution of an optical microscope is limited to Abbe's limit, about 1/2 of the wavelength of the light being diffracted through the optical lensing elements of the microscope [i.e., Abbe's formula: $R = \lambda/2NA$, with $NA = n \sin \theta_{max}$ (see Volume I, Equations 5.6 and 5.3)]. In theory, the R using visible light (shortest wavelength is 400 nm) and the best numerical aperture (NA) (1.4) is about 200 nm, but in practice it is challenging to get good optical resolution down to the 1-μm range. Based on Abbe's formula, the lateral R of a microscope can be improved by working at shorter wavelengths, λ, by using a higher aperture lens (Figure 6.3) and

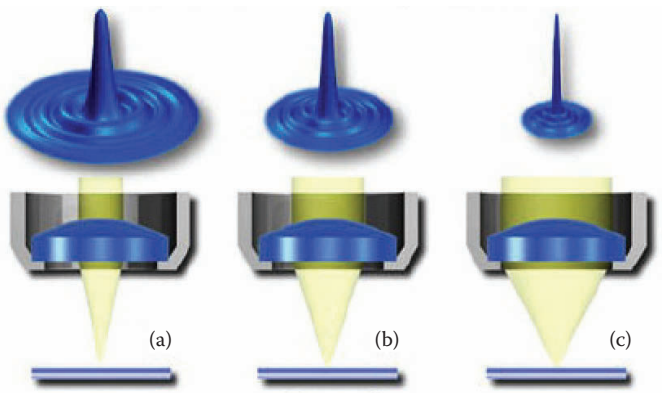

FIGURE 6.3 Increasing numerical aperture (NA) of the lens from (a) to (c). As NA increases, the acceptance angle increases and the Airy disc decreases.

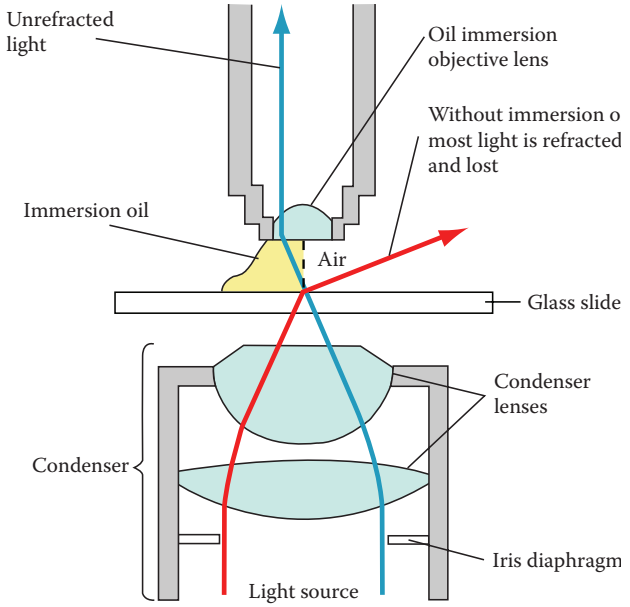

FIGURE 6.4 Oil immersion microscopy: increasing the refractive index of the medium (*n*).

in a medium with a higher index of refraction (*n*) (Figure 6.4). A larger NA means that the lens has a larger acceptance angle, so it can collect higher orders of diffracted light enhancing the resolution of the image. Working with oil between sample and objective lens, in so-called *oil immersion microscopy*, ensures a better capture of all diffracted wavelengths. The refractive index n (1.0 in air, 1.33 in water, and 1.55 in immersion oil) is the light-bending ability of a medium. The light coming from a sample under the microscope may bend in air so much that it misses the small, high-magnification lens. Immersion oil is used to keep light from bending too far.

The Abbe imaging resolution is a theoretical limit. Light passing through a circular aperture interferes with itself, creating ring-shaped diffraction patterns, known as *Airy patterns*, that blur the image (Volume I, Figures 5.13 and 5.14), and the Rayleigh criterion, which takes these Airy patterns into account, yields a minimum spatial resolution as follows:

$$R = \frac{0.61\,\lambda}{NA} \qquad \text{(Volume I, Equation 5.13)}$$

Objective lenses in a microscope are designed to correct for aberrations: achromats are the lowest level of correction, and apochromats, are the highest and most sophisticated. Eyepieces can have a reticle (graticle) etched inside to impose a scale on an image for measurement purposes. Light microscopy often is divided up into bright-field, dark-field, phase contrast, and fluorescence microscopy. In Figure 6.5 we illustrate bright-field (Figure 6.5a), dark-field (Figure 6.5b), and phase-contrast microscopy (Figure 6.5c). In bright-field microscopy, dark objects are

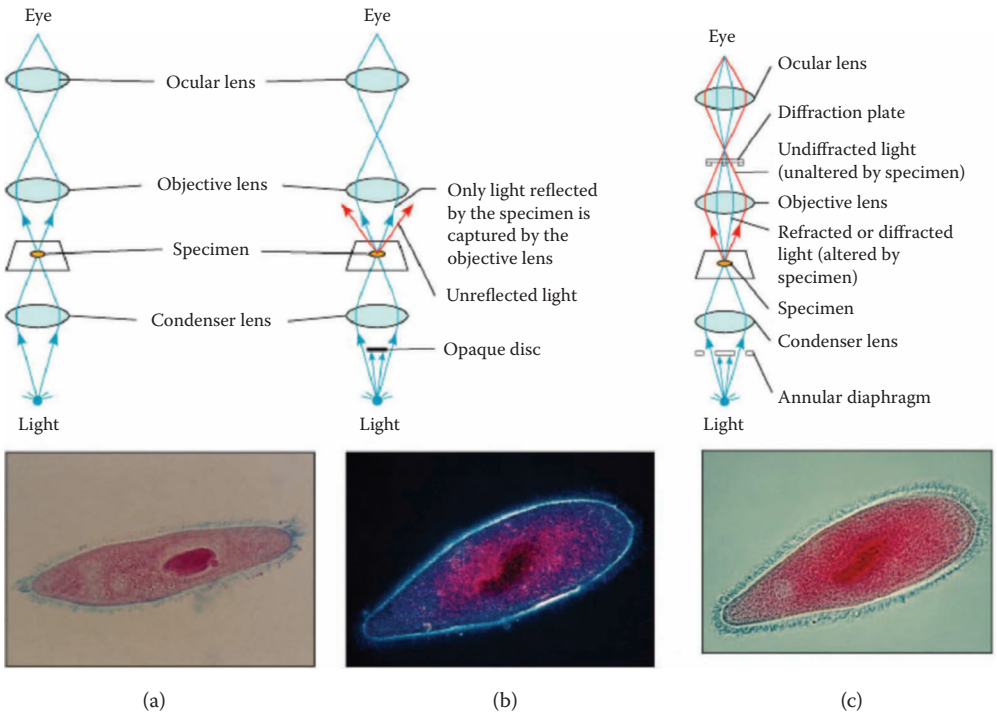

FIGURE 6.5 Comparison of (a) bright-field, (b) dark-field, and (c) phase-microscopy of a protozoa.

made visible against a bright background, and in dark-field microscopy, light objects are made visible against a dark background. In bright-field illumination, light reflected off the sample does not enter the objective lens, whereas in dark field it does.

The human eye does not see phase changes in a light beam directly. This is unfortunate, as phase changes carry a large amount of additional information about a sample. To make a phase change visible, one needs to combine the light passing through the sample with a reference so that the resulting interference reveals the phase information of the sample. In phase-contrast microscopy, one uses an annular transparent phase plate* so that the change in phase of light that passes through the sample is increased by shifting back ¼ wavelength relative to the background, while background light is shifted forward ¼ wavelength. When the waves recombine they produce a ½-wavelength shift, resulting in excellent contrast. The phase contrast microscope converts these phase changes to changes in brightness that the eye can see. A differential interference contrast (DIC) microscope, also known as a *Nomarski microscope*, is similar to a phase contrast microscope in that imaging again produces amplitude difference from phase differences in the specimen. The Nomarski microscope uses polarized light and emphasis differences in the refractive index of transparent samples. This gives relief to a sample corresponding to the variation of optical density. In Figure 6.6, we show a standard light microscope (Olympus BH2).

In Table 6.4, we compare the resolution of various types of optical microscopes. For a discussion of NSOM, see below.

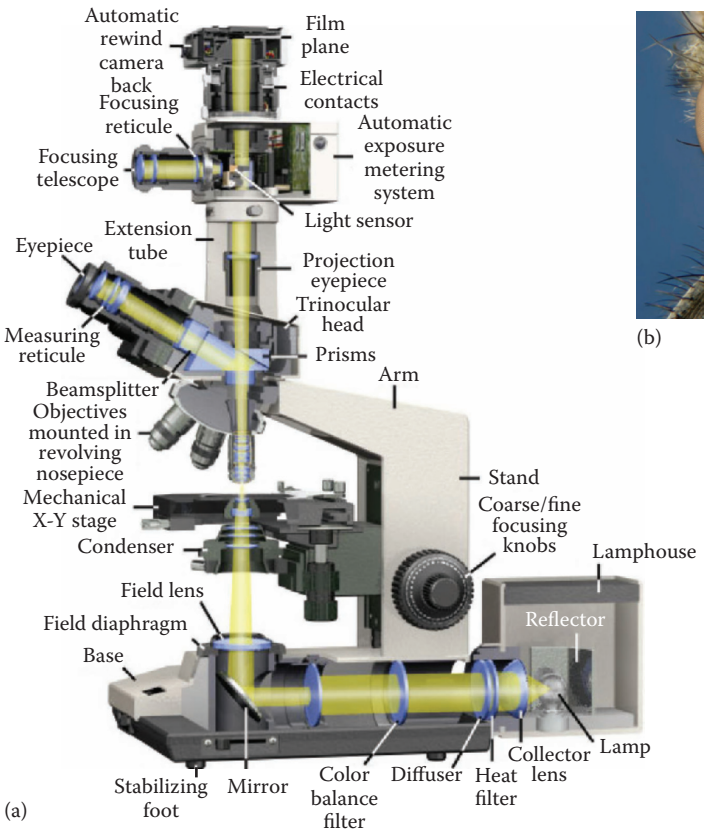
Vibration is a fundamental problem in all microscopy experiments. Buildings vibrate because of motors, air conditioners, passing vehicles, etc. Vibrations blur images since the excitation, detection, and sample regions of the microscopes may move with respect to each other during the course of the experiment. Most buildings have vibrational resonances in the 1–100 Hz range and feature amplitudes in the micrometer range. The effect of vibrations is mitigated by constructing the microscope on stages connected to each other either very rigidly or very loosely. The rigid connections permit the transmission of only high-frequency vibrations, while the loose connections permit only low-frequency vibrations. Compare this with the implementation of high-pass and low-pass filters in optics or electronics. Often, this filtering is achieved by building the microscope to be as small and rigid as possible and then mounting the entire system on pneumatically supported legs that couple only loosely to the building. Sometimes an additional stage using soft springs is included. While these procedures reduce mechanical vibration, acoustical vibrations may still couple to the microscope and circumvent these vibration isolation stages. Including a surrounding of acoustic-absorbing material is often necessary for the best microscopy work.

Light Microscopy Summary

Optical microscopes have the great advantages of being fast, in situ,† and nondestructive. Test parts usually do not have to be modified [e.g., coated with a conductive material, as in scanning electron microscopy (SEM)] from their original form/condition. Quantitation in light microscopy may be achieved with a reticle etched into one of the eyepieces. Images can be registered on film or, better, recorded electronically to a charge-coupled device (CCD) camera. Optical microscopes tend to be repeatable for features as small as 0.25 μm. Optical metrology hardware has a resolution that is diffraction limited, and it has a poor ability to produce images with clear intensity changes to accurately detect edges. Often locating the edge of a part is quite difficult, as location varies with lighting condition, noise, and assumptions made in the edge position algorithm.[2] Other significant errors of optical techniques typically stem from interference, resonance, shadowing, secondary reflections, and lens distortions. Perhaps the most important limitation of optical

* Rings in a phase plate can include attenuating layers (absorption but no phase shift), phase-shifting layers (phase shift but no absorption), or any combination of the two.

† In situ experiment: an experiment performed on a sample while it is still located in its native environment. With an in situ measurement, there is less risk of altering the sample's true properties. Ex situ experiment: an experiment performed on a sample after it has been removed from the location wherein it was formed. A wider range of experimental techniques are available.



(b)

microscopes for MEMS inspection is the inability to acquire true three-dimensional data. Some optical microscopes are integrated with software that uses image-processing techniques to determine the *z*-height at which the image is taking place. The current state-of-the-art software uses a projected grid (a Ronchi grid) to determine the height at which the microscope is focused in one region of the image. If the region selected has multiple focus points (i.e., the region selected is not all on one plane), the algorithm assigns the average value for the *z*-height. Further edge detection algorithms are run to extract *x* and *y* data from the microscope image. This technique, in theory, produces three-dimensional data from an image; however, the algorithms used after finding the *z*-height in one location of the image assume that all of the data are on the same plane. Thus, the data acquired from vision systems such as these can be characterized as 2.5D data sets.[2]

TABLE 6.4 Resolution of Various Types of Optical Microscopes

Objective (Magnification/ Numerical Aperture)	Illumination	Resolution (μm)
×10/0.25	White light	1.34
×20/0.40	White light	0.84
×100/0.95	White light	0.35

Fluorescence Microscopy

In BIOMEMS, fluorescence microscopy is a most important tool by which to study cells, DNA arrays, tissue, etc. It is used to study properties of samples

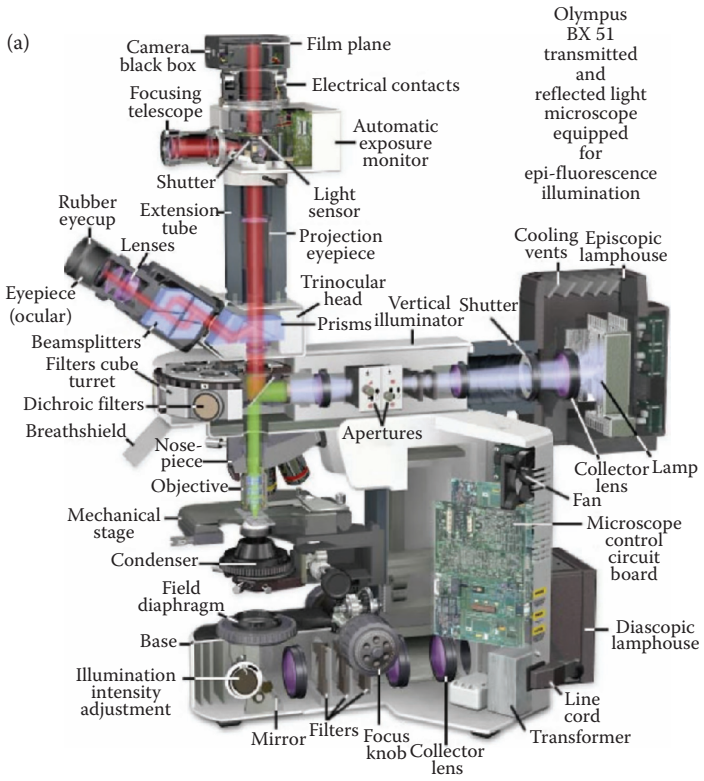

FIGURE 6.7 (a) Typical epifluorescence microscope. (b) Olympus Fluoview 300 LSM.

using the phenomena of fluorescence and phosphorescence (see Volume I, Chapter 7). Samples are labeled with dyes that emit visible light when bombarded with shorter ultraviolet (UV) rays (see Volume I, Figure 7.93). A fluorescence microscope is an optical microscope with an ultraviolet radiation source and a filter that protects the viewer's eye. The filter that the microscope uses is a special dichroic mirror (or more precisely, a dichromatic mirror). This mirror reflects light shorter than a certain wavelength and passes light longer than that wavelength. Thus the observer sees only the emitted red light from the fluorescent dye, rather than seeing scattered purple light. Most fluorescence microscopes are epifluorescence, i.e., excitation and observation of the fluorescence is from above (epi). In reflected light fluorescence, the intensity of the image, I, varies directly as the fourth power of the numerical aperture (NA) of the objective in use, as well as inversely as the square of the magnification, M:

$$I \propto \frac{(NA)^4}{(M)^2} \tag{6.1}$$

e.g., a ×40 objective with an NA of 1 will yield images more than a five times brighter than a ×40 objective with a NA of 0.65. Electronic sensors (e.g., a CCD) are typically used to measure the intensity, as they give a much higher sensitivity than film. To avoid fading of the fluorophore labels, a phenomenon known as *photobleaching*, the UV light intensity and duration need to be carefully chosen. In Figure 6.7 we show a typical fluorescence microscope.

Confocal Microscopy

Normally, in fluorescence microscopy, the sample is completely illuminated by the excitation light, so that the whole sample is fluorescing at the same time. The highest intensity of the excitation light is at the focal point of the lens, but nonetheless, the other parts of the sample do get some of this light and they do fluoresce as well.* This contributes to a background haze in the resulting fluorescence image. To get rid of this haze and make for a sharper image, one resorts to confocal microscopy. In such a microscope, patented in 1957 by Marvin Minsky (see inset in Figure 6.9), one places a small pinhole in a conjugate optical plane in front of the detector to eliminate out-

* From introductory optics, we remember the formula $1/s + 1/s' = 1/f$ for locating the image formed by a lens: points do not need to be at the focal point of the lens in order for the lens to form an image.

of-focus light (Figure 6.9). Because the focal point of the objective lens of the microscope forms an image where the pinhole is, these two points are known as *conjugate points*. The pinhole is conjugate to the focal point of the lens; thus, it is a confocal pinhole (or alternatively, the sample plane and the pinhole/screen are conjugate planes). Only light from the plane of focus will pass through the pinhole, so that the image quality is much better than that of wide-field images. Since only one point is illuminated at a time, 2D or 3D imaging requires that a focused laser beam be scanned across the field of view and the image be reconstructed electronically. This type of microscopy is called *confocal laser scanning microscopy* (CLSM), as it combines a confocal microscope with a scanning system in order to image an entire specimen. Although scanning can be performed in several different ways, it is most often done by moving the beam, which alleviates focus problems caused by objective lens scanning and is faster than specimen scanning. With a scanning system added, the system has the ability to scan multiple times on different imaging planes, resulting in a three-dimensional data set.

In confocal microscopy, the background rejection is thus substantially improved and the method allows for optical sectioning; moreover, the lateral and axial extent of the point spread function (see Volume I, Figure 5.12) is reduced by about 30% compared with that in a wide-field microscope. As a consequence, focal plane lateral resolution is improved by a factor of 1.5 over ordinary microscopy for incoherent imaging (Rayleigh limit or $R = 0.61\ \lambda/NA$; Volume I, Equation 5.13), as follows:

$$R_{xy} = 0.4\frac{\lambda_{emission}}{NA} \tag{6.2}$$

The vertical depth resolution of a confocal microscope enables optical sectioning and is poorer than the lateral resolution:

$$R_z = 1.4\frac{\lambda_{emission}n}{NA^2} \tag{6.3}$$

For typical objectives ($NA \leq 1.4$) and visible light ($\lambda \geq 400$ nm), the best lateral resolution is $R_{xy} = 0.13\ \mu m$ and the vertical resolution is $R_z = 0.43\ \mu m$, so that the depth discrimination is not comparable to the focal plane resolution.

Work has been done to use CLSM to perform 3D analysis of microstructures such as micro end mills and hot embossing tools, both with overall dimensions on the order of 1 mm^3. One of the most important advantages of confocal microscopy found is the ability of this microscope to measure steep slopes, up to almost 90° on a part with minimal surface roughness. This measurement requires a high-resolution, high-NA objective, which has a limited lateral measuring field unsuitable for measuring the entire sample. Because of this, a stitching procedure is used to combine scans taken with several objectives.

Two-Photon Microscopy

Using two-photon confocal microscopy further enhances the resolution of fluorescence microscopy. Multiphoton fluorescence microscopy is a relatively novel imaging technique that relies on the quasisimultaneous absorption of two or more photons (of either the same or different energies) by a molecule (see also quantum lithography in Volume II, Chapter 2). Two-photon microscopy was pioneered by Winfried Denk in the laboratory of Watt Webb at Cornell University.[4] He combined the idea of two-photon absorption with the use of a laser scanner.

The use of two-photon absorption has several important advantages. First, the probability of two-photon absorption increases quadratically with illumination intensity, essentially limiting excitation to a tiny focal volume (see Figure 6.8). This limits automatically out-of-focus background excitation and provides innate confocality, since only fluorophores in the plane of the focused beam are excited. One obvious benefit of this is to obviate the need for the confocal aperture in front of the detector used in one-photon confocal microscopy, maximizing the amount of light detected. Second, the use of longer wavelength excitation light slows the rate of photobleaching of the fluorescent labels on the sample, allowing the use of higher magnification objectives. Third, longer wavelength light is scattered less as it passes through a sample such as biological tissue, resulting in a greater penetration depth into the sample. These factors increase both the resolution and duration of measurement available with this technique. Fourth, the fact that two-photon excitation microscopy does not require a pinhole to obtain

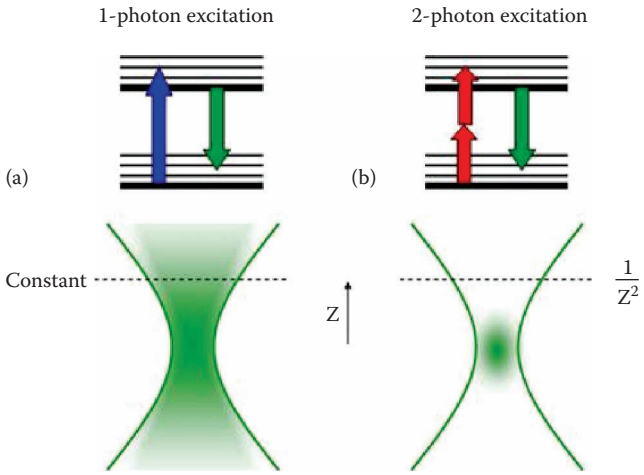

FIGURE 6.8 One-photon (a) and two-photon (b) excitation.

three-dimensional resolution allows more flexibility in detection geometry. Two-photon microscopy is thus a novel form of laser-based scanning microscopy that allows three-dimensional imaging and avoids many of the problems inherent in confocal microscopy.

In Figure 6.9 we compare confocal microscopy with laser scanning two-photon microscopy. Resolution limits of quantum lithography were analyzed in Volume II, Chapter 2. The results derived there directly apply to two-photon microscopy discussed here.

Interferometry

Another powerful method for MEMS part inspection is scanning white light interferometry (SWLI), also called *noncontact profilometry*. Interferometry, a method to determine a point in space on the basis of phase differences between a reflected probe beam and an isolated reference beam, has long been used by various industries as one of the most accurate ways to profile a surface. In Figure 6.10 and the example below, we illustrate how a typical interferometer can be used to measure distances in a number of wavelengths or to measure wavelengths. A Michelson interferometer, the particular two-path interferometer shown here, is constructed using a beam-splitter, i.e., a partially silvered mirror that transmits and reflects half of the incident intensity. This is useful because the reflected and transmitted beams are coherent, i.e., they have a definite common phase, even when the incident light has a time-varying random phase. This interferometer allows a

Inset

Prof. Marvin Minsky:

This is what I remember about inventing the confocal scanning microscope in 1955. When I read the following account, the plot seems more coherent now than it ever did in those times of the past. Perhaps, though, those activities which seemed to me the most spontaneous were actually those which unconsciously were managed the most methodically. The story actually begins in childhood ...

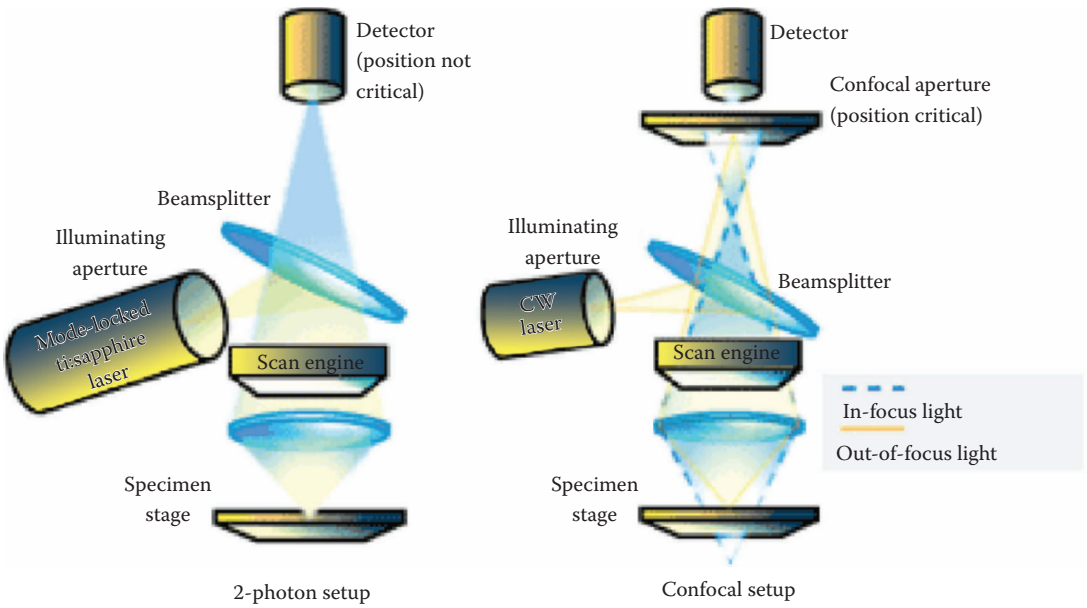

FIGURE 6.9 Comparison of a confocal microscope with a two-photon microscope. Inset, Marvin Minsky remembering the confocal microscope.

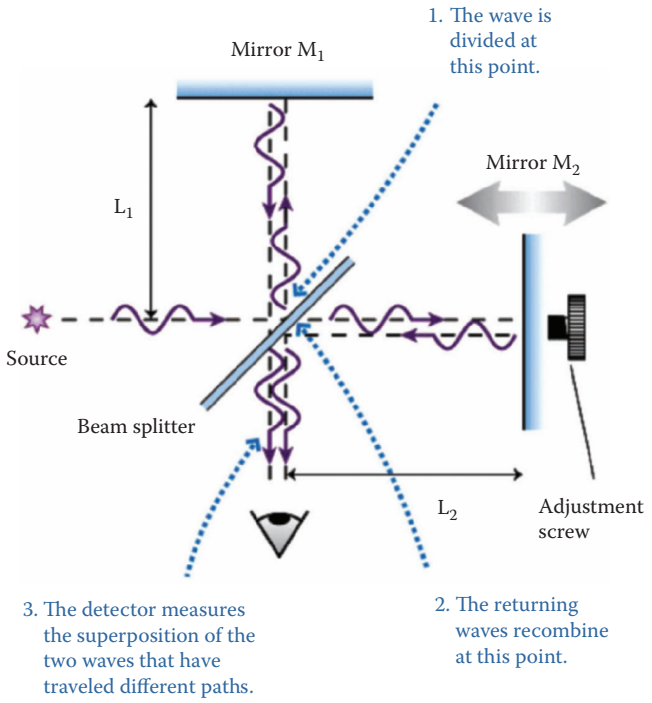

FIGURE 6.10 A Michelson interferometer. John G. Cramer, Professor of Physics, University of Washington.

beam of light to be sent along two paths, reflected, and recombined so that it can interfere. Reflection from a surface produces a "phase-flip" of 180° in the reflected light. However, when light is reflected at an angle other than 180°, the phase change in the reflected light is the same as the reflection angle. Thus, light reflected at 90° has a 90° change in phase. If the interferometer is set for an interference maximum, a new maximum will occur each time one of the arms is moved by λ/2.

Example 6.1 (Dr. J. G. Cramer): Measuring Wavelengths

Question: An experimenter uses the Michelson interferometer shown in Figure 6.10 to measure one of the wavelengths of light emitted by electrically excited neon atoms. She slowly moves the mirror M2 and uses a photo-detector and a computer to determine that 10,000 new bright central spots have appeared. She then determines with a micrometer that the mirror has moved 3.164 mm. What is the wavelength of the light?

Answer: $$\lambda = \frac{2\Delta L_2}{\Delta m} = \frac{2(0.003164\ \text{m})}{(10{,}000)} = 632.8\ \text{nm}$$

If the wavelength is known, then of course a distance can be determined.

In SWLI, recombined light is directed to image plane of a CCD camera. Points on a surface that are separated from the lens by an integer number of wavelengths are bright and those a half-integer apart are dark. Interference is strong only when the reflected light is in focus i.e., the sample-lens distance is at the focal position. The sample-lens distance is scanned around the focal length and ach pixel of the CCD will show a strong intensity change when the lens reaches the focal position corresponding to each point on the surface. High-resolution position information comes from a linear variable differential transformer (LVDT) connected to the lens scanning drive.

SWLI has the ability to quickly measure step heights changes and deflections (see also mechanical property measurements, below): it is possible to resolve step height changes greater than λ/4. Using white light increases the dynamic range of the measurement and allows for higher resolution by comparing data from multiple wavelengths. In addition, when integrated with an image processing system, SWLI can provide lateral dimensions. By using image processing, line widths, diameters, and feature positions can be measured as well. However, the lateral resolution of commercially available systems is poor, except when equipped with high-power objectives that severely limit the field of view. Moreover, these tools are limited in their ability to measure sloped surfaces. Indeed, interference can occur only if light is reflected back into the objective lens. If the surface angle is inclined beyond the acceptance angle of the lens, no interference is observed. The largest slope that can be identified is typically around 30° with a × 100 objective. As the objective power decreases, the identifiable slopes also decrease.

In practice, white light interferometers have subnanometer resolution in the scanning direction, at best submicrometer resolution in the lateral directions, and can be used on a multitude of parts with different surface finishes. A typical instrument, from Wyko, is shown in Figure 6.11. The equipment shown measures surface features with 0.45–11.8-μm lateral resolution and an approximately 0.10-nm vertical resolution. Although initially developed mostly for surface characterization, such as surface roughness, SWLI is currently used to make a wide variety of other measurements on MEMS parts.

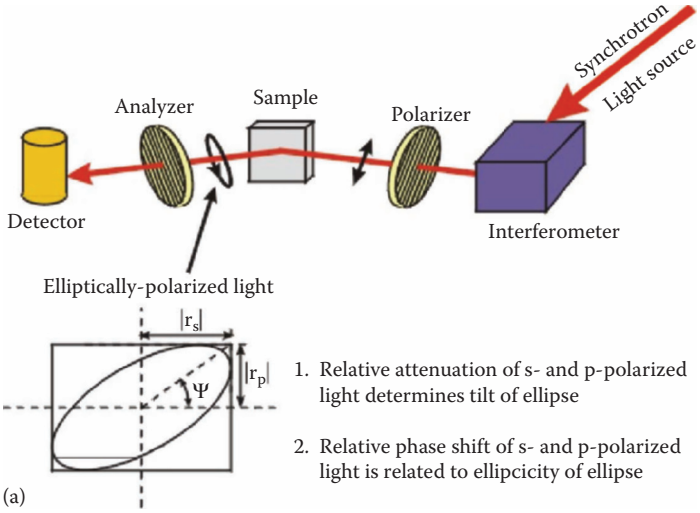
FIGURE 6.11 Optical Wyko white-light profilometers with dynamic microelectromechanical system capability. This capability enables both in-plane and out-of-plane resonant frequency measurements.

Ellipsometry

Introduction

Fresnel derived the equations that determine the reflection/transmission coefficients of light at interfaces in the early nineteenth century, and Paul Drude invented ellipsometry, based on these equations, in 1887. Ellipsometry is a noncontact optical technique used for analysis and metrology and became very important in the 1960s, as it was demonstrated to have the sensitivity required to measure nanometer-scale thin films used in microelectronics.

Ellipsometry allows one to establish very accurately and with high reproducibility the complex dielectric function of a given material. In Volume I, Chapter 3, we saw how the dielectric function is dependent on both frequency (ω) and wave-vector $\mathbf{k}$: $\varepsilon(\omega, \mathbf{k})$. In ellipsometry, one determines the change in polarization state of light reflected from a sample. This polarization change is represented as an amplitude ratio, Ψ, and a phase difference, Δ. Since ellipsometry is measuring the ratio (or difference) of two values (rather than the absolute value of either), it is very robust, accurate, and reproducible. For instance, it is relatively insensitive to scatter and fluctuations and requires no standard sample or reference beam. The measured response depends on optical properties and thickness of individual materials. Transparent films from subnanometers up to several micrometers can be measured, and the surface upon which the film is measured can be a semiconductor, dielectric or metal. The film can be transparent or absorbing on a transparent or opaque substrate as long as there is enough contrast between substrate and film. It is a model-based technique that, besides being used to determine film thickness and optical constants, can be employed to characterize composition, crystallinity, roughness, and doping level—in short, all material properties that can change the optical characteristics. In Figure 6.12 we illustrate a typical ellipsometer setup.



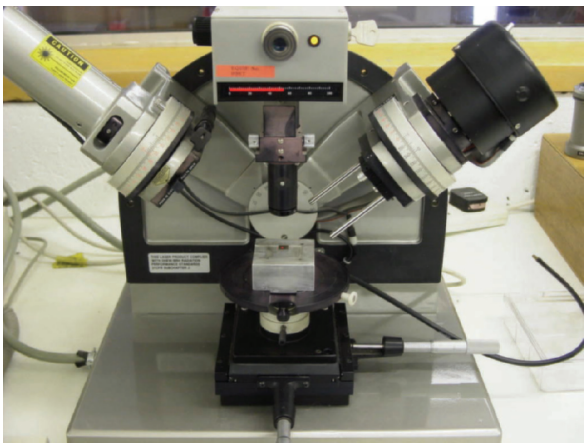


FIGURE 6.12 Schematic (a) and photograph (b) of an ellipsometer. The ellipsometer measures polarization changes in terms of two parameters: Δ (sometimes cosΔ) and Ψ.

From the schematic in Figure 6.12a, we see that a first polarizer linearly polarizes incident light with finite field components in the directions parallel (*p*-component) and perpendicular (*s*-component) to the plane of incidence of the light. The plane of incidence of light is the plane containing the surface that is normal to the sample and the incident direction of light. The wavelength of the measuring polarized light can range from the ultraviolet to the far-infrared. (In Figure 6.12a, a synchrotron light source is used in order to obtain a high-enough intensity of far-infrared light.) Upon reflection, the *s*- and *p*-components of the light undergo different attenuations and phase shifts, resulting in elliptically polarized reflected light, giving the technique its name. The ellipse of polarization of the reflected light is measured with a second polarizer (called the *analyzer*), as illustrated in Figure 6.12a.

Theory

When light interacts with a material, the Maxwell equations remain satisfied by imposing the proper boundary conditions at the interface (see Volume I, Table 5.2). At an interface a portion of light reflects, and the remainder transmits at the refracted angle (see Volume I, Figure 5.36). It is relatively easy to measure reflectance, R, of a material, and from this the more difficult-to-access complex refractive index, n_c, can be derived. The values for the refractive index, n, and extinction coefficient, κ, which make up the complex refractive index n_c, are not independent but are linked by the Kramers-Kronig relations. Either of these equations, plus a knowledge of $R(\omega)$ at all frequencies, permits one to disentangle the separate values of $n(\omega)$ and $\kappa(\omega)$.

With reference to Volume I, Figure 5.38, we obtained the four amplitude coefficients (the Fresnel equations) as follows:

$$r(\omega)_{||} = \left(\frac{E_m^r}{E_m^i}\right)_{\parallel} = \left[\frac{\tan(\theta_i - \theta_t)}{\tan(\theta_i + \theta_t)}\right]_{\parallel}$$

(Volume I, Equation 5.140)

$$r(\omega)_{\perp} = \left(\frac{E_m^r}{E_m^i}\right)_{\perp} = \left[\frac{\sin(\theta_i - \theta_t)}{\sin(\theta_i + \theta_t)}\right]_{\perp}$$

(Volume I, Equation 5.141)

$$t(\omega)_{||} = \left(\frac{E_m^t}{E_m^i}\right)_{\parallel} = \left[\frac{2\sin\theta_t\cos\theta_i}{\sin(\theta_i + \theta_t)\cos(\theta_i - \theta_t)}\right]_{\parallel}$$

(Volume I, Equation 5.142)

$$t(\omega)_{\perp} = \left(\frac{E_m^t}{E_m^i}\right)_{\perp} = \left[\frac{2\sin\theta_t\cos\theta_i}{\sin(\theta_i + \theta_t)}\right]_{\perp}$$

(Volume I, Equation 5.143)

where $r(\omega)$ is the dimensionless reflectivity coefficient defined as the ratio of the reflected electric field to the incident electric field, and $t(\omega)$ is the dimensionless transmission coefficient.

Reflection and transmission, we saw, are related by the following equation.

$$t(\omega) = 1 + r(\omega)$$

(Volume I, Equation 5.144)

A complex $r(\omega)$ [or $t(\omega)$] means that a phase shift is introduced at the interface upon reflection (or transmission). The link between reflectivity at normal incidence and the complex refractive index was calculated in Volume I, Chapter 5 as follows:

$$r(\omega) = \frac{E_m^r}{E_m^i} = \left(\frac{n + i\kappa - 1}{n + i\kappa + 1}\right) = \frac{n_c - 1}{n_c + 1}$$

(Volume I, Equation 5.147)

The quantity that is actually measured in experiments is not reflectivity, r, but reflectance, R, defined as the ratio of the reflected intensity to the incident intensity, as follows:

$$R(\omega) = \frac{\left|E_m^r\right|^2}{\left|E_m^i\right|^2} = \left|\frac{n_c - 1}{n_c + 1}\right|^2 = \frac{(n-1)^2 + \kappa^2}{(n+1)^2 + \kappa^2}$$

(Volume I, Equation 5.148)

The phase, $\theta(\omega)$, of the reflected wave, it can be shown, may be calculated from the measured reflectance, $R(\omega)$, if known over all frequencies (Kramers-Kronig). With both $R(\omega)$ and $\theta(\omega)$ known, we can use Volume I, Equation 5.147 to calculate $n(\omega)$ and $\kappa(\omega)$; as we saw earlier, $n(\omega)$ and $\kappa(\omega)$ are related to the complex dielectric function, ε_r, as follows:

$$n_c(\omega) = n(\omega) + i\kappa(\omega) = \sqrt{\varepsilon_r'(\omega) + i\varepsilon_r''(\omega)}$$

(Volume I, Equation 5.115)

Plugging the values for $n(\omega)$ and $\kappa(\omega)$ into Equation 5.115, we thus obtain the complex dielectric function.

We now need to explain how the Fresnel equations are linked to the experimental parameters obtained from ellipsometry. The reflectivity coefficients $r(\omega)_{||}$ and $r(\omega)_{\perp}$ in what follows are symbolized more simply as r_p (p for parallel) and r_s (s for senkrecht: German for normal or perpendicular). Using Snell's law (Volume I, Equation 5.19), the expressions for r_s and r_p (Volume I, Equations 5.140 and 5.141) can be rewritten as follows:

$$r_s = \left(\frac{E_m^r}{E_m^i}\right)_{\perp} = \left[\frac{n_t\cos\theta_i - n_t\cos\theta_t}{n_i\cos\theta_t + n_t\cos\theta_i}\right]_{\perp} \tag{6.4}$$

$$r_p = \left(\frac{E_m^r}{E_m^i}\right)_{\parallel} = \left[\frac{n_t\cos\theta_i - n_i\cos\theta_t}{n_i\cos\theta_t + n_t\cos\theta_i}\right]_{\parallel} \tag{6.5}$$

In these expressions we now see the explicit appearance of the refractive index of the two media (n_i and n_t; see Volume I, Figure 5.38). Thin-film and multilayer structures involve multiple interfaces, with Fresnel reflection and transmission coefficients applicable at each. The superposition of multiple waves introduces interference that depends on the relative phase of each light wave. To track the relative phase of each light component so as to correctly determine the phase of the overall reflected or transmitted beam, a film phase thickness is introduced as follows (see Figure 6.13).

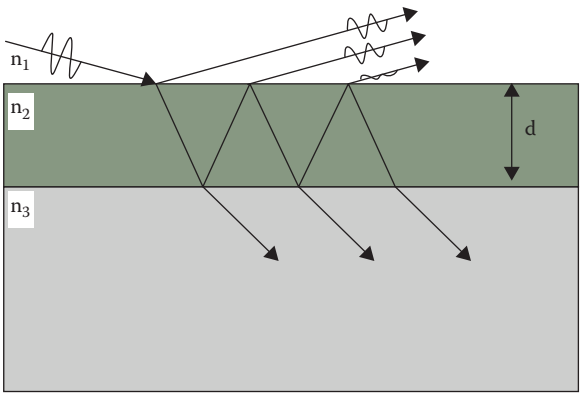

FIGURE 6.13 Light reflects and refracts at each interface, which leads to multiple beams in a thin film. Interference between beams depends on relative phase and amplitude of the electric fields. Fresnel: reflection and transmission can be used to calculate the response from each contributing beam.

$$\beta = 2\pi\left(\frac{d}{\lambda}\right)n_2\cos\theta_2 \tag{6.6}$$

The reflectivity coefficients r_p and r_s for this case are given as the following.

$$r_p = \frac{r_{p(1,2)} + r_{p(2,3)}\exp(-i2\beta)}{1 + r_{p(1,2)}r_{p(2,3)}\exp(-i2\beta)} \tag{6.7}$$

$$r_s = \frac{r_{s(1,2)} + r_{s(2,3)}\exp(-i2\beta)}{1 + r_{s(1,2)}r_{s(2,3)}\exp(-i2\beta)} \tag{6.8}$$

Ellipsometry determines how p- and s-components of the light change upon reflection or transmission in relation to each other. A known polarization is reflected or transmitted from the sample, and the output polarization is measured. The ellipsometer measures this polarization change of the light reflected from the sample in terms of two parameters: Δ (sometimes $\cos\Delta$) and Ψ (see Figure 6.12a). These values are related to the ratio of the Fresnel amplitude reflection coefficients for p- and s-polarized light as follows:

$$\frac{r(\omega)_{\parallel}}{r(\omega)_{\perp}} = \frac{r_p}{r_s} = \tan\Psi\exp(i\Delta) \tag{6.9}$$

This ratio is complex, with $\tan\Psi$ measuring the relative attenuation of s- and p-polarized light (which determines the tilt of the ellipse in Figure 6.12a) and Δ measuring the phase difference between p- and s-polarized reflected light (related to the ellipticity). In the case of an ideal bulk material, the result in Equation 6.9 can be directly converted to give the complex dielectric constant and complex refractive index as:

$$\varepsilon_r = n_c^2 = \sin^2(\phi)\left[1 + \tan^2(\phi)\left(\frac{1 - \frac{r_p}{r_s}}{1 + \frac{r_p}{r_s}}\right)\right] \tag{6.10}$$

This equation is an oversimplification implying that there are no surface layers of any type. A realistic bulk material comes with a surface oxide and at least some roughness, and Equation 6.10 would include these as part of the bulk optical constants. As a consequence, ellipsometry is used as an indirect method/model based technique, i.e., in general the measured Ψ and Δ cannot be converted directly into the optical constants of the sample. From Ψ, Δ, and an optical model, the desired information can be

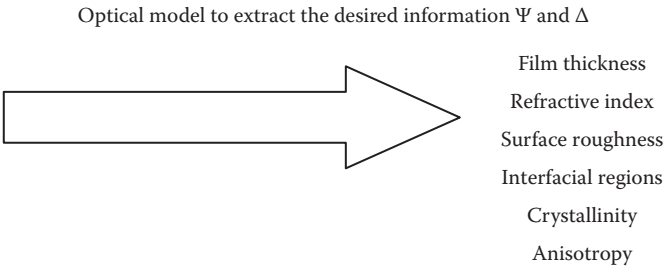

FIGURE 6.14 From Ψ, Δ, and an optical model the desired information can be extracted.

extracted, as illustrated in Figure 6.14. After a sample is measured, a model is constructed and is used to calculate the predicted response from the Fresnel's equations, which describe each material layer in the sample with its own thickness and optical constants. If these values are not all known, an estimate is made for a preliminary calculation. The calculated values are then compared with the experimental data, and any unknown material property can be varied to improve the match between experiment and calculation. Finding the best match between the model and the experiment is typically achieved through regression. An estimator, such as the mean squared error (MSE), is used to quantify the difference between curves. The unknown parameters are allowed to vary until the minimum MSE is reached.

Ellipsometers may be single-wavelength or spectroscopic and may be have single or multiple angles of incidence. They may also operate with a rotating element or as nulling ellipsometer, and they may be single-point or imaging. Spectroscopic ellipsometer allows the accurate characterization of a range of properties, including the layer thickness, optical constants, composition, crystallinity, anisotropy, and uniformity. Thickness determinations ranging from a few angstroms to tens of micrometers are possible for single layers and complex multilayer stacks.

Ellipsometry measures the ratio of two values, so it is highly accurate and reproducible, it does not need a reference sample, and it is not very susceptible to light source fluctuation. Since it measures phase, it is highly sensitive to the presence of thin films (down to submonolayer coverage). The sampling region ranges from 30 μm to 10 mm, and the depth of sampling, which depends on the absorption of the light in the sample, is typically 100 Å or more. For further reading we refer to the *Handbook of Ellipsometry*.[5]

Scanning Electron Microscopy

In ICs, MEMS, and NEMS, scanning electron microscopes (SEMs) like optical microscopes, are fabrication line workhorses. Scanning electron microscopy is one of the primary tools used for analysis of MEMS and NEMS devices, one that was used long before the development of scanning probe techniques. Ernst Ruska, the inventor of the electron microscope (1931),* received his Nobel in 1986, at age of 80, and shared the prize with Gerd Binnig and Heinrich Rohrer for the scanning tunneling microscope (STM) (see below), invented in 1981.

In an SEM, the surface or microvolume to be examined is irradiated with a finely focused electron beam; the beam may be swept in a raster† across the surface of the specimen, which is contained in a vacuum, to form images or can be static to obtain an analysis at just one position. The electrons are produced in an electron gun that accelerates them at the operating voltage. The operating voltage ranges from 0 to between 30 and 60 kV, depending upon the type of SEM.

Scanning electron microscopy requires a vacuum system so that the electrons can make the trip from the source in the electron gun, e.g., a thermal field emitter to the sample and to the detector (an electron multiplier). Insulating samples have traditionally required pretreatment in the form of coating with a conductive film, typically gold or carbon, before SEM examination. Nonconductive samples are subject to a buildup of electrons on their surface. This buildup of electrons, or charging, eventually causes scattering of the incoming electron beam, which interferes with imaging and analysis. Furthermore, samples that contain substantial water or other materials that volatilize in high vacuum also present challenges for SEM examination. These samples require controlled drying to allow the SEM chamber to reach high vacuum and to prevent deformation of the sample at the SEM vacuum. Coating with gold or

* There are two major types of electron microscopes: SEMs and TEMs. In the former, electrons scattered from a thick analyzed sample; in the latter, electrons transmitted through a very thin specimen are utilized. The first electron microscopes that were developed were actually TEMs (see "Transmission Electron Microscopy").

† The beam is scanned over the specimen in a series of lines and frames called a *raster,* just like the (much weaker) electron beam in an ordinary television.

carbon and drying are not needed if an environmental scanning electron microscope (ESEM) is used (see below). The focusing of electrons in an SEM is achieved magnetically instead of with a polished and shaped lens. Electron beams (probes) of sizes down to ~6 nm are attainable with conventional thermionic emission sources, although smaller probes, ~2 nm, can be achieved using field emission sources (for a listing of different electron sources, see Volume II, Figure 2.17). The SEM also does not have lenses to magnify the image as in the optical microscope; instead, magnification results from the ratio of the area scanned on the specimen to the area of the television screen [cathode ray tube (CRT)] (× 25 to × 250,000 or more). Increasing the magnification in an SEM is therefore achieved quite simply by scanning the electron beam over a smaller area of the specimen. The raster movement is accomplished by means of small coils of wire carrying the controlling current (the scan coils), and magnification is therefore controlled by the current supplied to the x, y scanning coils and not by objective lens power. A schematic drawing of an electron microscope is shown, together with a photograph of a commercial machine in Figure 6.15.

We remember that the resolution, R, of a light microscope can be calculated as $0.61\lambda/\mathrm{NA}$ (Raleigh criterion; Volume I, Equation 5.13). In this expression, $\mathrm{NA} = n\sin\theta_{max} = \frac{D}{2f} = \frac{1}{2F\#}$, with $F\#$ being the effective F-number, which equals f/D, or focal length over lens diameter. The assumption here is a large $F\#$, which implies $\theta \ll 1$ and $\mathrm{NA} = \sin\theta \sim \tan\theta \sim \theta$; this is called the *paraxial approximation* (see Volume I, Chapter 5). A good light microscope objective has an f/D (effective F-number) of about 2, so with λ = ~500 nm, a typical optical microscope R is about 1 μm. This resolution can be much improved by using a scanning electron microscope. The matter wave of an electron (accelerated at 1,000,000 V) is 0.001 nm (see de Broglie wavelength; Volume I, Equation 3.96) versus 450 nm for a light microscope; in other words, electron waves are 100,000 times shorter than the waves of visible light. So electrons have tremendous power to resolve minute structures because the resolving power is a function of wavelength. Moreover this wavelength depends on the applied voltage and increasing the voltage leads to faster electrons with yet shorter de Broglie

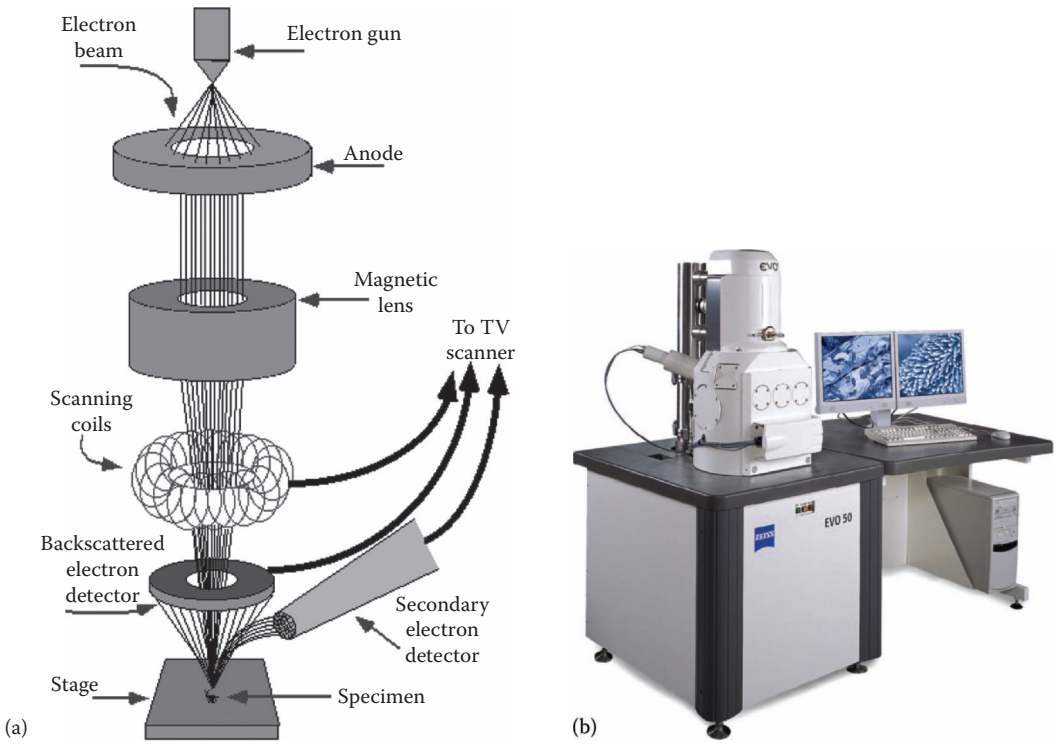

FIGURE 6.15 (a) Schematic of scanning electron microscope (SEM). (b) Carl Zeiss SEM. Scanning electron microscopy provides detailed three-dimensional view.

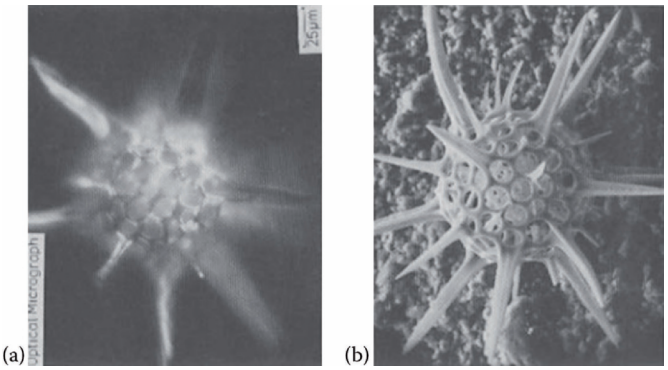

FIGURE 6.16 *Trochodiscus longispinus* in optical microscopy (a) and scanning electron microscopy (b). Note improved depth of field and resolving capability of the scanning electron microscopy experiment. (Taken from Goldstein, J., D. Newbury, D. Joy, C. Lyman, P. Echlin, E. Lifshin, L. Sawyer, and J. Michael. 2003. *Scanning electron microscopy and x-ray microanalysis.* New York: Kluwer Academic/Plenum Publishers.[6])

wavelengths. The effective F-number (also *F#* or *f*/*D*) for an electron microscope, on the other hand, is about 100 (quite large). The much shorter wavelength despite the poorer *f*/*D* gives an SEM a resolution 1000-fold better than that of the best light microscope. This improved resolution is dramatically illustrated in Figure 6.16, where we compare an image from an optical microscope (OM) with that of a SEM of the same *Trochodiscus longispinus*.

As the rastered focused electron beam irradiates the sample, secondary electrons are ejected from the sample. Secondary electrons are specimen electrons that obtain energy by inelastic collisions with beam electrons. They are defined as electrons emitted from the specimen with energy less than 50 eV and are predominantly produced by the interactions between energetic beam electrons and weakly bonded conduction-band electrons in metals or the valence electrons of insulators and semiconductors. With a flux amplitude that depends on the nature of the material and on the angle that the feature's surface makes with the incident beam, these secondary electrons are counted and used to create an image of the sample. The accuracy of the images captured is highly dependent on machine capability and the specific part being examined. An electron multiplier is used to detect and amplify the secondary electron intensity as a function of beam position to create the SEM image (see more on SEM detectors on page 308). The output generated from the electron detector is displayed on a CRT rastered in synchronization with the electron beam. The final result is a two-dimensional image on a screen. Since no coordinate data are directly output from the SEM, performing any analysis other than line width measurements directly with the SEM software becomes difficult. Thus, SEMs are ideal for visualizing MEMS parts but are inadequate tools for quantitative analysis.[2]

The type of particles produced from the interaction of an electron beam with a solid sample is not limited to secondary electrons but may include backscattered electrons (BSEs), elastically scattered electrons, characteristic x-rays, and other photons of various energies. One of the main features of the SEM is that, in principle, any radiation emitted from the specimen or any measurable change in the specimen can be used to provide the signal to modulate the CRT and thus provide the contrast.

From Figure 6.17, it is obvious that several processes occur when electrons bombard a solid surface and that different emission mechanisms arise from different depths within the sample. The two basic types of electron scattering events that take place in an SEM are elastic scattering, which causes backscattering of electrons without loss or little loss of kinetic energy, and inelastic scattering, which results in transfer of energy from the beam electrons to the sample. The inelastic scattering leads to the generation of secondary electrons but also to Auger electrons, x-rays (continuous and characteristic), electron-hole pairs in conductors and insulators, long wavelength electromagnetic radiation or cathodoluminescence [visible, UV, and infrared (IR) light], lattice vibrations (phonons), and electron oscillations in metals (plasmons, specimen current). The penetration depth of an electron into a solid depends on the beam energy, which in turn depends on the accelerating voltage, usually between 30 and 60 kV in a typical SEM and on the atomic number, *Z*, of the bombarded material. The probability of an incident electron being scattered varies, with larger atoms (large *Z*) having a higher probability of producing an elastic collision, so low-*Z* materials have a greater depth of penetration.

When a 20 KV e-beam is used, say for Ni (Z = 28), Auger electrons originate from very close to

Typical values given for the depth of electron penetration and the excited volume for a 30-keV, 100-nm-diameter electron probe.

the surface (10–30 Å), secondary electrons from 100 Å deep, backscattering electrons from 1–2 μm deep, and x-rays from 5 μm deep (the depth to which the incoming electrons may penetrate). Cathodoluminescence (CL), which arises from the recombination of electron-hole pairs generated by the incident beam, consists of visible photons (light). These can escape the sample only when emitted close to the surface, making cathodoluminescence very surface specific.

The interaction volume of the e-beam with the sample (pear shape shown in Figure 6.17) can be made visible in photoresist materials such as PMMA. Molecular bond damage (scission) during electron bombardment renders these materials sensitive to etching in a suitable solvent revealing the exposed volume. This phenomenon is the basis for e-beam lithography as detailed in Volume II, Chapter 2. The interaction volume as a function of beam energy can be estimated from Monte Carlo calculations (see also Volume II, Figure 2.15).

In Figure 6.18 the relative intensity versus abundance of the various emission phenomena under e-beam radiation are indicated. Whereas surface topography is obtained when low energy secondary electrons are collected, atomic number or orientation information is obtained from higher-energy backscattered electrons and elastically scattered electrons. The latter may be used to differentiate between surface roughness, porosity, granular deposits, stress-related gross microcracks (often used in conjunction with microsectioning), and the observation of grain boundaries in unetched samples.

Elastically scattered electrons have the same energy as the incident electron beam and retain orientation and phase information. These electrons are used, for example, in diffraction imaging experiments, such as low-energy electron diffraction (LEED). In surface

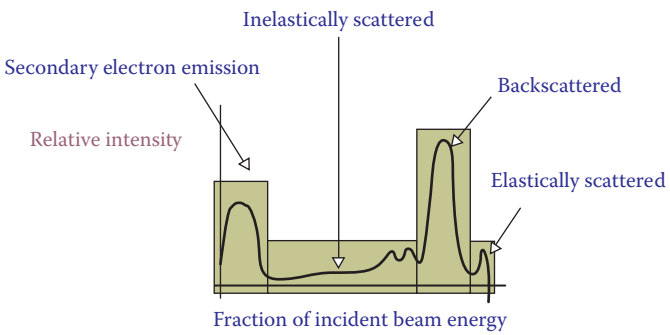

FIGURE 6.18 Relative intensity versus abundance of various emission phenomena under e-beam radiation.

science, well-ordered single-crystal surfaces are often investigated this way. Electrons penetrate (energy 50–300 eV) only a few monolayers into the sample; therefore, they are surface sensitive (for comparison, x-rays are more bulk sensitive). The observed diffraction pattern is the reciprocal lattice of the geometric surface lattice. Well-ordered surfaces exhibit sharp bright spots and low background intensity. The presence of surface defects and crystallographic imperfection results in broadening and weakening of the spots and increased background.

The backscattered electrons (BSEs) have an energy of about 80% of the incident beam. They are emitted more or less specularly. These electrons, just like secondary electrons, can be used to form topographic SEM images, but they have a higher energy than secondary electrons and also yield compositional information. Larger atoms (large atomic number, Z) have a higher probability of producing an elastic collision because of their greater cross-sectional area. Consequently, the number of BSEs reaching a BSE detector is proportional to the mean atomic number of the sample. Thus, a "brighter" BSE intensity correlates with greater average Z in the sample, and "dark" areas have lower average Z. BSE images are very helpful for obtaining compositional maps of a sample and for quickly distinguishing different phases. BSE images are limited to a grayscale range, though, because they only record one variable, average Z (a combination of all the elements in a sample). Thus, they do not convey as much information as can be obtained by elemental composition mapping using EDS* x-ray detectors (see "EDAX (EDX or EDS)").

SEM electron detectors can be based on different principles and oriented and operated differently to preferentially detect either secondary or backscattered electrons. A scintillator-photomultiplier system known as the *Everhart-Thorny* (E-T) *detector* detects the secondary electron signal, which is much more dependent on the sample topography than other electrons emitted from the sample. Topographic images obtained with secondary electrons actually look remarkably like images of solid objects viewed with light. A typical E-T detector consists of a Faraday cage in front of a scintillator, which in turn is coupled to a light pipe leading to a photomultiplier tube. The Faraday cage is kept at a positive potential of a few hundred volts so as to efficiently collect most of the secondary electrons emitted from the sample (remember they have an energy less than 50 eV). The scintillator typically has a positive voltage of several kilovolts applied to its surface, so that the electrons that pass the Faraday cage are accelerated onto the scintillator. When the electrons strike the scintillator they produce light, which is directed to the photomultiplier by a light pipe.

Using BSEs to construct topographical images either relies on a simplified scintillator–light pipe–photomultiplier (E-T), as used for secondary electrons, or uses solid state detectors. This stripped-down version of the E-T detector consists of scintillator coupled to a photomultiplier by a light pipe. Because there is no collection potential, the collection efficiency of these detectors is directly related to the scintillator size and its proximity to the sample. The simplest solid-state detector is a p-n junction with electrodes on the front and back of the sample. When hit by electrons, the holes tend to migrate to one electrode while the electrons migrate to the other, producing a current, the total of which is dependent on the electron flux and the electron energy. Response time of the detector is, unfortunately, slow but can be improved by putting a potential across the diode but this comes at the expense of increased noise in the signal. Often a set of solid-state detectors for simultaneous collection of backscattered electrons in different directions is used.

Detectors above the sample collect electrons scattered as a function of sample composition, whereas detectors placed to the side collect electrons scattered as a function of surface topography. BSE images can be obtained nearly instantly, depending on scan rate, and at any magnification within the instrument range.

The composition of samples is sensitive to the backscattered coefficient (η), which varies monotonically with Z. It has been shown that the coefficient can be expressed as follows.

$$\eta = -0.254 + 0.016Z - 1.86\times10^{-4}Z^2 + 8.3\times10^{-7}Z^3 \qquad (6.11)$$

* EDAX (EDX or EDS): Energy dispersive analysis of x-rays (EDAX) is also called *EDX* and, more and more frequently, EDS. See "EDAX (EDX or EDS)".

The magnitude of the compositional or atomic number contrast, C, from two phases of backscattered coefficients, η_1 and η_2, is readily calculated as follows.

$$C = \frac{\eta_1 - \eta_2}{\eta_1} \tag{6.12}$$

This method is not recommended for phases with similar atomic number, as the resolution may be poor.

The inelastically scattered electrons have interacted strongly with the substrate electrons, and in the process they have lost all information of their initial direction and phase. These include Auger electrons, photoelectrons, and e-h pair recombination processes. These have mainly spectroscopic value but can also be used for imaging (see SAM, "Auger Electron Spectroscopy and Scanning Auger Microscopy").

In general, a high vacuum is required in SEM, as the sample environment and the samples have to be clean, dry, and electrically conductive. An environmental SEM (ESEM) offers high-resolution secondary electron imaging in a gaseous environment of practical any composition, at pressures as high as 50 Torr and temperatures as high as 1500°C. In this case wet, oily, dirty, nonconductive samples may be examined in their natural states without modification or preparation. An immediate concern is that the gas molecules will scatter the electrons and degrade the beam. To avoid this, instead of using a single pressure-limiting aperture as used in conventional SEM, the ESEM uses multiple pressure limiting apertures to separate the sample chamber from the vacuum. This leaves the column still at very high vacuum, but the sample chamber may sustain pressures as high as 50 Torr.

An ESEM uses a special type of detector that can function in a nonvacuum environment. The detector uses the principle of gas ionization. A positive potential of a few hundred volts is applied to the detector, which attracts the secondary electrons emitted by the sample. As the electrons accelerate in the detector field, they collide with gas molecules, creating additional electrons, amplifying the original secondary electron signal, and generating more positive ions. The detector collects the amplified secondary electron signal and passes it on to an electron amplifier.

In nonconductive samples, the positive ions created in the gas ionization process are attracted to the sample surface, and they effectively suppress charging artifacts.

A short review of environmental scanning electron microscopy by Krisada Kimseng and Marcel Meissel can be found at http://www.calce.umd.edu/TSFA/ESEM.pdf.

Scanning Proximal Microscopes

Introduction

A scanning proximal microscope (SPM) is a mechanical imaging instrument in which a small (<1 μm) probe is scanned over a sample surface. All SPMs owe their ultimate existence to the scanning tunneling microscope (STM), invented by IBM research scientists Gerd Binnig and Heinrich Rohrer in the early 1980s.

By monitoring the motion of a tiny probe tip, the surface topography and/or images of surface physical properties are measured with an SPM. Because close proximity or contact between the specimen and probe is a general requirement, SPMs need a feedback system that precisely controls the physical separation between probe and sample. Several methods are available to monitor the z-position of the probe tip at all times:

- Interferometric measurement of the tip amplitude
- Electron tunneling (limited to conductive specimens)
- Detection of the light emitted through the probe tip
- Constant force (atomic force feedback) is the most common method; it can be further subdivided as follows:
  - Diffraction of a separate light source by the tip
  - Mechanical sensor attached to the tip (e.g., a quartz tuning fork)
- Capacitance detection

The two most commonly used mechanisms of tip positioning are optical methods that monitor the tip vibration amplitude (usually interferometric), and nonoptical tuning fork techniques.

In addition to the z-axis feed-back control, an x-y-z scanner (usually driven piezoelectrically) controls the movement of the probe over the sample

surface. The *x-y-z* scanner moves either the sample or the proximal probe. With the sample attached to the scanner, the sample moves under the fixed probe tip in a raster pattern, and an image is generated from the interaction of the tip and the sample. The size of the area that can be imaged depends on the maximum displacement of the scanner used. The typical size scale of features measured ranges from the atomic level (less than 1 nm) to more than 100 μm. A computer monitors the probe position and gathers data from the feedback system to control both the scanning of the tip (or sample) and the separation of the tip from the sample surface. The information generated by sensing the interaction between the probe and sample surface is collected and recorded by the computer point-by-point during the raster movement, and the computer renders the data into two-dimensional data sets (lines). The interactions between probe and sample used for imaging in scanning probe microscopes include electron tunneling, magnetic forces, electrical forces, electrochemical interactions, mechanical interactions, capacitance, ion conductance, Hall coefficient, thermal properties, and optical properties. SPMs offer an alternative to noncontact techniques and are characterized by their potential for very high resolution (subangstrom), limited only by the probe size and the property probed.

As illustrated in Table 6.5, SPMs are used in a wide range of applications. The three most used SPMs are the near-field scanning optical microscope (NSOM), the STM, and the atomic force microscope (AFM). In this section, we analyze the potential of these three SPMs for geometrical metrology. The utility of other specialized SPMs in property metrology is surveyed below (see "Tools to Measure Materials Property: Property Metrology").

NSOM or SNOM

To attain resolution beyond Abbe's diffraction limit of 200 nm, the textbook knowledge used to be that a complicated and costly SEM (0.1 nm resolution) or STM was required. Although these instruments do have a better resolution, they sacrifice many of the advantages of an optical microscope, such as nondestructiveness, low cost, high speed, reliability, versatility, accessibility, and ease of use. Thus, it would be very attractive to miniaturize a light microscope and have it operate below Abbe's diffraction limit. This objective is met by combining a scanning proximal probe technique with optical microscopy (OM) in so-called *scanning near-field OM*, a technique developed in the mid-1980s. We encountered NSOM first in Volume I, Chapter 5; here we give some additional background supplementing the information presented there.

The idea of using a subwavelength aperture to improve optical resolution was first proposed by E. H. Synge[7] in a letter to Einstein in 1928 and again, independently, in 1956 by John A. O'Keefe.[8] These ideas were realized only much later. First results were

achieved in 1972, by Ash and Nicholls,[9] in the microwave region of the spectrum, and in 1984, in the visible, by D. W. Pohl et al.[10] During image acquisition in NSOM, the point light source must be scanned over the surface, without touching it, and the optical signal from the surface must be collected and detected. To realize a constant probe-sample distance, a feedback mechanism that is unrelated to the NSOM/SNOM signal is utilized. Harootunian et al.[11] were the first to demonstrate SNOM microscopy in fluorescence mode. This result led eventually to single-molecule detection experiments by several groups.

During image acquisition in NSOM, a point light source is scanned very close to the surface, without touching it, and the optical signal from the surface is detected. In order to achieve an optical resolution better than Abbe's diffraction limit (the resolution limit of conventional OM), the probe tip must be brought within the near-field region, with the illumination source closer to the specimen than the wavelength of the illuminating radiation. For NSOM, the separation distance between probe and specimen surface is typically on the order of a few nanometers. Radiation near the source is highly collimated within the near-field region, but after propagation of a few wavelengths' distance from the specimen, the radiation experiences significant diffraction and enters the far-field regime. To make a point light source, laser light is fed to a microscopic aperture via an optical fiber. The aperture can be a tapered fiber with its shaft coated with a metal, a microfabricated probe, or a tapered pipette (see example aperture SNOM implementations in Volume I, Chapter 5). The aperture-based resolution is limited to about $\lambda/10$. With careful probe design and sample preparation a resolution of ~30 nm has been achieved.

One challenge for aperture based SNOM is the small aperture resulting in a very low light throughput. Scattering SNOM or apertureless SNOM, developed in the 1990s, is an alternative that avoids this low light intensity problem. Apertureless near-field optics, as we saw in Volume I, Chapter 5, uses a sharp, metallic subwavelength tip instead of an optical point source. The sharp metal tip acts as a nanoscopic light scatterer when placed in near-field distance to the sample. Oblique incident light is scattered at the tip, and the resulting strongly enhanced local plasmonic field is used for excitation of the sample. The resulting optical response signal is collected via an objective in far field and can be used for imaging and chemical analysis. The tip radius in this case is the only factor determining resolution. The best resolution attained today is 10 nm, and it is expected that this can be reduced to atomic level resolution. A significant problem with the scattering SNOM approach is that the light scattered by the tip carrying the information on tip-sample interaction is easily overwhelmed by background light. Therefore the method is particularly suitable for light-matter interaction processes where the light detected has a different wavelength from the excitation light (e.g., Raman scattering, fluorescence, second harmonic generation). Consider tip-enhanced Raman spectroscopy as an example. In tip-enhanced enhanced Raman spectroscopy (TERS), a silver-coated tip is scanned across the illuminated area, acting as a Raman signal enhancer. As we saw in Volume I, Chapter 5, Raman signals of molecules deposited on silver or in close proximity to silver nanoparticles can be increased by a factor of 10^{14}. It is believed that this enhancement results principally from the resonant enhancement of the surface plasmon mode localized at the apex of the sharp metallic tip. This technique represents an elegant combination of two Nobel Prize-winning discoveries: the Raman effect and the scanning tunneling microscope. TERS has created a new tool that achieves a long-awaited goal in surface science, namely the correlation of topographic and chemical information of the same sample region at nanometer scale. Although the enhancement processes allowing for TERS are still not fundamentally understood, the use of an illuminated scanning probe tip to greatly enhance Raman scattering from the sample underneath the tip is one of the most exciting developments in optical spectroscopy.

In the rest of this discussion, we focus on aperture-based SNOM only.

In an aperture-scanning NSOM instrument, the quantitative point-spread function in the near field can be approximated by a Gaussian profile whose 1/e intensity value is of the same order as the radius of the aperture at the tip of the NSOM probe. The mode of light propagation is primarily evanescent (and parallel to the specimen surface) when the

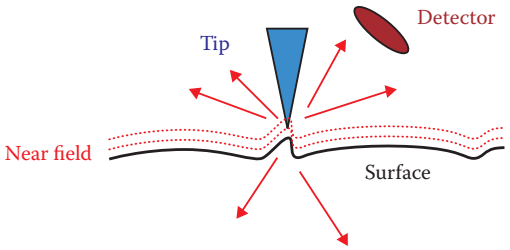

FIGURE 6.19 Light source is held in near-field to the surface.

radius of the illuminating source is less than one-third of the imaging light wavelength as shown in Figure 6.19. The NSOM configuration illustrated here positions the objective in the far field, in the conventional manner, for collection of the image-forming optical signal.

A schematic illustrating the control and information flow of an inverted optical microscope-based NSOM system is presented in Figure 6.20a. A laser source is coupled to a fiber optic probe for near-field specimen illumination. In the NSOM setup shown, the probe tip movements are controlled through an optical feedback loop incorporating a second laser that is focused on the tip. Two-dimensional data sets gathered by the NSOM instrument are registered and displayed as a 3D reconstruction on a computer monitor. Figure 6.20b is a photograph of an actual near-field scanning optical microscope set-up.

To improve signal-to-noise ratios for the feedback signal, the NSOM tip is oscillated at its resonance frequency. This allows for more sensitive lock-in detection techniques, eliminating positional detection problems associated with low-frequency noise and drift. As the oscillating tip approaches the sample surface, forces between the tip and specimen change both the peak resonance and the quality factor. These changes can be monitored by several techniques, classifiable in two broad groups: 1) shear-force mode and 2) tapping mode. In the shear-force mode, to control the tip-specimen gap during imaging, one utilizes lateral oscillation shear forces generated between a straight optical fiber and the sample (Figure 6.20a). The fiber is drawn to a sharp point and coated on the sides with an opaque material (usually Al). A small (~50-nm) hole is formed in the coating at the apex of the fiber and the evanescent field associated with this aperture is used to image the sample. In the optical feedback approach, illustrated in Figure 6.20a, a second laser is tightly focused as close to the end of the NSOM probe as possible. With the laser feedback established, the probe is then vibrated, at a known frequency, utilizing a dither piezo. A split photodiode collects the laser light, and the difference between the signals from each side of the detector is determined. The main problem associated with such an optical type of feedback mechanism is that the light source, which is used to detect the tip vibration frequency, phase, and amplitude, becomes a

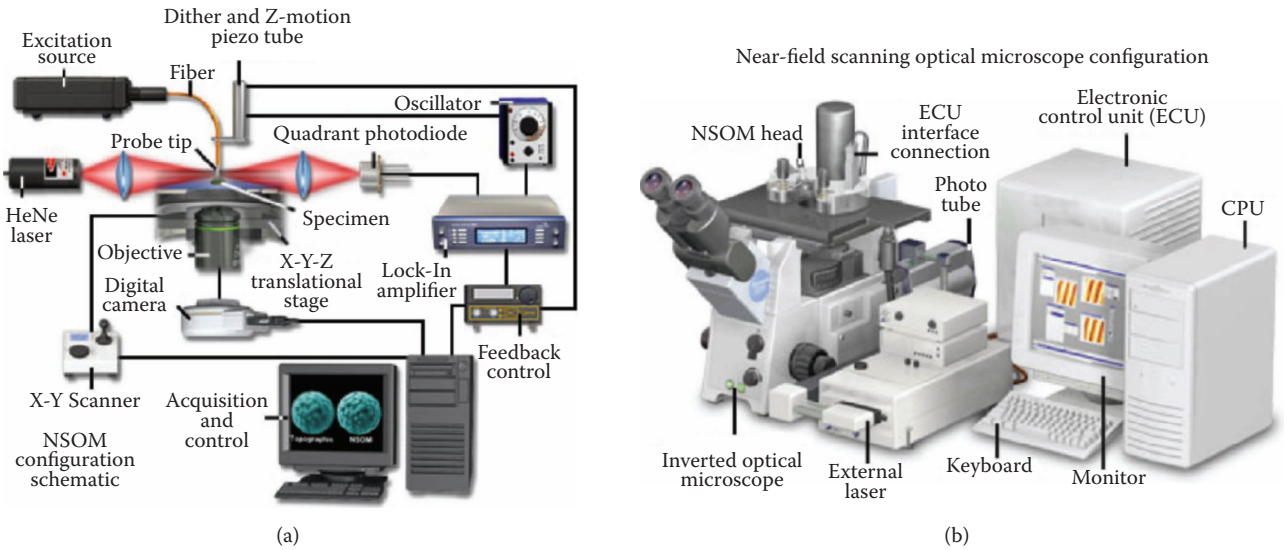

FIGURE 6.20 A schematic (a) illustrating the control and information flow of an inverted optical microscope-based scanning near-field optical microscopy system. (b) Actual photo of an Olympus NSOM system (http://www.olympusmicro.com/primer/techniques/nearfield/ nearfieldintro.html).

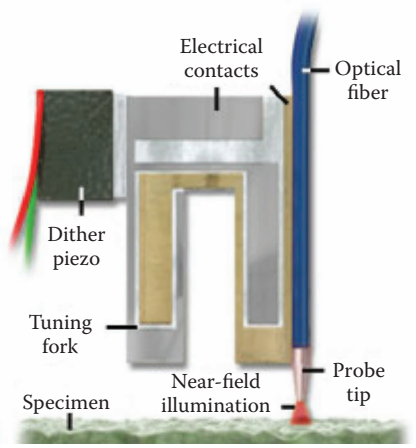

FIGURE 6.21 Tuning fork feedback (http://www.olympusmicro.com/primer/techniques/nearfield/nearfieldintro.html).

potential source of stray photons that can interfere with the detection of the NSOM signal. To realize a constant probe sample distance, a feedback mechanism that is unrelated to the NSOM signal is obviously preferred. This is the primary reason why the nonoptical feedback method based on the tuning-fork technique, illustrated in Figure 6.21, has become increasingly popular. Tuning forks are incorporated into the NSOM to serve as inexpensive and simple, nonoptical excitation and detection devices. When quartz tuning forks are utilized for regulation in a feedback loop, their very high mechanical quality factor, Q (as high as approximately 10,000), and corresponding high gain provide the system with high sensitivity to small forces, typically on the order of piconewtons. The fiber is typically fixed to one leg of a tuning fork, which is caused to oscillate. Interaction between the tip and the sample (due to shear forces—hence the name shear-force mode) leads to damping of this oscillation, and the height is adjusted to maintain a constant oscillation frequency.

In the tapping mode, to generate the feedback signal, one relies on atomic forces modulating the oscillation of a cantilever probe. In this case, a bent optical fiber, effectively functioning as an AFM cantilever probe, may be used as the light source. The nonoptical feedback method based on the tuning-fork technique, illustrated in Figure 6.21, is also applicable here. It is also possible to use an AFM-type cantilever probe, in which the cantilever has an aperture at its apex; a lens focuses light into the aperture and an AFM-type feedback mechanism is used.

For the best image quality, shear-force feedback techniques are restricted to specimens that have low surface relief, and longer scan times are required compared with operation in tapping mode. Moreover, the interactions that underlie shear force imaging are not very well understood. However, the straight probes employed in shear-force feedback techniques are easier to fabricate, are lower cost, and have a higher light throughput than their bent probe counterparts.

Previously developed high-resolution scanning techniques, such as scanning electron microscopy (SEM), transmission electron microscopy (TEM), scanning tunneling microscopy (STM), and atomic force microscopy (AFM), do not benefit from the wide array of contrast mechanisms available to an OM such as SNOM and, in most cases, are limited to the study of specimen surfaces only. Aside from the available contrast-enhancing techniques of staining, fluorescence, polarization, phase contrast, and differential interference contrast, optical methods have inherent spectroscopic and temporal resolution capabilities.

Advantages and disadvantages of SNOM and a list of applications are provided in Volume I, Chapter 5, "NSOM Applications."

Scanning Tunneling Microscope

The scanning tunneling microscope (STM) was the first and remains the most famous of the scanning probe microscope techniques. As detailed in Volume I, Chapter 3, scanning tunneling microscopy measures topography of surface electronic states using a tunneling current that is dependent on the separation between the probe tip and a conductive sample surface (metals or semiconductors). The violation of classical physics in tunneling is allowed by the quantum mechanical uncertainty principle. On the basis of this principle, a particle can violate classical physics by tunneling inside and even through an energy barrier, ΔE, for a short time, $\Delta t \sim \hbar/\Delta E$ (see Volume I, Equation 3.107). The exponential decay of the wave function inside a rectangular energy barrier that stretches from $x = 0$ to $x = L$ and has a height of V_0 is given as follows:

$$\psi(x) = Ae^{-\alpha x}$$

(Volume I, Equation 3.185)

with $\alpha^2 = \frac{2m(V_0 - E)}{\hbar^2}$ (Volume I, Equation 3.165). If the barrier is narrow enough (L is small), there will be a finite probability, P, of finding the particle on the other side of the barrier, as follows:

$$P = |\psi(x)|^2 = A^2 e^{-2\alpha L} \quad \text{(Volume I, Equation 3.186)}$$

where A is a function of the energy, E, of the particle and the barrier height, V_0. The probability of finding an electron on the other side of a barrier of width L can be probed with a fine needle tip from a STM. The tunneling current, picked up by the sharp needle point of an STM, based on Volume I, Equation 3.186, is given by the following equation:

$$I = f_w(E) A^2 e^{-2\alpha L} \quad \text{(Volume I, Equation 3.187)}$$

where $f_w(E)$ is the Fermi-Dirac function, which contains a weighted joint local density of electronic states (DOS) in the solid surface that is being probed and those states in the needle point (see Figure 6.22). Tunneling occurs between states of the same energy and the electron's energy does not change during the tunneling event. From Volume I, Equation 3.187, when L changes by 1 Å, the current changes by a factor of about 10. Obviously, the tunneling current is very sensitive to the gap distance. The size of the gap in STM experiments is kept on the order of a couple of angstroms. The DOS can vary as a function of position on the sample, which means that one can define a local density of states (LDOS). LDOS depends on both energy and on position. An intuitive way to think about LDOS is that it gives the density of electrons of a certain energy at that particular spatial location [LDOS (x, y, E)]. An STM measures and controls the current that flows between the tip and the sample (I), the bias voltage between the tip and the sample (V), the xy (in sample plane) position of the tip, and the z (perpendicular to sample plane) distance between the tip and sample. Using these variables, an STM is able to measure the LDOS of a material as function of position on the surface (controlled by where the tip is above the surface) and as a function of energy (controlled by the bias voltage between the tip and sample). The LDOS is proportional to the differential increase in tunneling current given a differential increase in bias voltage; in other words, one can measure the LDOS by measuring dI/dV. This was illustrated in Volume I, Figure 3.135, for a metallic and semiconducting carbon nanotube where singularities (sharp peaks) in the density of states function are observed directly in scanning tunneling microscopy images.

An STM may be viewed as an electron microscope that uses a single atom on a tip to attain atomic resolution. In a bit less lofty way, it may be described as a glorified phonograph needle, as illustrated in Figure 6.23. Resolution is determined by manufacturing a probe whose tip is of the same dimension we seek to resolve. If one can get a single atom at the tip, the vast majority of the current will run through it and thus give us atomic resolution. Tungsten is commonly used for the tip because one can use electrochemical-etching techniques to create very sharp tips like the one shown in Figure 6.24. This tip is brought to within a few angstroms of the surface that we wish to probe, and a small bias voltage (10 mV to 2 V) is applied between the tip and the sample while an electrical

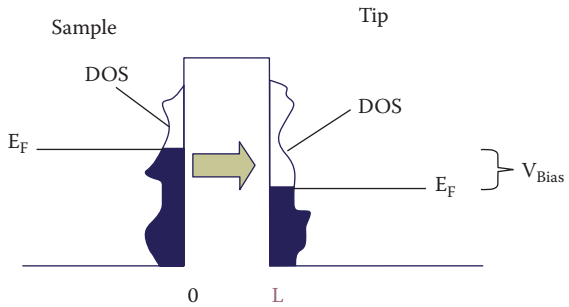

FIGURE 6.22 Density of state functions in sample and tip.

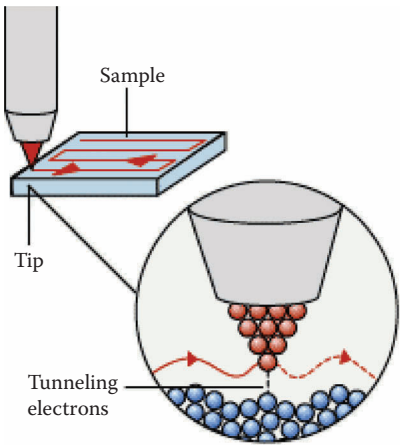

FIGURE 6.23 Scanning tunneling microscope.

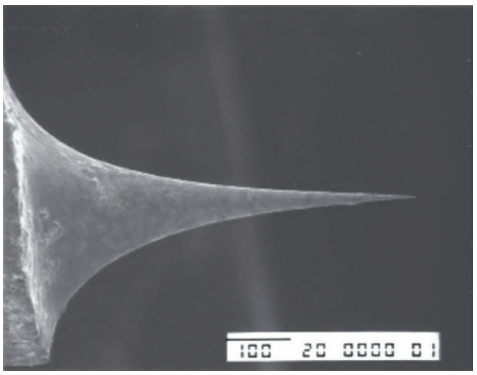

FIGURE 6.24 Tungsten scanning tunneling microscope tip; magnification ×150.

current flows by electrons tunneling across the gap between the two conductors. As we saw above, this tunneling current magnitude depends upon the gap voltage, the gap distance, and the local density of electron states (Volume I, Equation 3.187).

At its heart, a scanning probe microscope has a piezoelectric material (e.g., quartz) that expands or contracts slightly when a voltage is applied to it. These voltages can be carefully controlled and cause one end of the crystal to move with better precision than the width of a single atom. The needle or tip is brought very close to the surface and moved over it piezoelectrically and a tunneling current, resulting from the overlap of the tip's electron wave functions with the conducting surface is measured. This tunneling current is generated, even though there is a break in the circuit. Using a feedback servo loop, the tip slowly scans across the surface and is raised and lowered in order to keep the signal constant and maintain a distance of a couple of angstroms, where the tunneling current is at a measurable level.

An STM does not measure nuclear position directly; rather, it measures the electron density clouds on the surface of the sample. In some cases, the electron clouds represent the atom locations pretty well, but not always. The trace from an STM (Figure 6.25A) can be interpreted as a grid (Figure 6.25Ba) that can be shown as a grayscale picture (Figure 6.25Bb). The grayscale picture can be interpreted as a contour map (Figure 6.25Bc), which can then be averaged out to make it smooth (Figure 6.25Bd) and finally can be colored (Figure 6.25C). This explains the color of the Kanji character, made by manipulation of individual iron atoms on a copper surface with an STM, in Figure 6.26.

The vertical resolution of an STM is remarkably good because of the exponential dependence of the current on vertical height (L in Volume I, Equation 3.187). This means that 1-Å change in height corresponds to almost 1 order of magnitude difference in current. The noise floor is in the tens of femtometer

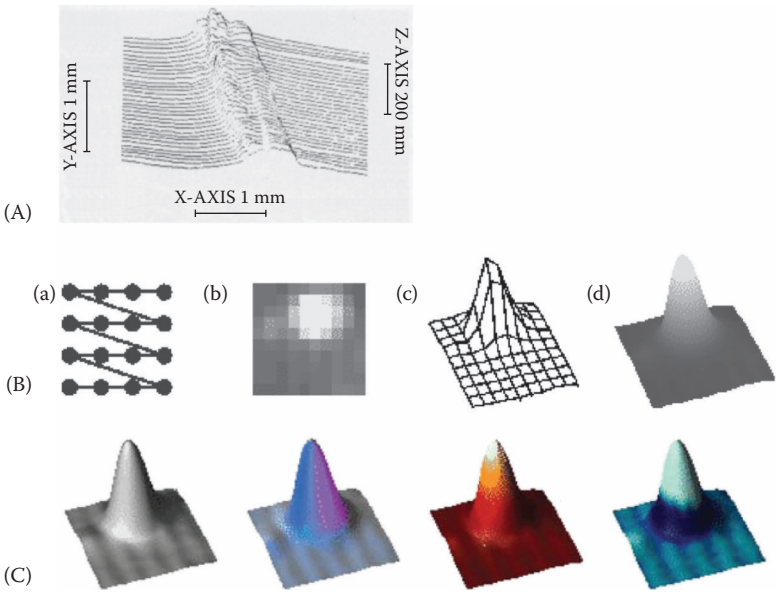

FIGURE 6.25 (A) Trace of a scanning tunneling microscope (STM). Shown is a trace of an individual turn mark on a diamond-turned aluminum substrate to be used for subsequent magnetic film deposition for a high-capacity hard disc drive. (B) The trace from an STM can be interpreted as a grid (a), which can be shown as a grayscale picture (b). The grayscale picture can be interpreted as a contour map (c) that can then be averaged out to make smooth (d) and finally colored (C).

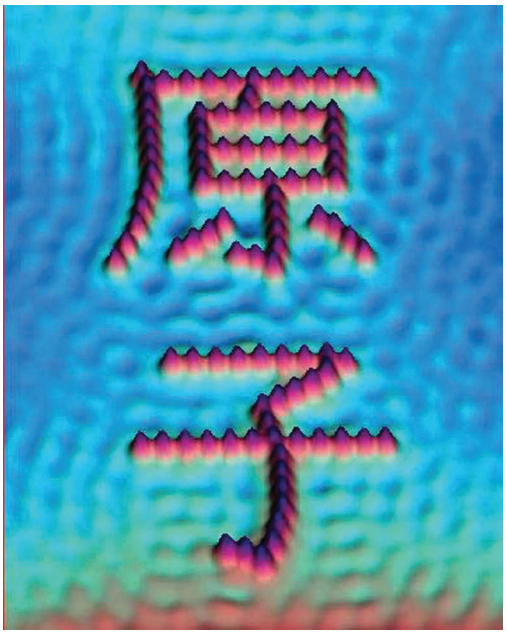

FIGURE 6.26 Kanji character for *atom*, by Lutz and Eigler (IBM Almaden). An example of manipulation/mechanosynthesis of iron atoms on a Cu surface with a scanning tunneling microscope. (Courtesy of D. Eigler.)

range. The lateral resolution depends on the tip radius as clarified in Figure 6.27. A tip with radius R = 1000 Å actually focuses 90% of the current in a circle of radius (Δx in Figure 6.27) of 45 Å. A 100-Å tip focuses 90% of the current in a circle of radius 14 Å. In practice, a 2-Å lateral resolution is routine. These numbers can be ascertained by rewriting $I = f_w(E)A^2e^{-2\alpha L}$ (Volume I, Equation 3.187) as:

$$I(\Delta x) = f_w(E)A^2e^{-2\alpha\frac{\Delta x^2}{2R}} \qquad (6.13)$$

There are two major modes of operation for an STM: constant current and constant height. In constant current mode one maintains a constant tunneling current by adjusting the height (separation between tip and sample). In constant height mode one, maintains the height and measures the current.

STMs can be used in solution, as there still is a vacuum gap, even in water. This mode of STM operation is called *scanning electrochemical microscopy*, which we encountered in Volume II, Chapter 4. To minimize faradaic processes the tip shank must be shielded with melted wax or plastic to expose only the last few nanometers of metal. The tunneling current to the exposed metal tip must be large compared with faradaic current to the tip shank.

STMs are limited to imaging parts with conductive surfaces, and electronic inhomogeneities can have significant effects on the acquired topographical images. Vibrations in the probing mechanism limits gap width stability, which, in turn, can affect the fidelity of the measurements. All SPMs are limited, in the same sense as white light interferometers, to a maximum measurable slope. When features with perpendicular sidewalls are scanned, the data typically exhibit a slope that is actually not present. The height of measurable features is also limited to the probe tip length, which is typically <10 μm in commercial systems. This limitation severely prohibits the inspection of high-aspect ratio parts with dimensions on the order of millimeters. Though these tools have extremely high resolution, it is unfeasible to collect scans that cover all of the surfaces of a part, given the limited scan range of the tools.

Gerd Binning and Heinrich Rohrer (Figure 6.28) invented the scanning tunneling microscope at IBM

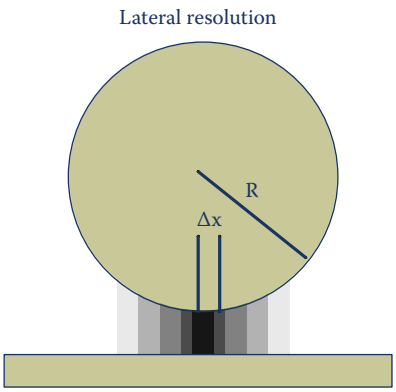

FIGURE 6.27 Lateral resolution of a scanning tunneling microscope.

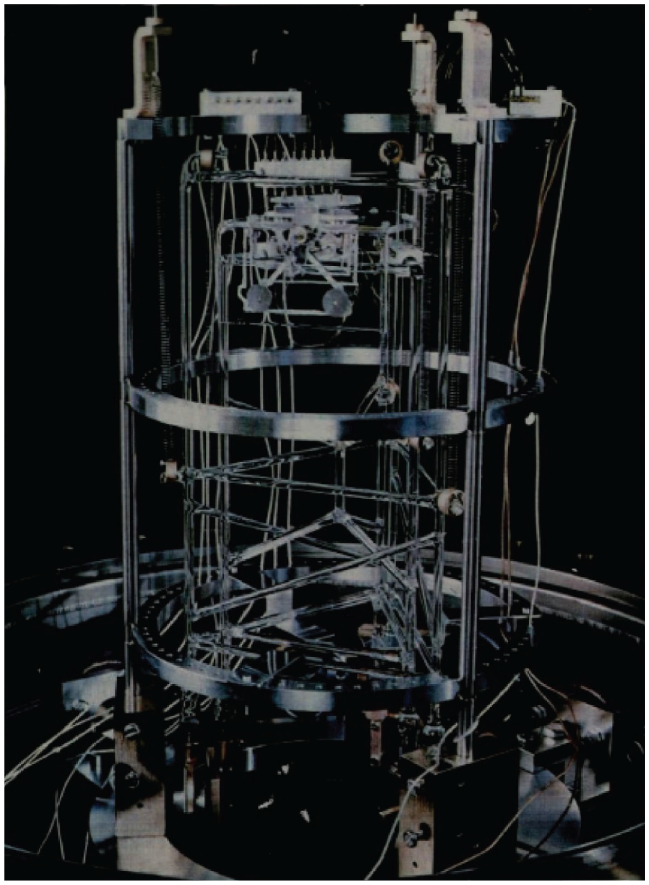

FIGURE 6.29 Binning and Rohrer's original scanning tunneling microscope.

Zürich in 1981. They shared the Nobel Prize for Physics in 1986 for their microscope (Figure 6.29).

Atomic Force Microscopy

Scanning force microscopy, also called *atomic force microscopy* (AFM), constitutes a major extension of the STM technique. The technique, first described in 1986, depends on forces (repulsive or attractive) between atoms of a sample and a probe (Figure 6.30).

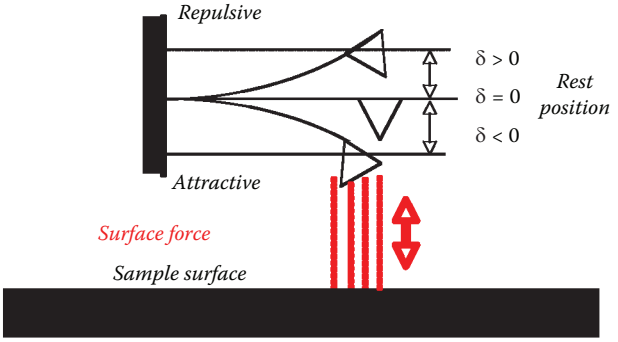

FIGURE 6.30 An atomic force microscope measures surface forces.

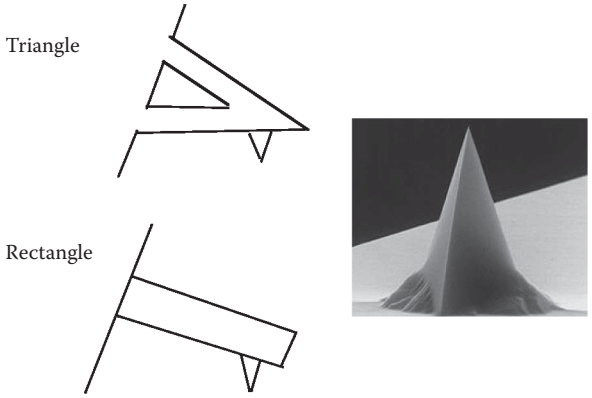

FIGURE 6.31 Cantilevers are either triangular or rectangular. Material can be silicon on silicon nitride (plastic in development). Probes shapes can be pyramidal or conical and may be sharpened.

No current flows between sample and AFM tip, so the sample need not be conducting.

In a typical AFM, a cantilever with a tip (the probe; see Figure 6.31) is oscillated above the sample surface. The oscillation amplitude is less than10 nm, and in the so-called *noncontact mode*, the tip does not touch the sample. Constant oscillation amplitude is maintained and surface forces, which extend from 1 to 10 nm above the surface, decrease the resonant frequency of the cantilever. This in turn changes the amplitude of oscillation. Typical surface forces range from the piconewton to the nanonewton [quantum mechanical (covalent, metallic bonds): 1–3 nN; Coulomb (dipole, ionic): 0.1–5 nN; polarization induced (dipoles): 0.02–0.1 nN].

A cantilever must now be designed to convert these very small mechanical forces into measurable deflection, δ.

A microfabricated cantilever beam and probe tip, as shown in Figure 6.32, deflects in response to an applied force and can be represented as a linear elastic, Hookean spring:

$$F = -k\delta \tag{6.14}$$

where δ = displacement at the end of cantilever (in meters) (this is what we actually measure in a force spectroscopy experiment)
F = external force applied to cantilever (in newtons) (this we can calculate from δ)
k = cantilever spring constant

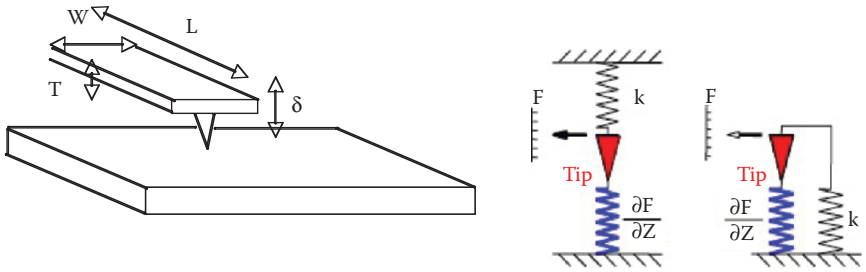

FIGURE 6.32 Atomic force microscope cantilever model. T = cantilever thickness (m), W = cantilever width (m), L = cantilever length (m), and δ = deflection of the end of the cantilever.

For the cantilever in Figure 6.32 the spring constant (in N/m) is given as follows:

$$k = \frac{EW}{4}\left(\frac{T}{L}\right)^3 \tag{6.15}$$

where T = cantilever thickness (in meters)
W = cantilever width (in meters)
L = cantilever length (in meters)
E = Young's (elastic) modulus of cantilever material (in pascals or N/m^2)

For Si, $E = 11 \times 10^{10}$ N/m^2.

We can calculate k independently, and typical values are 0.01–100 N/m. The resonance frequency f, of the cantilever is given as follows:

$$f = 0.162\sqrt{\frac{E}{\rho}}\frac{T}{L^2} \tag{6.16}$$

where ρ is the density of the cantilever material. Typical values for f are 7–500 kHz.

The interaction of surface forces with this cantilever can now be modeled as a spring in series with the cantilever spring, as pictured in Figure 6.32 or, remembering that $\omega = \sqrt{\frac{k}{m}}$:

$$\omega = \sqrt{\frac{k - \frac{\partial F}{\partial z}}{m}} \tag{6.17}$$

where $\partial F/\partial z$ is the force gradient (F'). For small amplitudes, a Taylor expansion of the force can be carried out, and a frequency shift proportional to the force gradient is found, as follows:

$$\frac{\Delta\omega}{\omega} = -\frac{1}{2k}\frac{\partial F}{\partial z} \tag{6.18}$$

In practice one needs to compromise between a cantilever with a small k and a large resonance frequency f. The resonance frequency (f) should indeed be higher than the data acquisition rate and the noise level (kHz range). To increase the resonance frequency, the cantilever should be stiff (large k), short and thin. On the other hand, to maximize sensitivity, a soft cantilever (small k) is preferred. But making k too small, one might have a problem of cantilevers crashing into the sample. With a k value of ~1 N/m, an AFM can measure forces of pN, and even fN is feasible. The force detection limit is the Brownian motion of the cantilever (thermal noise limited).

In Table 6.6 we list some example AFM cantilevers with their force sensitivity, Young's modulus, spring constant, resonant frequency, density and type of material, and shape. For an excellent discussion and references on cantilever design, consult http://www.asylumresearch.com/springconstant.asp.

Example 6.2

Exercise: In atomic force microscopy, an ultrasharp tip on the end of a silicon cantilever beam is used to probe a surface at the nanoscale. By how much is the beam deflected by thermal motion? The cantilever has a spring constant of ~10 N/m.

Answer: The energy required for deflection of the beam by a distance δ is $E = ½\ k\delta^2$. At a temperature of 300 K, the thermal energy is on the order of $kT = 6 \times 10^{-21}$ J.

This energy will cause an average deflection of the beam by $\delta = (2E/k)^{0.5} = 1 \times 10^{-7}$ m, or 100 nm.

A light lever is the most common deflection measurement (δ) sensor used in atomic force microscopes. In this approach, when the cantilever moves up and down, the position of a laser spot on a photodetector moves up and down. As a

Table 6.6 Example Atomic Force Microscope Cantilevers

Force Sensitivity (N)	k (N/m)	ω	ρ (g/cm^{-3})	Module Young E (10^{10} N/m^2)	Dimensions (mm)	Material
~10^{-8}	5000	22 kHz	8.9	22	4 × 0.25 diameter	Ni wire
~10^{-11}	2.5	33 MHz	2.3	11	2 × 0.5 × 0.1 μm	Si bar
~10^{-14}	0.004	8 kHz	3.1	32	0.2 × 0.036 × 0.3 μm	Si_3N_4 (V-shape)
10^{-12}	0.4	14 kHz	2.2	7	0.25 × 5 μm diameter	Quartz fiber

position-sensitive photodetector, a four-quadrant photodiode (current in each quadrant changes with light intensity) is used, as illustrated in Figure 6.33.

In an alternative approach a piezoresistive sensor is embedded in the cantilever. This approach was discussed in Volume I, Example 4.1.

There are three main AFM techniques in use: contact, noncontact, and tapping mode. In the "repulsive" contact AFM, the tip is in perpetual contact with the sample as it slides across the surface. The tip is attached to the end of a cantilever with a low spring constant, *k*, while the feedback keeps the vertical deflection of the cantilever constant. In contact mode, the AFM measures hard-sphere repulsion forces between the tip and sample. Forces range from nano- to micronewtons in ambient conditions and even lower (0.1 nN or less) in liquids. This method provides the highest resolution but may damage the surface. It is the only AFM technique that can provide atomic-resolution images.

In noncontact mode, the AFM derives topographic images from measurements of the van der Waals attractive forces. The tip does not touch the sample; instead, the cantilever with the tip oscillates (amplitude <10 nm) above the surface. The resonant frequency of the cantilever is decreased by the attractive surface force, which extends from 1 to 10 nm above the surface (see Volume I, Chapter 7, "Calculating Interaction Forces between Surfaces and Particles"). The noncontact mode has the lowest resolution of the three main AFM approaches.

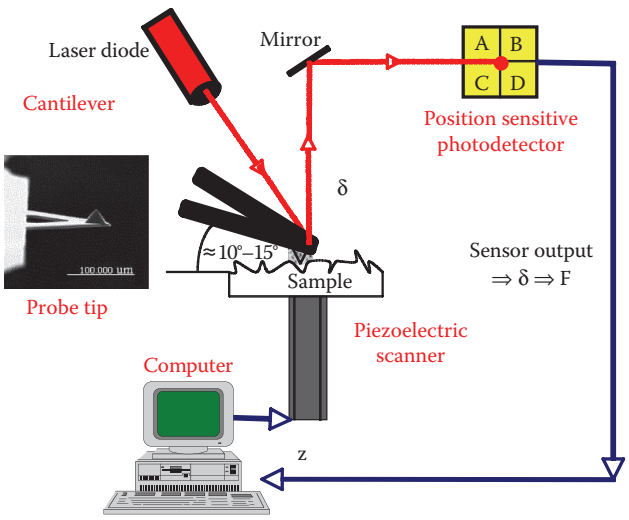

FIGURE 6.33 A light lever atomic force microscope setup.

Tapping mode AFM, the most commonly used of all AFM modes, is a patented technique (Veeco Instruments) that maps topography by lightly tapping the surface with an oscillating probe tip. This eliminates the shear forces potentially damaging to soft samples. The AFM tip taps the sample surface during the closest point of approach in each oscillation cycle, the amplitude of which is kept unchanged by the feedback loop. In this intermittent tip contact, force is measured with improved resolution over noncontact AFM. Surface forces again cause an oscillation frequency shift, but the tap also causes the cantilever/tip to lose energy, giving additional information about the surface. Another major advantage of tapping mode is related to limitations that can arise because of the thin layer of liquid that forms on most sample surfaces in an ambient imaging environment, i.e., in air or some other gas. The amplitude of the cantilever oscillation in tapping mode is typically on the order of 20–100 of nanometers, which ensures that the tip does not get stuck in this liquid layer. The amplitude used in noncontact AFM is much smaller (<10 nm; see above), and as a result, the noncontact tip often gets stuck in the liquid layer. In general, tapping mode is much more effective than noncontact AFM for imaging larger scan sizes that may include large variations in sample topography. Tapping mode can be performed in gases, liquids, and some vacuum environments.

The presence of a feedback loop is one of the subtler differences between AFMs and older

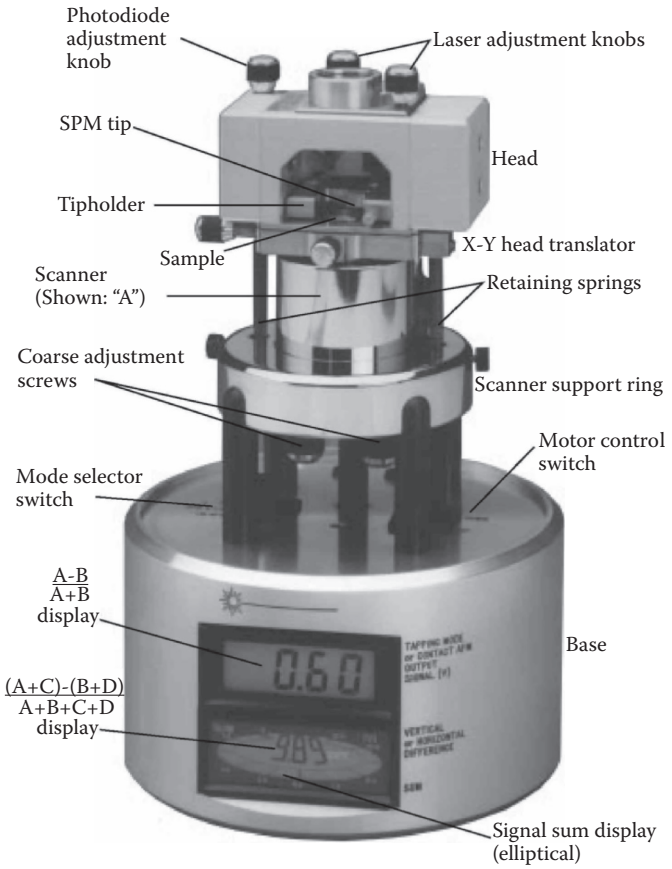

FIGURE 6.34 Veeco Instruments atomic force microscope.

stylus-based instruments such as record players and stylus profilometers (see Figure 6.40). The AFM not only measures the force on the sample but also regulates it, allowing acquisition of images at very low forces. One point of interest: the faster the feedback loop can correct deviations of the cantilever deflection, the faster the AFM can acquire images; therefore, a well-constructed feedback loop is essential to microscope performance. AFM feedback loops tend to have a bandwidth of about 10 kHz, resulting in image acquisition times of about 1 min.

In Figure 6.34 we show a photograph of a typical AFM.

Tools to Measure Materials Properties: Property Metrology

Introduction

While most MEMS metrology techniques focus on dimensional metrology and some on dynamic metrology, few systems exist for measuring other properties of microsystems, such as electrical, magnetic, thermal, and mechanical characteristics. In the category of material property measuring equipment, we start with a review of scanning proximal probe microscopes (SPMs) for determination of material properties, such as magnetic, thermal, and mechanical behavior. We then consider tools used to measure conductivity and carrier type of a material. MEMS devices are often mechanically dynamic by nature. Therefore, there is also a need to measure dynamic motion of MEMS devices. We cover two mechanical property metrology techniques: using interferometry with a stroboscopic LED to freeze device motion and laser Doppler vibrometry to measure contactless velocity and displacement of vibrating structures.

Material Property Measuring Scanning Proximal Probe Microscopes

The scanning proximal microscopes introduced above also can be utilized for a variety of material property metrology tasks (see Table 6.5). We briefly describe a number of the best-known techniques.

Magnetic force microscopy (MFM) is an imaging mode derived from atomic force microscopy (AFM) used in the noncontact mode that maps magnetic force gradients above a sample surface with a resolution of 10–25 nm. An image acquired with a MFM probe tip coated with a magnetized material (e.g., CoCr or NiFe) contains information about both the topography and the magnetic properties of a surface. Which effect dominates depends upon the distance of the tip from the surface, because the magnetic force persists for greater tip-to-sample separations than the van der Waals force. If the tip is close to the surface, in the region where standard noncontact AFM is operated, the image will be predominantly topographic. As the separation between tip and the sample increases, magnetic effects become apparent. While scanning in the latter mode, it is the magnetic field's dependence on tip-sample separation that induces changes in the cantilever's amplitude, resonance frequency, or phase. MFM can be used to image both naturally occurring and deliberately written magnetic domains. A MFM typically

measures magnetic properties and topography of a surface in a two-pass fashion. The first pass is a standard AFM trace that maps out the surface topography by gently tapping the tip along the surface. A second pass then samples the magnetic stray field by scanning at a constant height above the surface (see Figure 6.35).

Indentation (hardness) testing is very common for bulk materials where the direct relationship between bulk hardness and yield strength is well known. It can be measured by pressing a hard, specially shaped point into the surface and observing indentation. This type of measurement is of little use for measuring thin films below 5×10^4 Å. Consequently, very little is known about the hardness of thin films. Nanoindenting and scratching are new AFM-based methods to characterize material mechanical properties on a very small scale. Features less than 100 nm across, as well as thin films less than 5 nm thick, can be evaluated. Test methods include indentation for comparative and quantitative hardness determination and scratching for evaluation of wear resistance and thin-film adhesion. During nanoindentation, a hard tip of known geometry makes an impression in a sample, with a penetration depth and force dynamically measured at resolutions of nanometers and micronewtons, respectively. The resulting force-depth curve can be analyzed to give bulk properties such as modulus and hardness, as well as to study deformation mechanisms. Empirical relations have correlated hardness with Young's modulus and with uniaxial strength of thin films. Hardness calculations must include both plastic and long-distance elastic deformation. If the indentation is deeper than 10% of the film, corrections for elastic hardness contribution of the substrate must also be included.[12]

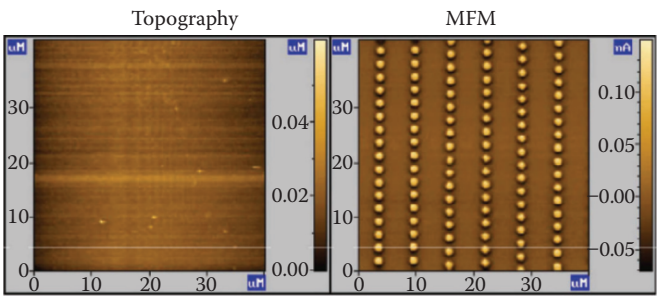

FIGURE 6.35 Magnetic force microscopy of a magneto-optical disc. (Veeco Instruments.)

Since in this new specialized instrument, load and displacement data are collected while the indentation is being introduced to the thin film; this eliminates the errors associated with later measurement of indentation size and provides continuous monitoring of load/displacement data similar to a standard tensile test. Load resolution may be 0.25 μN, displacement resolution 0.2–0.4 nm, and *x-y* sample position accuracy 0.5 μm. Diamond and sapphire are the primary materials of nanoindenting tips, but other hard materials also can be used, such as quartz, silicon, tungsten, steel, tungsten carbide, and almost any other hard metal or ceramic.

Bushan provides an excellent introduction to this field in the *Handbook of Micro/Nanotribology*.[13] In Figure 6.36 an indentation and scratch on polyurethane film is shown (17-μm scan).

In electrostatic force microscopy (EFM) a grounded tip first acquires the surface topography using the tapping mode. A voltage between the tip and the sample is applied in the second scan to collect electrostatic data (50–100 nm above the surface). EFM measures electric field gradient and distribution above the sample surface. EFM is used to monitor continuity and electric field patterns on samples such as semiconductor devices and composite conductors, as well as for basic research on electric fields on the microscopic scale. For thermal microscopy, there are quite a few options, as listed in Table 6.7, but scanning thermal microscopy (SThM) provides by far the best spatial resolution.

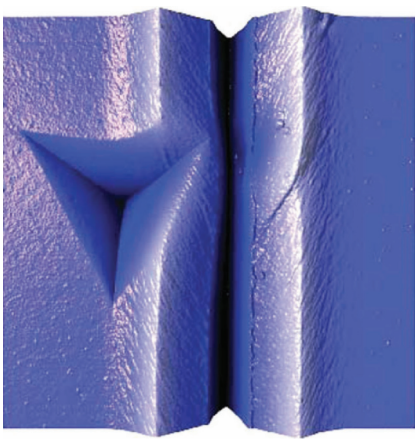

FIGURE 6.36 Indentation and scratch on polyurethane film (17-μm scan). (Asylum Research, http://www.asylumresearch.com/Products/NanoI/NanoIndenter.pdf.)

Table 6.7 Thermal Microscopy for Micro-Nano Devices

Techniques	Spatial Resolution
Infrared thermometry	1–10 μm*
Laser surface reflectance	1 μm*
Raman spectroscopy	1 μm*
Liquid crystals	1 μm*
Near-field optical thermometry	<1 μm
Scanning thermal microscopy	<100 nm

* Diffraction limit for far-field optics.

When an ultraminiaturized resistance is used as the scanning probe in an AFM, the image contrast reflects variations in thermal properties across the sample. The probe can be used as a thermometer or as a localized DC or AC heat source. When used as a thermometer, the image contrast represents variations in temperature across the surface. Hot spots, and also defects causing hot spots, in integrated circuits (ICs) and semiconductor devices may be detected this way. When used as a highly localized DC heat source, thermal conductivity/diffusivity variations across the surface can be mapped. In the AC heat source mode, thermal waves can be generated. Because of the evanescent nature of these waves, one can control the maximum depth of the sample that is imaged, according to the depth of penetration of the wave, which varies with the frequency chosen. SThM therefore looks below the surface in a controlled manner.

Conductivity and Carrier Type of a Material

In this section we cover how to go about measuring the conductivity and carrier type of thin films, such as thin-film resistors. In ICs and MEMS/NEMS devices, resistors are either thin-film metals or semiconductors. Metal resistors are deposited by evaporation, sputtering, or plating, whereas doping a semiconductor substrate creates semiconductor resistors. Metal resistors are patterned by wet etch, dry etch, or lift off and come in typical thicknesses of 0.1–10 μm and widths between 1 and 100 μm. Typical resistivity values range from 3 μΩcm for Al to 100 μΩcm for Nichrome. Metal films have nearly linear resistance-temperature behavior over wide temperature ranges, with a typical resistivity coefficient of 10^{-3}/°C. Issues that arise with metal resistors are morphological variations such as grain size changes and surface passivation. Semiconductor resistors, created by doping a semiconductor substrate, have a typical resistivity from 10^{-3} to 10^{7} Ωcm. The resistance-temperature behavior of semiconductor is much more dependent on temperature and impurities than that of metals and feature a typical resistivity coefficient per °C of −0.05. The biggest issues with semiconductor resistors are dopant concentration uniformity and deleterious effects of high-temperature processing.

In Volume I, Chapter 3, we saw that the Hall effect enables the measurement of the free-carrier type and concentration in semiconductors. Here we review two simpler techniques to determine these parameters, i.e., hot-point probe and four-point probe.

In Figure 6.37 we consider a very thin conductor film, of length l, width W, and thickness t, so that the current path area A = tW. The resistance, R, of this thin conductive layer is proportional to the resistivity, ρ, and inversely proportional to the thickness, t. It is convenient to define a sheet resistance, R_s, that is equal to ρ/t. Sheet resistance may be thought of as a material property for conductors that are essentially two-dimensional. For the resistance of a thin deposited conductor layer of length L, thickness t, and width W, we can write the following equation:

$$R = \frac{\rho}{t}\frac{L}{W} = R_s\frac{L}{W} \tag{6.19}$$

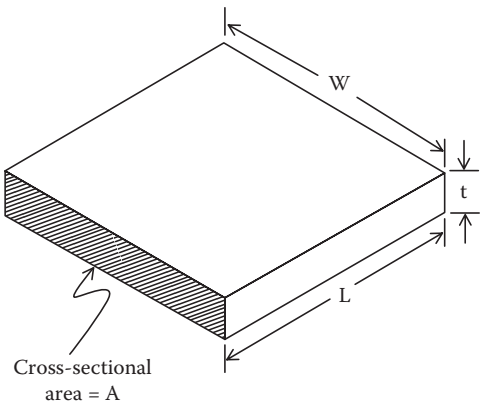

FIGURE 6.37 Sample geometry for a conductor thin film.

The ratio L/W is referred to as the number of squares (∼) and is dimensionless. The sheet resistance has the units of ohms, but it is convenient to refer to it as ohms per square (Ω/∼). The resistance of a rectangular thin layer is therefore the sheet resistance times the number of squares (L/W). The thickness and the number of squares, which can be accurately controlled with lithography, primarily determine the sheet resistance of a thin film.

The latter can be accurately controlled with lithography, whereas the sheet resistance primarily is determined by the film thickness carrier type and conductivity. Sheet resistance of a newly deposited thin film is typically measured with a four-point probe, an important tool in any IC or MEMS laboratory. For measuring resistance of a thin film, one could just measure the current that flows for a given applied voltage between two electrodes contacting the sample. However, in that case, contact resistances associated with the probes and current spreading problems around the probes can be significant and are not easily accounted for. Using four metal probes, as shown in Figure 6.38, allows one to force the current through the two outer probes using a constant current source and measure the voltage between the two inner probes. There still might be contact resistance and current spreading problems around the two outer probes, but since the voltage drop is measured between the two inner probes, problems with probe contacts are eliminated since no current flows through these inner contacts. The measured resistance (V/I) is converted to resistivity using the following relationship:

$$\rho = \frac{V}{I}.2\pi SF \tag{6.20}$$

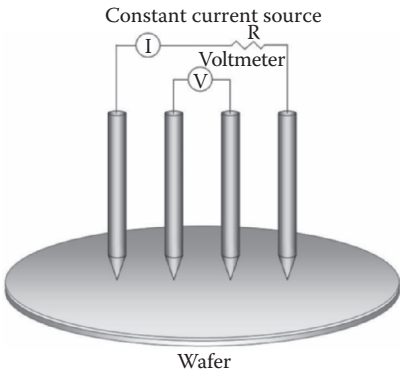

FIGURE 6.38 Four-point probe measurement arrangement.

with S the distance in centimeters between the metal probe needles and F a correction term. In the case the thickness, t, of the wafer or a measured film is much larger than S ($t >>>> S$), the correction factor F in Equation 6.18 equals 1. For thin films with $S >>> t$, Equation 6.20 must be replaced by the following:

$$\rho = \frac{\pi t}{\ln 2}\frac{V}{I} \tag{6.21}$$

and since $R_s = \rho/t$, we can calculate the sheet resistance as follows:

$$R_s = \frac{\pi}{\ln 2}\frac{V}{I} = 4.53\frac{V}{I} \tag{6.22}$$

The latter expression is most handy and easy to memorize.

The technique is more powerful than the sheet resistance method described above because it can determine the material type, carrier concentration, and carrier mobility separately. To determine whether a wafer is n- or p-type, a hot-point probe is a simple and reliable tool. The basic operation of this probe is illustrated in Figure 6.39. Two metal probes make ohmic contact with the semiconductor surface, and one probe is heated 25–100°C higher than the other. A voltmeter measures a potential difference across the probes, and the voltage polarity indicates whether the material is n- or p-type. In the case of an n-type sample, the majority carriers are electrons. At the hot probe, the thermal energy of the electrons is higher than at the cold probe, so the electrons will tend to diffuse away from the hot probe driven by the temperature gradient. As the electrons diffuse away from the hot probe, they leave behind a positively charged zone at the hot probe and the negatively charged mobile electrons tend to build up near the cold probe. This results in the hot probe becoming positive with respect to the cold probe. By a similar set of arguments, if the material were p-type, positively charged holes would be the majority carriers, and the polarity of the induced voltage would be reversed.

Dynamic Mechanical Properties

Interferometry with a stroboscopic LED and laser Doppler vibrometry can both be used to measure

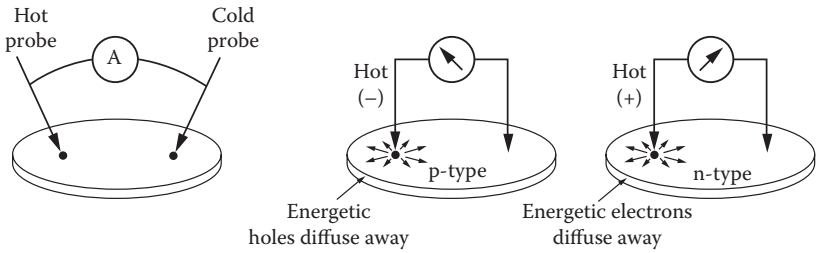

FIGURE 6.39 Using a hot-point probe to determine whether a semiconductor is n- or p-type.

contactless velocity and displacement of vibrating structures. A stroboscopic LED freezes device motion and enables an interferometer, as shown in Figure 6.11, to measure in-plane and out-of-plane motion at frequencies up to 10 MHz (this addition to an interferometer is called a *dynamic MEMS capability*).

A laser Doppler vibrometer is an interferometry system for accurately measuring velocity and displacement of vibrating structures again without contact. The system is based on the principle of the detection of the Doppler shift of coherent laser light scattered from a small area of the moving test structure. This system detects the Doppler shift of a coherent laser and then converts the frequency shift to velocity. As the laser light has a very high frequency, a direct demodulation of the light is impossible; therefore, an optical interferometer is used to mix the scattered light coherently with a reference beam. Such an arrangement can be based on a Michelson interferometer, as shown in Figure 6.10.

Structure Metrology

Introduction

Structural metrology measures crystallinity, defects, surface roughness, etc. In the structural metrology category, we review stylus profilometry for surface roughness and transmission electron microscopy (TEM) for crystallinity.

Stylus Profilometry

Surface texture of a sample is, in general, broken up into three components: roughness, waviness, and form (see also Volume II, Chapter 6, on mechanical energy-based removing). Roughness refers to the marks made on a sample surface by the machining tool itself, e.g., grooves from the tool or from each grinding granule on a grinding wheel. Waviness is the result of the distance between the tool and the workpiece changing during machining. This may be caused by vibration in the tool caused by sources outside the machining tool (e.g., a truck passing by) or by sources inside the tool (e.g., a worn spindle). Form errors are yet larger dimensional errors because the machine tool path is not always straight or it may be worn. This creates surface irregularities, but in a consistent manner, because the machine follow the same wrong path. All three surface finish components exist simultaneously and overlap one another. One often will want to look at each (roughness, waviness, and form) separately, so we make the assumption (a correct one, in most cases) that roughness has a shorter wavelength than waviness, which in turn has a shorter wavelength than form.

A stylus profilometer uses a hard tip (e.g., diamond) dragged over a surface with very light pressure and simultaneously measures form, dimension, texture, and step height. The first such devices for surface roughness measurement came about around 1930. The movement of the tip actuates a linear variable differential transducer (LVDT) that converts movement in an electrical signal. The tip of the profilometer is conical and has a finite rounded shape, which interacts with the sample being scanned. It may measure film thickness (step height) changes of 200 Å to 65 µm with a vertical resolution of about 1 nm. The vertical sensitivity is in the nanometer range, but steep edge profiles are distorted because of the shape of the tip, as indicated in Figure 6.40. The horizontal resolution depends on tip radius, so small-radius tips are better but are more likely to be damaged by mishandling.

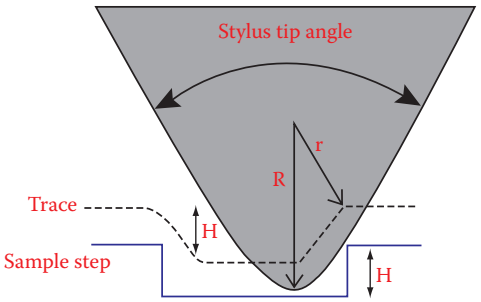

FIGURE 6.40 The stylus of a stylus profilometer.

As we saw earlier, an atomic force microscope (AFM) is a new instrument for measuring roughness of a sample surface. As for its design, an AFM has similarities to a conventional stylus profilometer; however, an AFM can image a sample surface and precisely measure up to nanometer size in three dimensions. Because of the sharper tip and small loading force, the lateral resolution in AFM is greatly improved in comparison with the conventional profilometer. In Table 6.8 we compare the major types of profilometers.

Transmission Electron Microscopy

Ernst Ruska and Max Knoll built the first transmission electron microscope (TEM) in 1931. As in the case of the first optical microscope, this was a very crude machine compared with its modern descendants. It did, however, put some important ideas about how to image with electrons to the test. For example, instead of using glass lenses to bend and focus light, electron microscopes use magnetic coils to do the same for electrons (H. Busch was the first to use a magnetic coil like a lens in 1926). Ruska used his first electron microscope to take pictures of gold and copper surfaces and produced images at about ×10 (about the same magnification as the 1595 Janssen microscope). The development of the electron microscope was much faster, though, than that of the optical microscope, and it was not long before electron microscopes far surpassed the resolution of optical microscopes (Ruska constructed a microscope that surpassed the 200-nm optical limit in 1933). Following the development

TABLE 6.8 Profilometers Compared

	White Light Interferometry and Phase Shift Technology	Stylus Contact	Atomic Force Microscope
Advantages	Excellent depth resolution, 0.1 nm; very good lateral resolution down, to 0.3 μm	Lowest-price technique for standard systems	Best lateral resolutions for detail imaging
	Use charge-coupled device camera to take roughness measurement in a few seconds	Depending on design can test steep angular surfaces	Can reveal surface structure in details
	Stitching technique allows coverage of large surfaces		
	Ideal for many microelectronic applications		
Disadvantages	Difficulty on high-angular surfaces or surface where line of interference pattern is difficult to see; chromatic aberration technique works better on these surfaces	Tip size often larger than 10 μm but can be down to 1 μm in higher-priced systems	Slow compared with white light systems
	More limited than white light chromatic aberration in the *z*-direction; stitching allows a few millimeters	Depending on size of probe and load applied, deformation may occur on softer materials, such as polymers or plastics	Requires more knowledge for use
		Normally two-dimensional instruments	Relatively small surfaces can be tested (100 μm by 100 μm)
		Slow, especially if three-dimensional imaging is performed

of the first commercial available electron microscope by Ruska and the company Siemens in 1939, the electron microscope rapidly became an invaluable tool to science and engineering. Much of what we know about the nanoworld we owe indeed to the electron microscope. Although the technique of x-ray diffraction preceded the invention of the electron microscope and provided compelling evidence for atomic crystal structure, atoms themselves had never been seen until high-resolution TEMs came about.

A TEM maybe compared to a slide projector. In a slide projector, a beam of light passes through (transmits) a slide, and as the light passes through, the structures and objects on the slide modulate it. This transmitted beam is then projected onto the viewing screen, forming an enlarged image of the slide. TEMs work much the same way except that they shine a beam of electrons through a very thin specimen, and whatever electrons are transmitted are projected onto a phosphor screen or recorded on film or by a digital camera for the user to see. TEMs are used to characterize the microstructure of materials with very high spatial resolution. The electron gun, condenser lenses, and vacuum system in a TEM are similar to the ones in an SEM (see above), but in a TEM, a higher acceleration voltage of 120–200 kV is used (the operating voltage in an SEM ranges from 30 to 60 kV). In a scanning transmission electron microscope (STEM), the beam is rastered across the sample to form the image.

With a TEM, information about the morphology, crystal structure, defects, crystal phases, and composition is obtained by a combination of electron-optical imaging, electron diffraction, and small probe (20 Å) capabilities. The trade-off for this diverse range of structural information and high resolution is the challenge of producing very thin samples for electron transmission (Figure 6.41). A TEM sample must be 1000 Å or less in thickness in the area of interest. Sample preparation for TEM is more tedious and time consuming than for almost any other analytical technique.

There are three basic modes of TEM operation: the bright-field imaging mode, the dark-field imaging mode, and the diffraction mode. The way to choose which electrons form the image is by

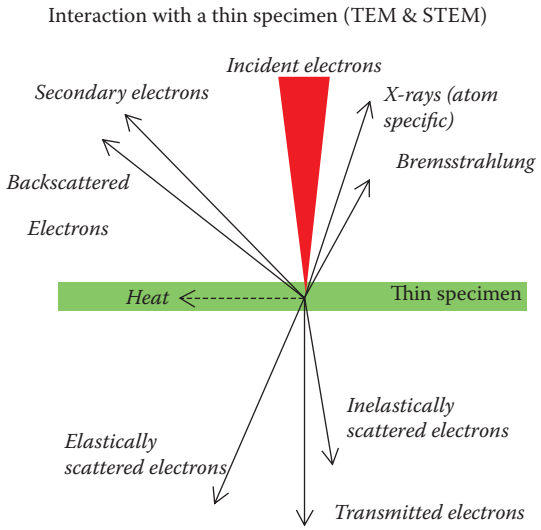

FIGURE 6.41 Electron path through a thin specimen (<1,000 Å) in transmission electron microscopy and scanning transmission electron microscopy.

inserting an aperture into the back focal plane of the objective lens.

In the bright-field (BF) mode of the TEM, an aperture is placed in the back focal plane of the objective lens, which allows only the direct beam to pass (Figure 6.42a). In this case, the image results from a weakening of the direct beam by its interaction with the sample. Therefore, mass-thickness and diffraction contrast contribute to image formation: thick areas, areas in which heavy atoms are enriched, and crystalline areas appear with dark contrast.

In dark-field (DF) images, the direct beam is blocked by the aperture while one or more diffracted beams are allowed to pass the objective aperture. Since diffracted beams have strongly interacted with the specimen, very useful information is present in DF images, e.g., about planar defects, stacking faults, or particle size (Figure 6.42b).

We can also think of the TEM as a diffraction camera. To obtain lattice images, a larger objective aperture is selected to allow many beams, including the direct beam, to pass (Figure 6.42c). The image is formed by the interference of the diffracted beams with the direct beam (phase contrast). If the point resolution of the microscope is sufficiently high and a suitable sample is oriented along a zone axis, then high-resolution TEM (HRTEM) images are obtained. In many cases, the atomic structure of a specimen can directly be investigated by HRTEM.

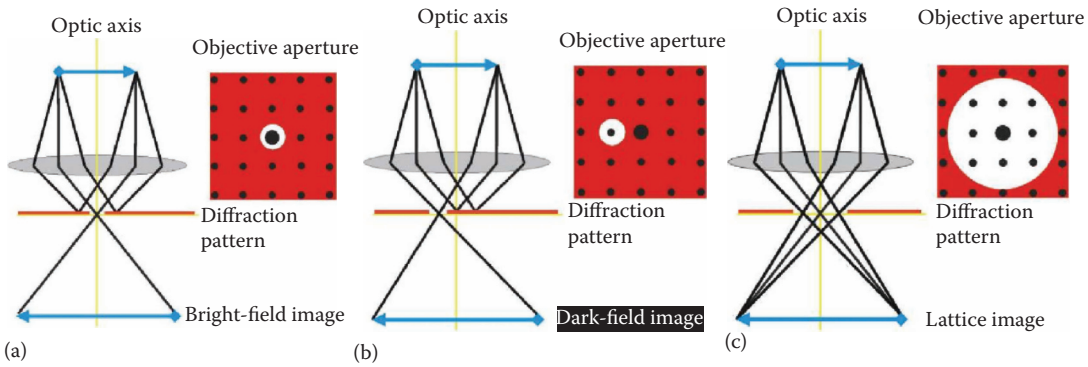

FIGURE 6.42 Bright-field image (a), dark-field image (b), and diffraction (c) in scanning transmission electron microscopy.

The objective lens forms a diffraction pattern in the back focal plane with electrons scattered by the sample and combines them to generate an image in the image plane (first intermediate image) as illustrated in Figure 6.43. Thus, diffraction pattern and image are simultaneously present in the TEM. In imaging mode (left panel in Figure 6.43), an objective aperture can be inserted in the back focal plane to select one or more beams that contribute to the final image (BF, DF, and HRTEM). In selected area electron diffraction (SAED), an aperture in the plane of the first intermediate image defines the region for which the diffraction is obtained (Figure 6.43, right panel). Which of them appears in the plane of the second intermediate image and is magnified by the projective lens on the viewing screen depends on the intermediate lens. Switching from real space (image) to reciprocal space (diffraction pattern) is easily achieved by changing the strength of the intermediate lens. By manipulating the magnetic lenses of the microscope, the diffraction pattern may thus be observed by projecting it onto the screen instead of the image (Figure 6.43).

An example of what a diffraction pattern obtained in this way may look like is shown in Figure 6.44. The center spot in this figure corresponds to the transmitted electron beam, and the other spots are diffracted portions of the initial electron beam. The location of the spots is governed by Bragg's law ($n\lambda = 2d \sin\theta$; see Volume I, Figure 2.17 and Equation 2.20).

Transmission and scanning transmission electron microscopy can produce images of atomic lattices with 2.3-Å point-to-point resolution. In Table 6.9, we compare scanning electron microscopy (SEM) and transmission electron microscopy (TEM) with optical microscopy (OM) and scanning proximal microscopy (SPM) (using both STMs and AFMs).

Compositional Metrology

Introduction

As examples of chemical composition metrology we discuss energy dispersive analysis of x-rays (EDAX) [also known as *energy dispersive x-ray spectroscopy* (EDX) or EDS], a standard procedure for identifying and quantifying elemental composition of specimen surfaces to shallow depths and Auger electron spectroscopy (AES) and scanning Auger

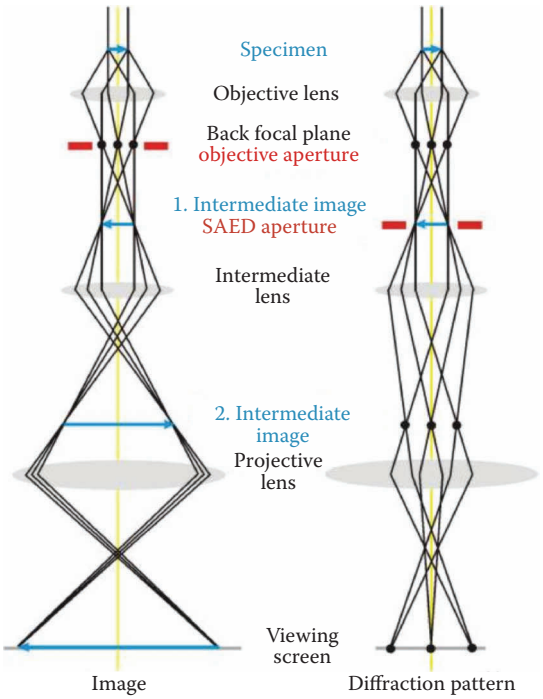

FIGURE 6.43 Switching from imaging to diffraction in scanning transmission electron microscopy. SAED = selected area electron diffraction.

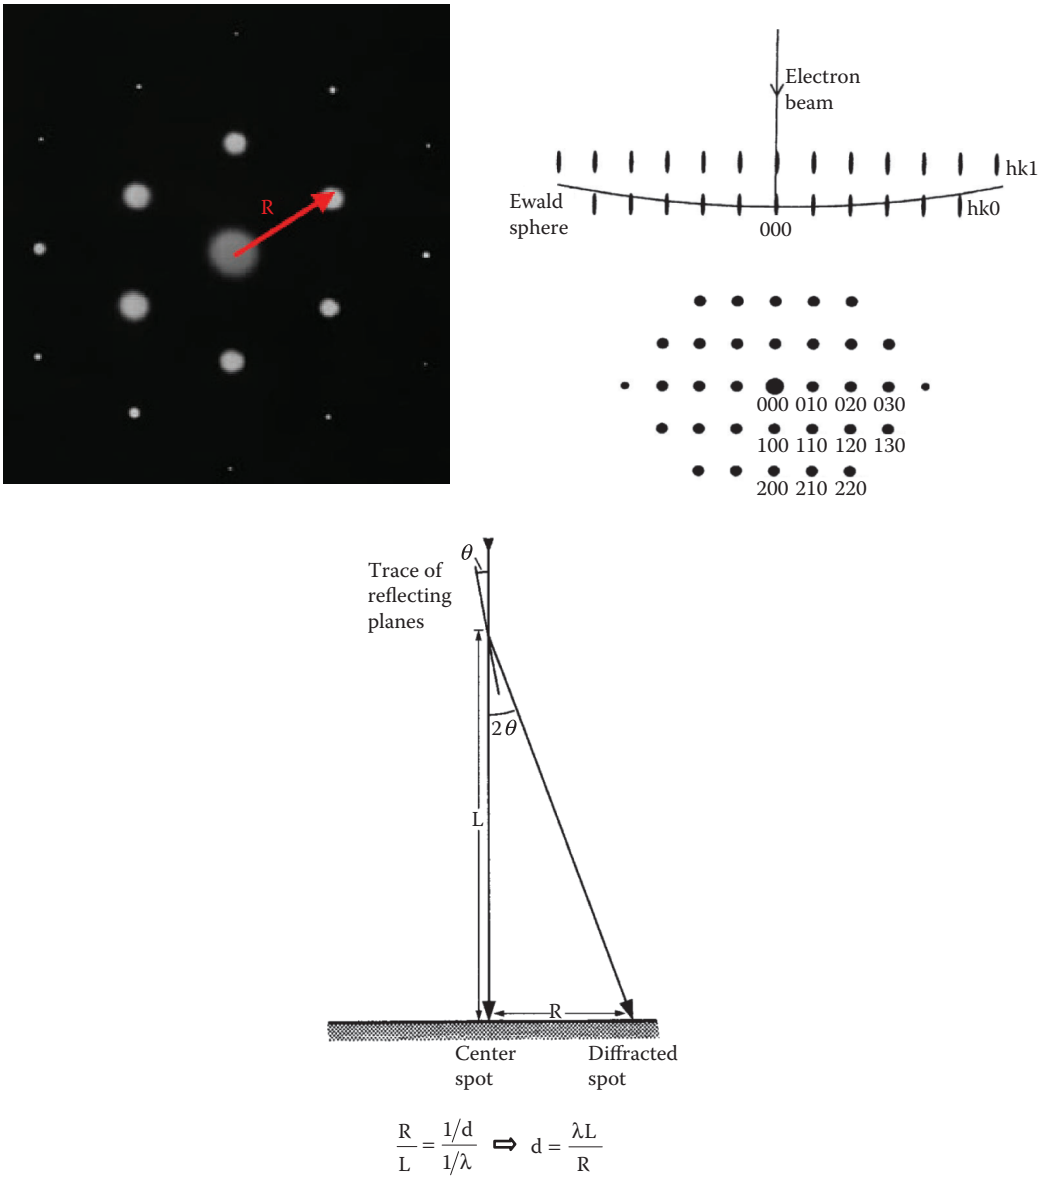

FIGURE 6.44 An example of what a diffraction pattern in a scanning transmission electron microscope may look like. The center spot corresponds to the transmitted electron beam, and the other spots are diffracted portions of the initial electron beam. The locations of the spots are governed by Bragg's law.

TABLE 6.9 The Use of SEMs and TEMs Compared with OM and Scanning Proximal Microscopy (Using Both STMs and AFMs)

	OM	SEM/TEM	Scanning Proximal Probe Microscopy
Environment	Air, liquid	Vacuum	Air, liquid, UHV
Depth of field	Small	Large	Medium
Lateral resolution	1 μm	1–5 nm: SEM 0.1 nm: TEM	2–10 nm: AFM 0.1 nm: STM
Vertical resolution	N/A	N/A	1.1 nm: AFM 0.2 0.01 nm: STM
Magnification	Up to 2,000	Up to 1,000,000	Up to 100,000,000
Sample	Not completely transparent	Unchargeable, vacuum compatible; thin film: TEM	Surface height <10 mm
Contrast	Absorption/reflection	Scattering/diffraction	Tunneling

microscopy (SAM), which can identify every atom from Li on up.

EDAX (EDX or EDS)

Energy dispersive analysis of x-rays (EDAX) is also called *EDX* and, more and more frequently, *EDS*. This compositional metrology technique is carried out in conjunction with scanning electron microscopy (SEM) and transmission electron microscopy (TEM). A modern trend in electron microscopy is indeed to fit x-ray analysis equipment as a bolt-on accessory to electron microscopes. Bombarding a specimen with electrons causes x-rays of characteristic wavelengths and energies to be emitted from the spot where the beam strikes the sample, and an EDS detector analyzes the x-ray photons by energy rather than wavelength. The EDS detector (sometimes called *EDX detector*) converts the energy of each individual x-ray into a voltage signal of proportional size. The detector involves a large single-crystal Si that either has been treated to approximate an ideal semiconductor or is of high-enough purity to truly be an intrinsic semiconductor. Front and back contacts on the Si piece are kept at several kilovolts potential relative to each other, and x-rays are converted into a charge by ionization of atoms in the crystal. To keep electronic noise at a minimum, the Si detector is cooled in liquid nitrogen. X-rays that pass through the front contact tend to dissipate their energy, creating electron-hole pairs in the intrinsic region. Next, this charge is converted to a voltage signal by a field effect transistor (FET) preamplifier, and the voltage signal is input into a pulse processor for measurement. Since each electron-hole pair has a characteristic creation energy, the total number of charge carriers created is proportional to the energy of the incident x-ray. A computer keeps track of the number of counts within each energy range, and the total collected x-ray spectrum can then be determined. Computer analysis of energy spectra makes it possible to measure accurately the nature and quantity of different elements in the material. This can then be used to make a chemical map of the surface. The technique is of little use to biologists because light elements such as carbon produce too weak an x-ray signal. However, it is of great value in materials science, particularly because an area as small as 1 μm^2 can be analyzed with precision (http://www.edax.com).

Typically, x-ray analysis is a bulk sensitive technique because of the small cross-section [10^{-6} $Å^2$ compared with 1 $Å^2$ for LEED (see above)], but grazing incidence (<1°) makes it surface sensitive (total reflection, because the refractive index of x-rays is slightly smaller than unity). The refracted wave becomes an evanescent wave traveling along the surface within a few 10 Å. This is called *gracing incidence x-ray diffraction* (GIXRD).

Auger Electron Spectroscopy and Scanning Auger Microscopy

Upon electron bombardment of metals, Pierre Auger, in 1925, observed (at first in a cloud chamber, and then on photographic plates) the occurrence of electron emissions with precisely determined energies. These electrons were later named Auger electrons and may serve to identify their parent atoms. It was J. J. Lander, who in 1953 suggested the idea of using Auger electron spectroscopy (AES) for surface analysis. AES was implemented as an analytic tool in 1967 (by Larry Harris), after increasing the sensitivity of the method by using differential spectra to discriminate the small Auger peaks in the electronic spectra. AES is now the most commonly used method by which to investigate surface composition.

The Auger process is a three-electron concerted process, as illustrated in Figure 6.45. An incident electron beam (2–10 keV) hits an atom and ejects a core electron, leaving a hole in a highly excited atom. The ionized atom relaxes by emitting either an x-ray photon (x-ray fluorescence) or by ejecting another electron (Auger electron). For lighter elements Auger emission is favored over x-ray fluorescence. In Auger spectroscopy the state of excitation is quenched by another electron falling into the hole left by the ejected core electron. The binding energy of the first electron is always very much greater than that of the second, so that there is still considerable excess energy in the system. This extra energy is shed by the ejection of a third electron from another shell. The residual kinetic energy of the ejected electron is measured and is a unique quantity determined by the binding energies of the three electrons and the work function of the materials involved.

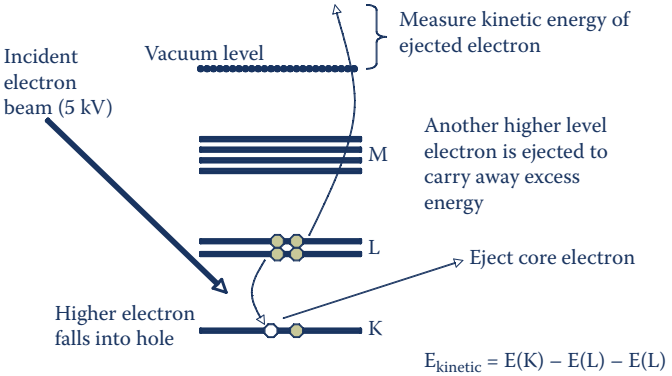

FIGURE 6.45 The Auger process.

An Auger process is identified by the three letters of the atomic shells that participate in the process. The transition in Figure 6.45, for example, is a KLL Auger transition.

In Figure 6.18 above, we showed the relative intensity versus abundance of the various emission phenomena from a sample under e-beam radiation in an SEM and a TEM. Some of the electrons, in the energy region between backscattered and secondary electrons, arise from the Auger process occurring in atoms near the surface. Many Auger electrons will fully lose their energy via inelastic collisions in the solid. Therefore, the analyzer will collect only those Auger electrons originating from the near surface region. The number of emitted electrons N(E) versus energy is redrawn in Figure 6.46, with emphasis on the Auger electron peaks. Electrons emitted in the 100–1000 eV range (higher than secondary, lower than backscattered) are energy analyzed, and a spectrum is obtained that is unique to every atom. Often, hemispherical analyzers are used because of its better geometric properties. Hence, it gives very specific atomic identity information rather than the general small/large *z*-guidance provided by backscattered electrons (BSEs) in an SEM. Auger spectroscopy can identify every atom from Li on up (since three electrons are involved in the Auger process, H and He do not produce Auger electrons). Auger spectra for all elements are compiled in an Auger atlas.

Typically, the relatively small Auger signals N(E) are superimposed on a large background. Therefore the spectra are usually taken in the derivative mode, by applying a modulation voltage on the analyzer and detecting with a lock-in amplifier. This is demonstrated in the AES example of Figure 6.47.

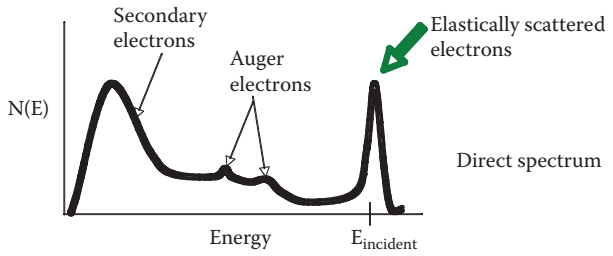

FIGURE 6.46 Auger peaks in the electron spectra of an scanning electron microscope or transmission electron microscope.

Since the electron beam can be can be focused to a spot of <1 nm, one can carry out SAM. In the excitation process, the backscattered electrons also find their way into neighboring regions of the sample and can excite electrons and induce an Auger process in regions of the sample that were not in the original excitation volume. The Auger signal then arises from an apparently larger region of the sample than the incident electron beam directly excites. This degrades the spatial resolution in the SAM process by a factor of 2–5 compared with the same SEM experiment. As a consequence, the penetration depth and scattering within the solid typically limits the SAM resolution to ~20 nm, but recent instruments claim a resolution of ~6 nm. By correlating a specific signal with the excitation beam's location, a chemical map of a surface can be produced, as illustrated in Figure 6.48. Although chemical shifts lead to changes in the Auger energies, AES is usually not used to get chemical binding information because of the three electrons involved.

Summary: Microscope Comparisons

In Figure 6.49 we compare the lateral resolutions of optical microscopes (OMs), scanning electron microscopes (SEMs), interference microscopes (IMs), and proximal probe techniques such as the use of scanning tunneling microscopes (STMs) and atomic force microscopes (AFMs).

OM is usually what one thinks of when studying microscopy. It is prevalent and widely available. Its resolution is limited by the diffraction of light, which is limited to about ½ of the wavelength of the light being diffracted through the optical lensing elements of the microscope. While this is several

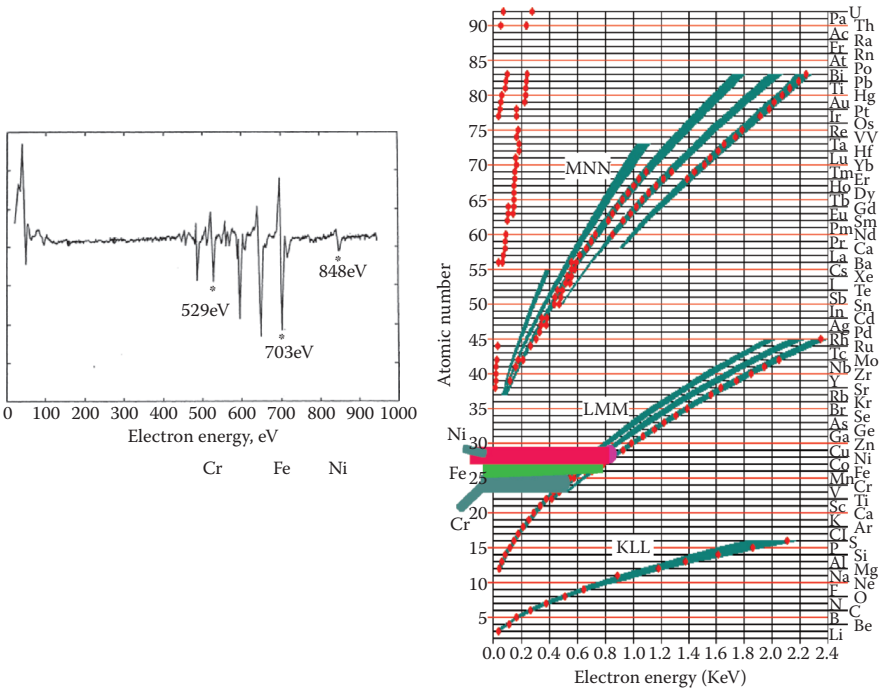

FIGURE 6.47 Example of an Auger electron spectroscopy (AES) spectrum. From the differential AES spectrum, Cr, Fe, and Ni have been identified.

hundred nanometers, in practice it is challenging to get good optical resolution down to the 1-μm range. Interference microscopy is a newer technique that uses optical wavelength light. Its lateral resolution is controlled exactly like that of optical microscopy, and it has the same limitations. As we will see below, its virtue comes from its vertical resolution and its wide dynamic range.

In an SEM, the resolution is limited by the diffraction of electron waves. Since these are in the angstrom range, SEMs with resolution of a few nanometers and a wide magnification range, from × 20 to × 650,000 are quite widely deployed. Recent reports have even described a new instrument able to observe atoms (a few angstroms), but these are not available for use yet. Probe microscopes such as STMs and AFMs have a resolution that is controlled by the sharpness of the probe tip. This can be in the range of a few nanometers, but the differing contrast mechanisms mean that an STM can easily achieve

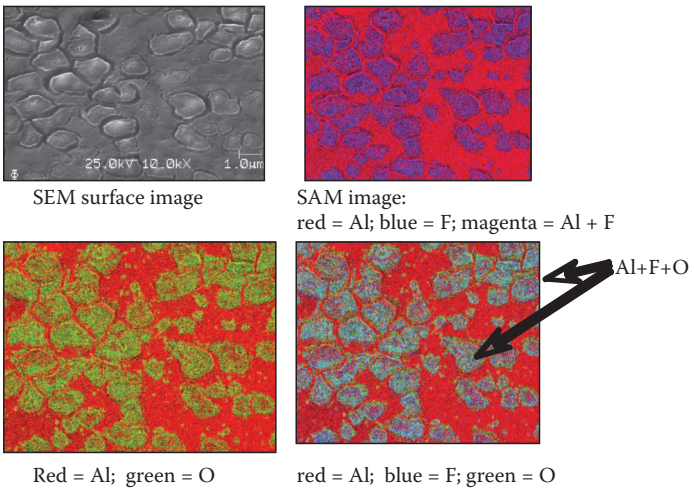

FIGURE 6.48 Scanning electron microscopy and Auger images of an aluminum oxide surface, in the absence and presence of fluorine contamination.

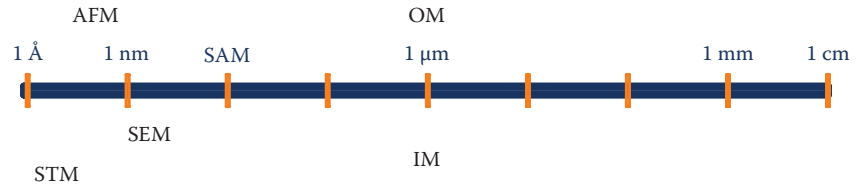

FIGURE 6.49 Lateral resolution of microscopies: optical microscopy (OM), scanning electron microscopy (SEM), scanning Auger microscopy (SAM), interference microscopy (IM), scanning tunneling microscopy (STM), and atomic force microscopy (AFM).

atomic resolution, whereas atomic resolution for an AFM is difficult to achieve.

AFM comes with lateral resolutions down to 30 Å and a vertical resolutions to 0.1 Å. STM has a lateral resolution of 1 Å and a vertical resolution of 0.1 Å. SAM is closely related to SEM, except that the scattering in the sample leads to a "smearing" of the incident beam and broadens the effective spot size. Its resolution general lags behind that of an SEM by a factor of 2–5.

Vertical resolutions for the types of microscopes listed above are quite different from their lateral resolutions, as is evident from Figure 6.50. OMs, SEMs, and SAMs do not give much vertical information at all. While it is rather straightforward to derive quantitative lateral data, these techniques do not provide for quantitation in the vertical direction. To counter this, it is possible to tilt samples and image their sides. However, in a specific image, the vertical information is very poor. Hence, these techniques have much better lateral resolution than vertical resolution. In contrast, probe microscopes and IMs have much better vertical resolution than lateral resolution. The IM, even though it is an optical technique, has a resolution limit approaching 1 nm. The AFM and the STM have vertical resolutions in the subatomic range of tens of picometers. The best instruments can resolve down to a few hundred femtometers.

We need to image large things as well as small. So another important point is, which instrument can provide the largest field of view? What is the range of features, largest to smallest, that can be observed? The resolution limits listed above do define the lower limits of the dynamic range of the microscopes reviewed, and the upper limit is controlled by the size of the field of view that can be imaged at once. OM is able to image from macroscopic features down to its resolution limit. The scanning electron techniques generally have a maximum field of view of a few millimeters. The proximal probe microscopes are quite limited in their maximum field of view. Also, the limitations are different for the lateral and vertical directions. Lateral limits range from a few micrometers to over 100 μm. By contrast, the range in the vertical direction is limited to around a few micrometers. These limits often are determining factors in assessing the applicability of a probe microscope technique for a particular application. IM has a very wide dynamic range. It is able to image features varying in vertical displacement of over a millimeter. The lateral range is set by its maximum field of view, which is around 5 mm. The dynamic ranges of the various

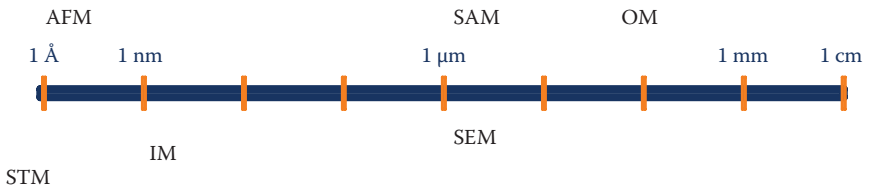

FIGURE 6.50 Vertical resolution of microscopies: optical microscopy (OM), scanning electron microscopy (SEM), scanning Auger microscopy (SAM), interference microscopy (IM), scanning tunneling microscopy (STM), and atomic force microscopy (AFM).

microscopes, considered here, are summarized in Figure 6.51.

MEMS Based Metrology: In Situ Stress-Measuring Techniques

Introduction

A stressed thin film will bend a thin substrate by a measurable degree. A tensile stress bends the surface and makes it concave, while a compressive stress renders the surface convex (see Volume II, Figure 7.58). The most common methods for measuring the stress in a thin film are based on this substrate bending principle. The deformation of a thin substrate due to stress is measured either by observing the displacement of the center of a circular disk or by using a thin cantilevered beam as a substrate and calculating the radius of curvature of the beam and hence the stress from the deflection of the free end. More sophisticated local stress measurements use analytical tools such as x-ray,[14] acoustics, Raman spectroscopy,[15] infrared spectroscopy,[16] and electron-diffraction techniques. Local stress does not necessarily mean the same as the stress measured by substrate bending techniques, since stress is defined microscopically, while deformations are induced mostly macroscopically. The relationship between macroscopic forces and displacements and internal differential deformation, therefore, must be modeled carefully. Local stress measurements may also be made using in situ surface micromachined structures such as strain gauges made directly out of the film to be tested.[17–22] The dimensions and structure of a thin suspended and pressurized micromachined membrane, as we learned above, may be measured by stylus profilometry, light microscopy, or interferometry. Intrinsic stress influences the frequency response of mobile microstructures (see Volume II, Equation 7.29), which can be measured by laser Doppler vibrometer or with an interferometer equipped with a stroboscope (see Figure 6.11: optical WYKO white-light profilometer with dynamic MEMS capability). Whereas residual stress can be determined from wafer curvature and dynamic deflection data, material structure of the film can be studied by x-ray diffraction and transmission electron microscopy (TEM). Krulevitch, among others, attempted to link the material structure of polysilicon and its residual strain.[23] Below, we will review stress-measuring techniques, starting with the more traditional ones and subsequently clarifying the problems and opportunities in stress measuring with in situ surface micromachined devices.

Disk Method: Biaxial Measurements of Mechanical Properties of Thin Films

For all practical purposes, only stresses in the x and y directions are of interest in determining overall thin-film stress, as a film under high stress can only expand or contract by bending the substrate and deforming it in a vertical direction. Vertical deformations will not induce stresses in a substrate because it freely moves in that direction. The latter condition enables us to obtain quite accurate stress values by measuring changes in bow or radius of curvature of a substrate. The residual stresses in thin films are large, and sensitive optical gauges may measure the associated substrate deflections.

The disc method most commonly used is based on a measurement of the deflection in the center of the disc substrate (say a Si wafer) before and after processing. Since any change in wafer shape is directly attributable to the stress in the deposited film, it

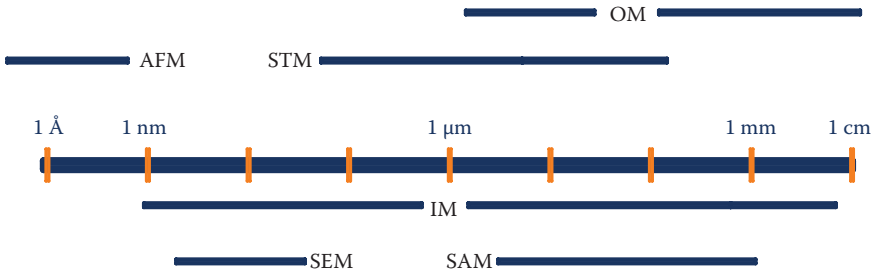

FIGURE 6.51 Dynamic range of microscopies: optical microscopy (OM), scanning electron microscopy (SEM), scanning Auger microscopy (SAM), interference microscopy (IM), scanning tunneling microscopy (STM), and atomic force microscopy (AFM).

is relatively straightforward to calculate stress by measuring these changes. Stress in films using this method is found through the Stoney equation,[24] relating film stress to substrate curvature, as follows:

$$\sigma = \frac{1}{R}\frac{E}{6(1-\nu)}\frac{T^2}{t} \qquad (6.23)$$

where R = measured radius of curvature of the bent substrate
E/(1 – ν) = biaxial modulus of the substrate
T = thickness of the substrate
t = thickness of the applied film[25]

The underlying assumptions include the following:

- The disc substrate is thin and has transversely isotropic elastic properties with respect to the film normal.
- The applied film thickness is much less than the substrate thickness.
- The film thickness is uniform.
- The temperature of the disk substrate/film system is uniform.
- The disc substrate/film system is mechanically free.
- The disc substrate without film has no bow.
- Stress is equibiaxial and homogeneous over the entire substrate.
- Film stress is constant through the film thickness.

For most films on Si, we assume that t ≤ T; for example, t/T measures ~10^{-3} for thin films on Si. The acceptability of the uniform thickness, homogeneous, and equibiaxial stress assumptions depend on the deposition process. Chemical vapor deposition (CVD) is a widely used process, as it produces relatively uniform films; however, sputter-deposited films can vary considerably over the substrate. In regard to the assumption of stress uniformity with film thickness, residual stress can vary considerably through the thickness of the film. Equation 6.23 gives only an average film stress in such cases. In cases where thin films are deposited onto anisotropic single-crystal substrates, the underlying assumption of a substrate with transversely isotropic elastic properties with respect to the film normal is not completely justified. Using single-crystal silicon substrates possessing moderately anisotropic properties such as <100> or <111> oriented wafers (Volume I, Equation 4.87) satisfies the transverse isotropy argument. Any curvature inherent in the substrate must be measured before film deposition and algebraically added to the final measured radius of curvature. To give an idea of the degree of curvature, 1 μm of thermal oxide may cause a 30-μm warp of a 4-inch silicon wafer, corresponding to a radius of curvature of 41.7 m.

The following companies offer practical disc method-based instruments to measure stress on wafers: ADE Corp. (Newton, MA; acquired by KLA-Tencor in 2006), Corning Tropel (Fairport, NY; http://www.corning.com/metrology), Ionic Systems (San Jose, CA; http://www.ionic.com), and KLA Tencor Instruments (Mountain View, CA; http://www.kla-tencor.com).[25] Figure 6.52a illustrates the sample output from KLA Tencor's optical stress analysis system. Figure 6.52b represents the measuring principle of Ionic Systems' optical stress analyzer. None of the above techniques satisfies the need for measuring stress in low modulus materials such as polyimide. For the latter applications, the suspended membrane approach (see below) is more suited.

Dog-Bone Method: Uniaxial Measurements of Mechanical Properties of Thin Films

Many problems associated with handling thin films in stress test equipment may be bypassed by applying micromachining techniques. One simple example of problems encountered with thin films is the measurement of uniaxial tension to establish the Young's modulus. This method, effective for macroscopic samples, proves problematic for small samples. The test formula is illustrated in Figure 6.53. The gauge length, L, of the bar-shaped structure in Figure 6.53a represents the region we allow to elongate, and the area, A (= $W \times H$), is the cross-section of the specimen. A stress, F/A, is applied and measured with a load cell; the strain, $\delta L/L$, is measured with an LVDT or another displacement transducer (a typical instrument used is the Instron 1123). The Young's modulus is then deduced from the following equation.

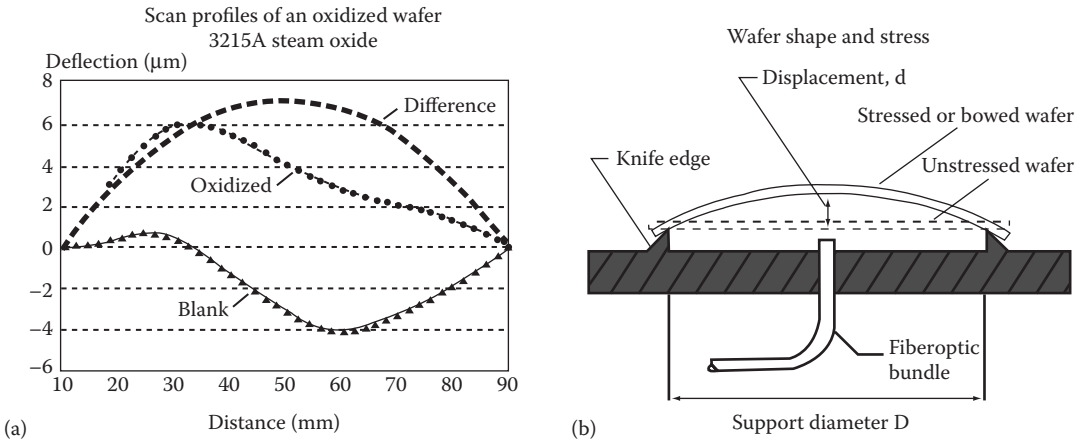

FIGURE 6.52 Curvature measurement for stress analysis. (a) Sample output from KLA Tencor's FLX 2908 stress analysis instrument, showing how stress is derived from changes in wafer curvature. (b) The reflected light technique, used by Ionic Systems to measure wafer curvature. (From Singer, P. 1992. Film stress and how to measure it. *Semicond Int* 15:54–58. With permission.[25])

$$E = \left(\frac{F}{A}\right)\left(\frac{L}{\delta L}\right) \tag{6.24}$$

The obvious problem, for small or large samples, is how to grip the sample without changing A. Under elongation, A will indeed contract by $(W + H)\delta\nu L$. In general, making a dog-bone shaped structure (also called an *Instron specimen*) solves that problem, as shown in Figure 6.53b. Still, the grips introduced in an Instron sample can produce end effects and uncertainties in determining L. Making Instron specimens in thin films is even more of a challenge, since the thin film needs to be removed from the surface, possibly changing the stress state, while the removal itself may modify the film.

As in the case of adhesion (see Volume II, Figure 7.56), some new techniques for testing stress in thin films, based on micromachining, are being explored. These microtechniques prove more advantageous than the whole wafer disc technique in that they are able to make local (in situ) measurements.

The fabrication of micro-Instron specimens of thin polyimide samples is illustrated in Figure 6.54A.[26] Polyimide is deposited on a p+ Si membrane in multiple coats. Each coat is prebaked at 130°C for 15 minutes. After reaching the desired thickness, the film is cured at 400°C in nitrogen for 1 h (Figure 6.54Aa). The polyimide is then covered with a 3,000-Å layer of evaporated aluminum (Figure 6.54Ab). The aluminum layer is patterned by wet etching (in phosphoric-acetic-nitric solution, referred to as the *PAN etch*) into the Instron specimen shape (Figure 6.54Ac). Dry etching transfers the pattern to the polyimide (Figure 6.54Ad). After removing the Al mask by wet etching, the p^+ support is removed by a wet isotropic etch (HNA) or an SF_6 plasma etch (Figure 6.54Ae), and finally the side silicon is removed along four pre-etched scribe lines, releasing the residual stress (Figure 6.54Af). The

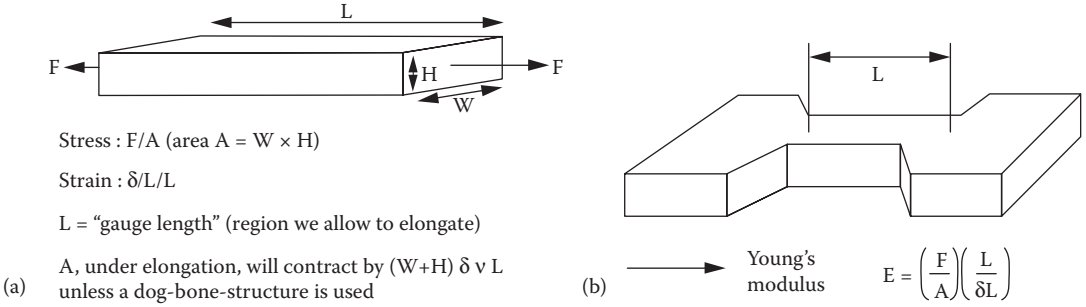

FIGURE 6.53 Measuring Young's modulus. (a) With a bar-shaped structure. (b) With a dog-bone; Instron specimen. (From Senturia, S. D., and R. T. Howe. 1990. Lecture notes. Boston: Massachusetts Institute of Technology.[26])

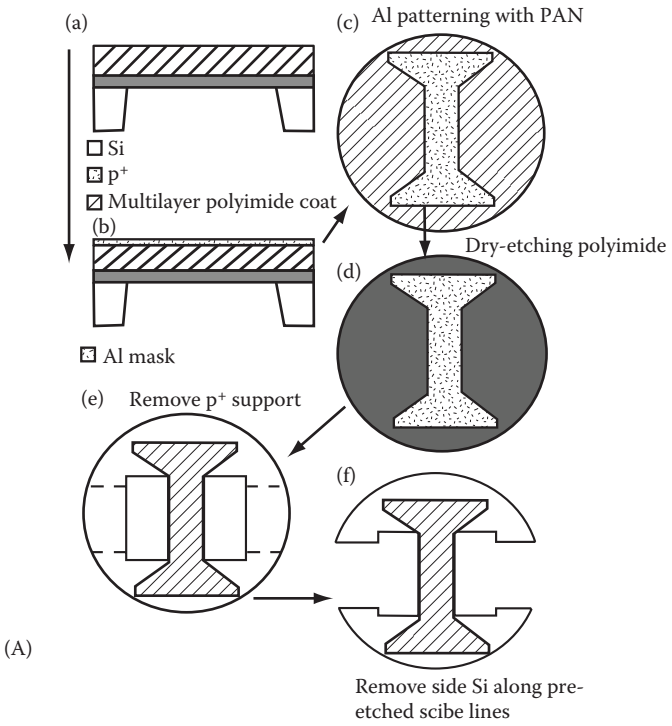

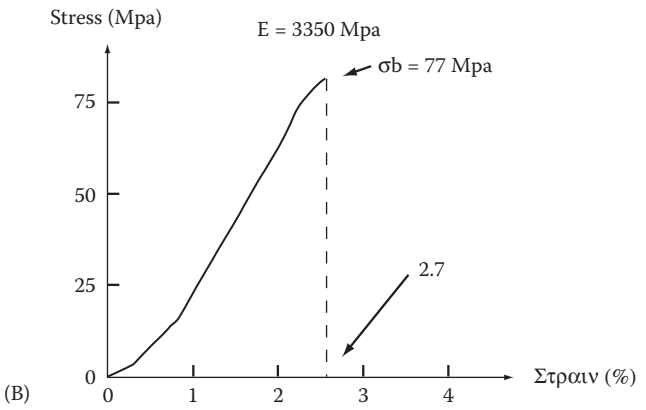

FIGURE 6.54 Uniaxial stress measurement. (A) Fabrication process of a dog-bone sample for measurement of uniaxial strain. (B) Stress versus strain for DuPont's 2525 polyimide. (Courtesy of Dr. F. Maseeh, IntelliSense.)

remaining silicon acts as supports for the grips of the Instron.[27] The resulting structure can be manipulated like any other macrosample without the need for removal of the film from its substrate. This technique enables the gathering of stress/strain data for a variety of commercially available polyimides.[28] A typical measurement result for DuPont's polyimide 2525, illustrated in Figure 6.54B, gives a break stress and strain of 77 MPa (σ_b) and 2.7% (ε_b), respectively, and 3350 MPa for the Young's modulus.

Figure 6.55a illustrates a micromachined test structure able to establish the strain and the ultimate stress of a thin film.[29] A suspended rectangular polymer membrane is patterned into an asymmetric structure before removing the thin supporting Si. Once released, the wide suspended strip (width, W_1) pulls on the thinner necks (total width, W_2), resulting in a deflection, δ, from its original mask position toward the right to its final position after release. The residual tensile stress in the film drives the deformation, δ, as shown in Figure 6.55a. By varying the geometry, it is possible to create structures exhibiting small strain in the thinner sections as opposed to others that exceed the ultimate strain of the film. For structures where the strain is small enough to be modeled with linear elastic behavior, the deflection, δ, can be related to the strain as follows:

$$\varepsilon = \frac{\sigma}{E} = \frac{\delta\left(\frac{W_1}{L_1} + \frac{W_2}{L_2}\right)}{W_1 - W_2} \qquad (6.25)$$

where the geometries are defined as illustrated in Figure 6.55a. Figure 6.55b displays a photograph of two released structures, one with thicker necks, the other with necks so thin that they fractured upon release of the film. On the basis of the residual tensile strain of the film and the geometry of the structures that failed, the ultimate strain of the particular polyimide used was determined to be 4.5%.

Using similar micromachined tensile test structures, Biebl et al.[30] measured the fracture strength of undoped and doped polysilicon and found 2.84 ± 0.09 GPa for undoped material and 2.11 ± 0.10 GPa in the case of phosphorus doping, 2.77 ± 0.08 GPa for boron doping, and 2.70 ± 0.09 GPa for arsenic doping. No statistically significant differences were observed between samples released using concentrated HF or buffered HF. However, a 17% decrease of the fracture stress was observed for a 100% increase in etching time. These data contrast with Greek et al.'s[31] in situ tensile strength test result of 768 MPa for an undoped polysilicon film, a mean tensile strength approximately one-tenth that of single-crystal Si (6 GPa).[32] We normally expect polycrystalline films to be stronger than single-crystal films (see Volume II, Chapter 7). Greek et al.[31] explain this discrepancy for polysilicon by pointing out that their polysilicon

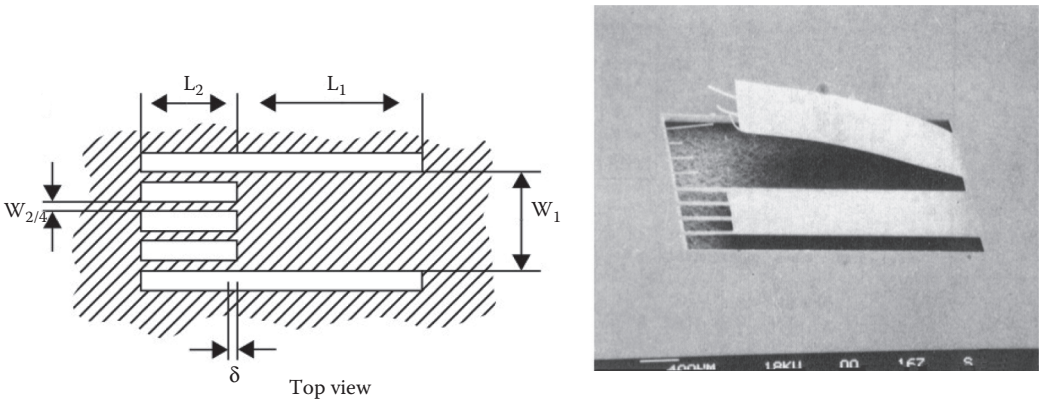

FIGURE 6.55 Ultimate strain. (a) Test structures for stress-to-modulus (strain) and ultimate stress measurements. (b) Two released structures, one of which has exceeded the ultimate strain of the film, resulting in fracture of the necks. (From Senturia, S. 1987. In *Proceedings: IEEE Micro Robots and Teleoperators Workshop* 3/1–5. Hyannis, MA. With permission.[29])

films have a very rough surface compared with single-crystal material, containing many locations of stress concentration where a fracture crack can be initiated.

Biaxial Measurements of Mechanical Properties of Thin Films: Suspended Membrane Methods

Disc stress-measuring techniques are not suitable for measuring stress in low modulus tensile materials such as polyimides, whereas suspended membranes are very convenient for this purpose. The same micromachined test structure used for adhesion testing, sometimes called the *blister test*, as shown in Volume II, Figure 7.56, can measure the tensile stress in low-modulus materials. This type of test structure ensues from shaping a silicon diaphragm by conventional anisotropic etching, followed by applying the coating, and finally removing the supporting silicon from the back with an SF_6 plasma.[29] By pressurizing one side of the membrane and measuring the deflection, one can extract both the residual stress and the biaxial modulus of the membrane. Pressure to the suspended film can be applied by a gas or by a point-load applicator.[33] The load-deflection curve at moderate deflections (strains less than 5%) answers to the following equation:

$$p = C_1 \frac{\sigma t d}{a^2} + C_2 \left(\frac{E}{1-\nu} \right) \frac{t d^3}{a^2} \qquad (6.26)$$

where

p = pressure differential across the film
d = center deflection
a = the initial radius
t = the membrane thickness
σ = the initial film stress

In the simplified Cabrera model for circular membranes, the constants C_1 and C_2 equal 4 and 8/3, respectively. For more rigorous solutions for both circular and rectangular membranes and references to other proposed models, consult Maseeh-Tehrani.[27] The relationship in Equation 6.26 can simultaneously determine σ and the biaxial modulus $E/1 - \nu$; plotting pa^2/dt versus $(d/a)^2$ should yield a straight line. The residual stress can be extracted from the intercept and the biaxial modulus from the slope of the least-squares best-fit line.[29] A typical result obtained via such measurements is represented in Figure 6.56. For the same DuPont polyimide 2525, measuring a Young's modulus of 3350 MPa in the uniaxial test (Figure 6.54B), the measurements give 5540 MPa for the biaxial modulus and 32 MPa for the residual stress. The residual stress-to-biaxial modulus ratio, also referred to as the residual biaxial strain, thus reaches 0.6%. The latter quantity must be compared with the ultimate strain when evaluating potential reliability problems associated with cracking of films. By loading the membranes to the elastic limit point, yield stress and strain can be determined as with the uniaxial test.

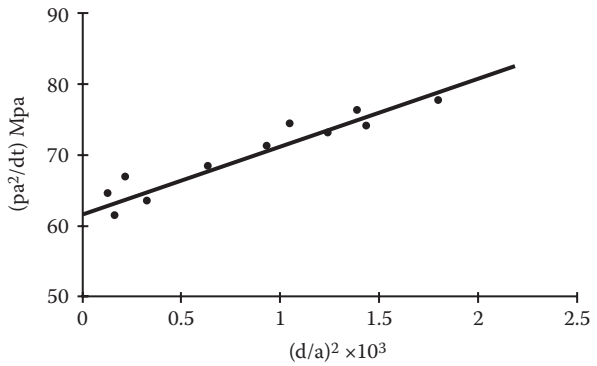

FIGURE 6.56 Load deflection data of a polyimide membrane (DuPont 2525). From the intercept, a residual stress of 32 MPa was calculated, and from the slope, a biaxial modulus of 5540 MPa was calculated. (From Senturia, S. 1987. In *Proceedings: IEEE Micro Robots and Teleoperators Workshop* 3/1–5. Hyannis, MA. With permission.[29])

Poisson Ratio for Thin Films

The Poisson ratio for thin films presents us with more difficulties to measure than the Young's modulus, as thin films tend to bend out of plane in response to in-plane shear. Maseeh and Senturia[28] combine uniaxial and biaxial measurements to calculate the in-plane Poisson ratio of polyimides. For example, for the DuPont polyimide 2525, they determined 3350 MPa for E and 5540 MPa for the biaxial modulus $[E/(1 - \nu)]$, leading to a Poisson ratio (ν) of 0.41 ± 0.1. The errors on both the biaxial and uniaxial measurements need to be reduced in order to develop more confidence in the extracted value of the Poisson ratio. At present, the precision on the Poisson ratio is limited to about 20%.

Other Surface Micromachined Structures to Gauge Intrinsic Stress

Introduction

Various other surface micromachined structures have been used to measure mechanical properties of thin films. We will give a short review here, but the interested reader might want to consult the original references for more details.

Clamped-Clamped Beams

Several groups have used rows of clamped-clamped beams (bridges) with incrementally increasing lengths to determine the critical buckling load and hence deduce the residual compressive stress in polysilicon films (Figure 6.57a).[34,35] The residual strain, $\varepsilon = \sigma/E$, is obtained from the critical length, L_c, at which buckling occurs (Euler's formula for elastic instability of struts):

$$\varepsilon = \frac{4\pi^2}{A}\frac{I}{L_c^2} \tag{6.27}$$

where A is the beam cross-sectional area and I the moment of inertia. As an example, with a maximum beam length of 500 µm and a film thickness of 1.0 µm, the buckling beam method can detect compressive stress as small as 0.5 MPa. This simple Euler approach does not take into consideration additional effects such as internal moments resulting from gradients in residual stress.

Ring Crossbar Structures

Tensile strain can be measured by a series of rings (Figure 6.57b) constrained to the substrate at two points on a diameter and spanned orthogonally by a clamped-clamped beam. After removal of the sacrificial layer, tensile strain in the ring places the spanning beam in compression; the critical buckling length of the beam can be related to the average strain.[37]

Vernier Gauges

Both clamped-clamped beams and ring structures need to be implemented in entire arrays of structures. They do not allow easy integration with active microstructures because of space constraints. As opposed to proof structures, one might use vernier gauges to measure the displacement of structures induced by residual strain.[36] The idea was first explored by Kim,[38] whose device consisted of two cantilever beams fixed at two opposite points. The end movement of the beams caused by the residual strain is measured by a vernier gauge. This method requires only one structure, but the best resolution for strain measurement reported is only 0.02% for 500-µm beams. Moreover, the vernier gauge device may indicate an erroneous strain when an out-of-plane strain gradient occurs.[36] Other types of direct strain measurement devices are the T- and H-shaped structures from Allen et al.[20] and

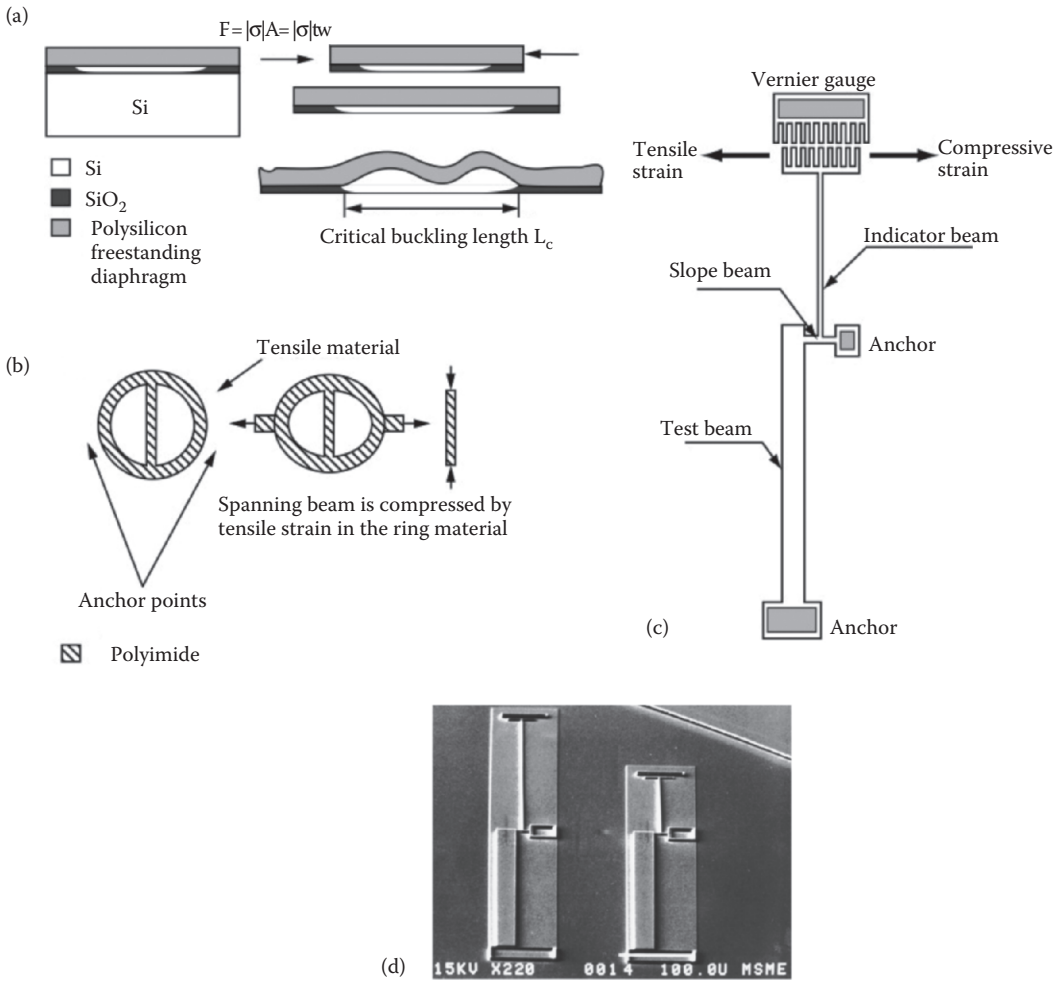

FIGURE 6.57 Some micromachined structures used for stress measurements. (a) Clamped-clamped beams: measuring the critical buckling length of clamped-clamped beams enables measurement of residual stress. (b) Crossbar rings: tensile stress can be measured by buckling induced in the crossbar of a ring structure. (c) A schematic of a strain gauge capable of measuring tensile or compressive stress. (d) Scanning electron microscope microphotograph of two strain gauges. (c and d from Lin, L. 1993. Selective encapsulations of MEMS: Micro channels, needles, resonators, and electromechanical filters. PhD thesis, University of California, Berkeley. With permission.[36])

Mehregany et al.[17] Optical measurement of the movement at the top of the T- or H-shape structures becomes possible only with very long beams (greater than 2.5 mm). They occupy large areas, and their complexity requires finite element methods to analyze their output. The same is true for the strain magnification structure by Goosen et al.[39] This structure measures strain by interconnecting two opposed beams such that the residual strain in the beams causes a third beam to rotate as a gauge needle. The rotation of the gauge needle quantifies the residual strain. A schematic of a micromachined strain gauge capable of measuring tensile or compressive residual stress, as shown in Figure 6.57c, was developed by Lin at University of California, Berkeley.[36] Figure 6.57d represents an SEM photograph of Lin's strain gauge. This gauge by far outranks the various in situ gauges explored. The strain gauge uses only one structure, can be fabricated in situ with active devices, determines tensile or compressive strain under optical microscopes, has a fine resolution of 0.001%, and resists the out-of-plane strain gradient. When the device is released in the sacrificial etch step, the test beam (length L_t) expands or contracts, depending on the sign of the residual stress in the film, causing the compliant slope beam (length L_s) to deflect into an S shape. The indicator beam (length L_i), attached to the deforming beam at its point of inflection, rotates through an angle θ, and the deflection, δ,

is read on the vernier scale. The residual strain is calculated as follows:

$$\varepsilon_f = \frac{2L_s\delta}{3L_iL_tC} \tag{6.28}$$

where C is a correction factor due to the presence of the indicator beam.[36] This equation was derived from simple beam theory relationships and assumes that no out-of-plane motion will occur. The accuracy of the strain gauge is greatly improved, because its output is independent of both the thickness of the deposited film and the cross-section of the microstructure. Krulevitch used these devices to measure residual stress in in situ phosphorus-doped polysilicon films,[23] while Lin tested LPCVD silicon-rich silicon nitride films with it.[36]

An improved micromachined indicator structure, inspired by Lin's work, was built by Ericson et al.[40] By reading an integrated nonius scale in an SEM or an optical microscope, internal stress was measured with a resolution better than 0.5 MPa.[40,41] Both thick (10 µm) and thin (2 µm) polysilicon films were characterized this way.

Lateral Resonators

Biebl et al.[42] extracted the Young's modulus of in situ phosphorus-doped polysilicon by measuring the mechanical response of polysilicon linear lateral comb-drive resonators (see Volume II, Figure 7.76). The results reveal a value of 130 ± 5 GPa for the Young's modulus of highly phosphorus-doped films deposited at 610°C with a phosphine-to-silane mole ratio of 1.0×10^{-2} and annealing at 1050°C. For a deposition at 560°C with a phosphine-to-silane ratio of 1.6×10^{-3}, a Young's modulus of 147 ± 6 GPa was extracted.

Stress Nonuniformity Measurement by Cantilever Beams and Cantilever Spirals

Introduction

The uniformity of stress through the depth of a film introduces a property that it is extremely important to control. Variations in the magnitude and direction of the stress in the vertical direction can cause cantilevered structures to curl toward or away from the substrate. Stress gradients present in the polysilicon film must thus be controlled to ensure predictable behavior of designed structures when released from the substrate. To determine the thickness variation in residual stress, noncontact surface profilometer measurements on an array of simple cantilever beams[43,44] or cantilever spirals can be used.[25]

Cantilever Beams

The deflections resulting from stress variation through the thickness of simple cantilever beams after their release from the substrate are shown in Figure 6.58A. The bending moment causing deflection of a cantilever beam follows out of prerelease residual stress and is given by the following equation:

$$M = \int_{-t/2}^{t/2} zb\sigma(z)dz \tag{6.29}$$

where $\sigma(z)$ represents the residual stress in the film as a function of thickness and b stands for cantilever width. Assuming a linear strain gradient Γ (physical dimensions 1/length) such that $\sigma(z) = E\Gamma z$, Equation 6.29 converts as follows:

$$\Gamma = \frac{12M}{Ebt^3} = \frac{M}{EI} \tag{6.30}$$

where the moment of inertia, I, for a rectangular cross-section is given by $I = bt^3/12$. The measured deflection z, i.e., the vertical deflection of the cantilever's endpoint, from beam theory for a cantilever with an applied end moment, is given as follows.

$$z = \frac{ML^2}{2EI} = \frac{\Gamma L^2}{2} \tag{6.31}$$

Figure 6.58B represents a topographical contour map of an array of polysilicon cantilevers. The cantilevers vary in length from 25 to 300 µm by 25-µm increments. Notice that the tip of the longest cantilever resides at a lower height (approximately 0.9 µm closer to the substrate) than the anchored support, indicating a downward-bending moment.[43] The gradients can be reduced or eliminated with a high-temperature anneal. With integrated electronics on the same chip, long high-temperature processing must be avoided. Therefore, stress gradients can limit the length of cantilevered structures used in surface-micromachined designs.

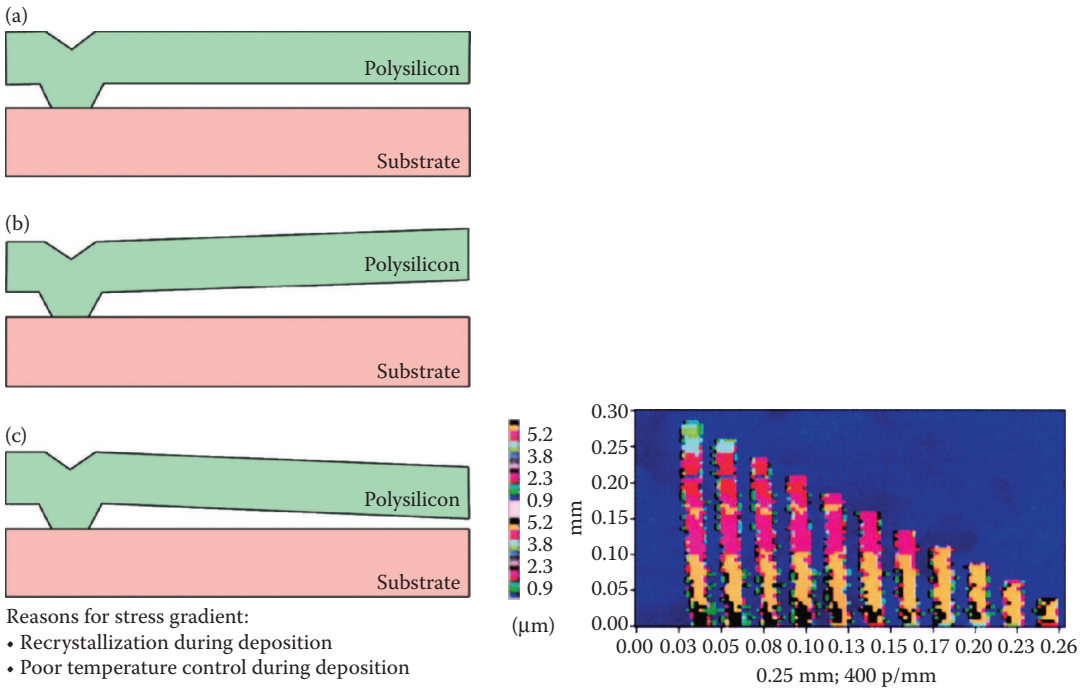

FIGURE 6.58 Microcantilever deflection for measuring stress nonuniformity. (A) Micro-cantilever deflection for measuring stress nonuniformity. (a) No gradient. (b) Higher tensile stress near the surface. (c) Lower tensile stress near the surface. (B) Topographical contour map of polysilicon cantilever array. (From Core, T. A., W. K. Tsang, and S. J. Sherman. 1993. Fabrication technology for an integrated surface-micromachined sensor. *Solid State Technol* 36:39–47. With permission.[43])

The use of silicon-on-insulator (SOI)-based micromachined cantilevers for measuring surface stress induced during adsorption of biomolecules is illustrated in Volume I, Example 4.1.

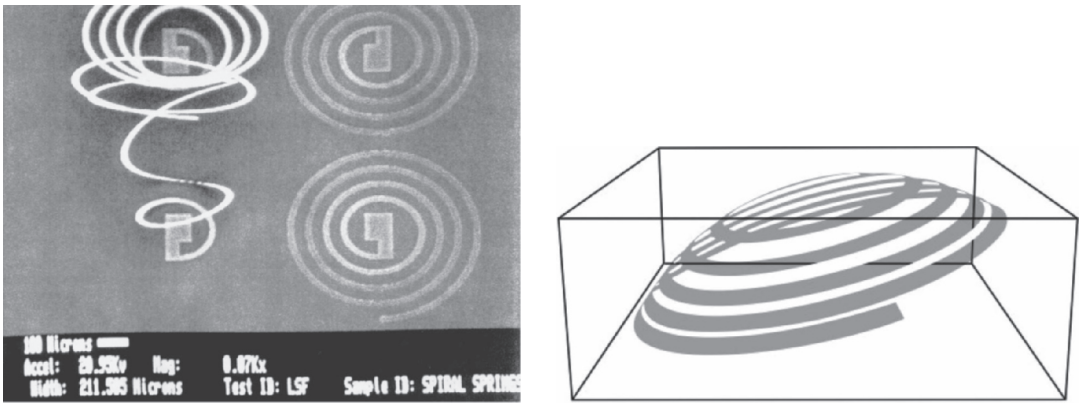
Cantilever Spirals

Residual stress gradients also can be measured by Fan's cantilever spiral, as shown in Figure 6.59a.[45] Spirals anchored at the inside spring upward, rotate, and contract with positive strain gradient (tending to curl a cantilever upward), whereas spirals anchored at the outside deflect in a similar manner in response to a negative gradient. Theoretically, positive and negative gradients produce spirals with mirror symmetry.[45] The strain gradient can be determined from spiral structures by measuring the amount of lateral contraction, the change in height, or the amount of rotation. Krulevitch presented the computer code for the spiral simulation in his doctoral thesis.[23] Figure 6.59b shows a simulated spiral with a bending moment of $\Gamma = \pm 3.0\ \text{mm}^{-1}$ after release.

Krulevitch compared all the above surface micromachined structures for stress and stress gradient measurements on polysilicon films. His comments are summarized in Table 6.10.[23] He found that the fixed-fixed beam structures for determining compressive stress from the buckling criterion produced remarkably self-consistent and repeatable results. Wafer curvature stress profiling proved reliable for determining average stress and the true stress gradient as compared with micromachined spirals. Measurements of curled cantilevers could not be used a lot, as the strain gradients mainly were negative for polysilicon, leading to cantilevers contacting the substrate. The strain gauge dial structures were useful over a rather limited strain-gradient range. With too large a strain gradient, curling of the long beams overshadows expansion effects and makes the vernier indicator unreadable.

Modeling

Modeling is the use of mathematical equations to simulate and predict real events and processes. In this modeling section we introduce finite element analysis and review software packages helpful in the



(a) (b)

FIGURE 6.59 Cantilever spirals for stress gradient measurement. (a) Scanning electron microscope micrographs of spirals from an as-deposited polysilicon. (Courtesy of Dr. L.-S. Fan, IBM, Alamaden Research Center.) (b) Simulation of a thin-film micromachined spiral with $G = 3.0\ mm^{-1}$. (From Krulevitch, P. A. 1994. design phase of miniaturized devices, that is, software for computer-aided design (CAD).

After brainstorming about sensor specifications and sensor transduction principles and making preliminary designs on paper and the white board, it is a good idea to initiate a CAD of the overall microsystem to grasp how all the components, including the package, fit together. In Figure 6.60 we show a three-dimensional visualization (construction) of a NiTi-based valve (the principle of this shape memory type valve is discussed in Chapter 8, this volume, on actuators).

More than visualization is needed though for CAD, and a software package in general is structured as sketched in Figure 6.61 with the design aids used to create the design, simulation to develop the technology, and verification to check the design. The final verification is during fabrication itself; the goal here is to avoid wasteful and slow experiments by carrying out less costly computer work and to get the fabrication "right" the first time.[53]

During design, the process may be separated in a conceptual design and simulation phase and a phase of final design of masks and processes. The ideal suite of CAD tools required for each activity is summarized in Table 6.11;[54] besides visualization, simulation, and verification, a good MEMS CAD package typically includes an extensive materials database.

With CAD for MEMS application in mind, IC development software packages have been expanded with finite element analysis (FEA) programs and

TABLE 6.10 Summary of Various Techniques for Measuring Residual Film Stress

Measurement Technique	Measurable Stress State	Remarks
Wafer curvature	Stress gradient, average stress	Average stress over entire wafer, provides true stress gradient, approximately 5 MPa resolution
Vernier strain gauges	Average stress	Local stress, small dynamic range, resolution = 2 MPa
Spiral cantilevers	Stress gradient	Local stress, provides equivalent linear gradient
Curling beam cantilevers	Large positive stress gradient	Local stress, provides equivalent linear gradient
Fixed-fixed beams	Average compressive stress	Local stress measurement

materials databases. This type of software is paying off, even for IC development where there is a growing need for the ability to perform mechanical analysis of microelectronic devices, both in ensuring structural reliability against failure of thin film layers and in evaluating the effects of various external loads, including the effects of temperature and humidity. An understanding of the required processes and materials properties that ensure reproducibility for commercial MEMS products has emerged slowly, and several CAD systems that have facilitated the wider acceptance of MEMS are now on the market. Most include a materials database that can be updated by the user. Details on CAD packages for MEMS is preceded by a short introduction to finite element analysis. We finish this chapter by referring to software packages of interest in NEMS and bio-NEMS modeling.

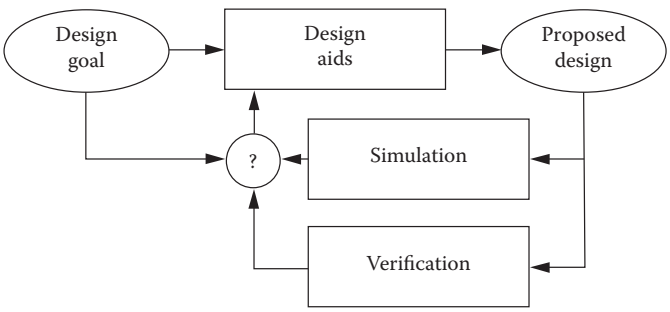

FIGURE 6.61 Design, simulation, and verification.[54]

Finite Element Analysis

Introduction

Finite element analysis is used in almost every engineering discipline. Early FEA packages were limited to simulators using linear static stress analysis. Today, they have been extended to include nonlinear static stress, dynamic stress (vibration), fluid flow, heat transfer, electrostatic forces, etc. These capabilities are frequently combined to perform coupled-force analyses that consider multiple physical phenomena and are tightly integrated within a CAD interface. The best-developed application areas, which also happen to be very important for microsystem design, are electrostatics, stress/strain analysis of solid structures, heat conduction analysis, and fluid dynamics. FEA typically includes the steps outlined below, where we will assume that we are dealing with a stress/strain analysis of a solid structure.

Geometry Development

The essence of FEA is "divide and conquer," and the first step consists of dividing the whole MEMS structure under analysis into a finite number of subdivisions of special shapes or elements that are interconnected at specific points, called *nodes* (Figure 6.62). The nodes are discrete points of the MEMS structure where the analysis will reflect the

Table 6.11 Ideal Tool Suites for MEMS

Conceptual Design and Simulation	Final Design of Masks and Process
Rapid construction and visualization of three-dimensional solid models	Process simulation or process database, including: • Lithographic and etch process biases (the difference between as-drawn and as-fabricated dimensions) • Process tolerances on thicknesses, lateral dimensions, doping and resistivity levels
A database of materials properties	Design optimization and sensitivity analysis: • Variation of device sizing to optimize performance • Analysis of effects of process tolerances
Simulation tools for basic physical phenomena. For example: • Thermal analysis: heat flow • Mechanical and structural analysis: deformation • Electrostatic analysis: capacitance and charge density • Magnetostatic analysis: Inductance and flux density • Fluid analysis: pressures and flow	Mask layout
Coupled-force simulators. For example: • Thermally induced deformation • Electrostatic and magnetostatic actuators • Interaction of fluids with deformable structures	Design verification, including: • Construction of a three-dimensional solid model of the design, using the actual masks and process sequence • Checking the design for violation of any design rules imposed by the process • Simulation of the expected performance of the design, including the construction of macromodels of performance useable in circuit simulators to assess overall system performance
Formulation and use of macromodels. For example: • Lumped mechanical equivalents for complex structures • Equivalent electric circuit of a resonant sensor • Feedback representation for coupled-force problems

response of the component to an applied loading. This response is defined in terms of nodal degrees of freedom. In the case of stress analysis, up to six degrees of freedom are possible at each node (three components of translation and three components of rotation), depending on the element type selected (e.g., beam, plate, 2D, and 3D elements). Element selection is a function of product geometry and loading conditions. The element selected affects the results as each element has characteristic properties. A model can use more than one type of element.

Material Property Assignment

In the second stress/strain finite element analysis step, the modulus of elasticity or rigidity and Poisson ratio are used to define material properties for each element. For a nonlinear material condition (elastic-plastic), a stress-strain curve represents the material properties.

Mesh Generation

The grid of connecting elements at common nodes is called the *mesh* (Figure 6.62). Based on the element

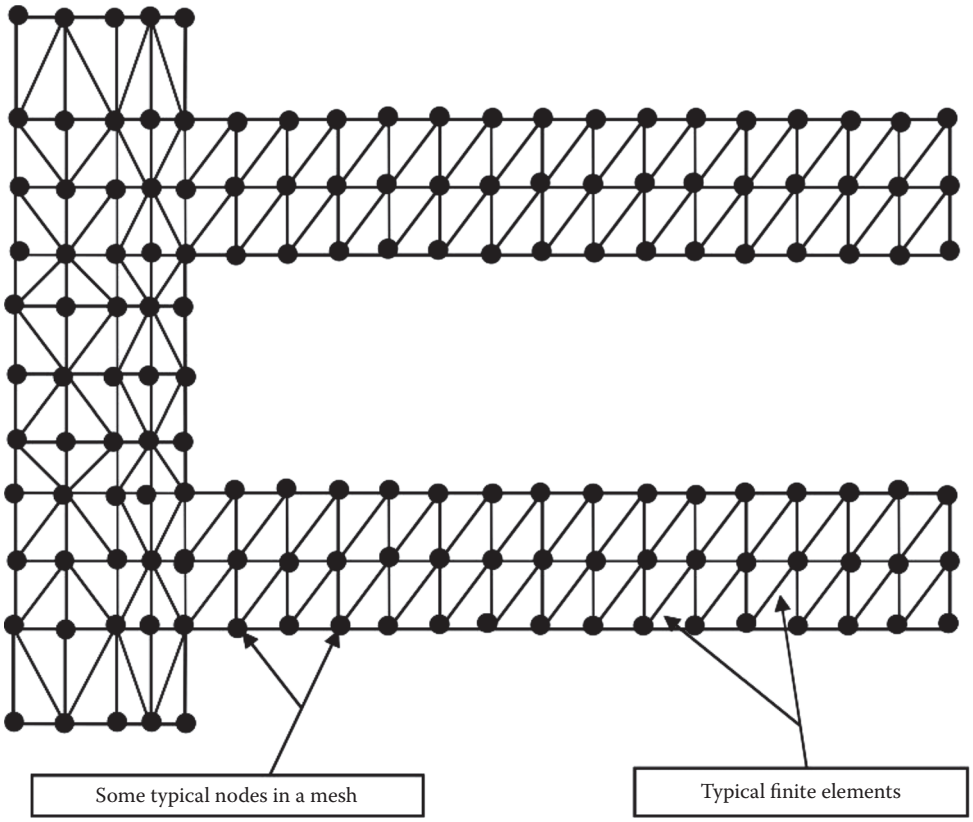

FIGURE 6.62 Finite element analysis mesh.

types selected, automatic mesh generation subdivides the geometry into finite elements in a third step of the FEA process. The element density within each segment of the structure is either chosen or automatically determined. When adjacent elements share nodes, the displacement field is continuous across the shared element boundaries and loads can be transferred between the elements. Analysis is performed on the elements instead of the whole structure, and solutions at the element level are "assembled" to get the corresponding solutions for the whole structure. Mathematically, this is achieved by calculating nodal stiffness properties for each element and arranging these into matrices. The appropriate matrix transformation generates a global stiffness matrix from the existing element matrix.

Boundary and Loading Conditions

In a fourth step, the appropriate boundary and loading conditions apply constraints to the model. In stress analysis, the boundary conditions specify displacement constraints (i.e., in the *x*-, *y*-, or *z*-direction), and the loading conditions apply loads to the model such as concentrated forces at specified nodes or pressure at specified edge surfaces of the element.

Run Analysis

During analysis, in a fifth step, the program processes the equation matrices with the applied loads and boundary conditions to calculate displacements, strain, natural frequencies, or other data specified by the user. This provides a stress distribution across the entire MEMS structure. The high-stress regions should have the highest element density, as a finer mesh increases the accuracy of the model. Various adaptive methods find the critical regions in the model and make the necessary mesh refinement to reduce the error for the next iteration before reaching convergence.

Results

Results obtained in a sixth step include nodal and element information, displacement at nodes, stresses and strains in each element, and various forms of graphical display of the solution. In this regard, a von Mises stress plot often is used. The von

Mises stress (also called *effective* or *equivalent stress*) is defined as follows:

$$\sigma_M = \sqrt{\frac{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_1 - \sigma_3)^2}{2}} \quad (6.32)$$

where σ_1, σ_2, and σ_3 are the three principal stresses. The von Mises stress is compared with the yield strength for plastic yielding and for the prediction of rupture of the structure.[55]

Data Correlation and Design Optimization

Finally, in a seventh step, experimental data are collected to correlate the FEA model results and to formulate a baseline. After comparing the baseline results, design modification and remodeling are available. This iterative process constitutes design optimization, namely, combining the engineering requirements, geometric parameters, CAD model, and performance goals into a computer simulation to achieve the optimum design.

As mentioned in the introduction, in addition to considering a part's ability to withstand mechanical stresses, today's FEA software also enables engineers to predict other real-world stresses. These might include the effects of extreme temperatures or temperature change (heat transfer analysis), the flow of fluids through and around objects (fluid flow analysis), or voltage distributions over the surface or throughout the volume of an object (electrostatic analysis). As these effects often are coupled, it is important that the FEA program consider their effects on one another. For instance, a MEMS chip may be heating up over time, cooling down by airflow from a fan, vibrating against other parts, and be electrically charged. A typical approach is to isolate and calculate each variable then feed the results into the FEA program one at a time. But since each variable could also affect the others, either a coupled analysis or tools for relating results is required.

CAD for MEMS

Introduction

CAD tools were essential to the evolution of MEMS from laboratory status to a bona fide and accessible manufacturing process. Without them, fabrication would have remained in the domain of experts, and evolution of the design process would still rely on empirical approaches. Early developments in CAD for MEMS evolved from 2D IC circuit work and often lacked the tools for a priori design of micromechanical devices in 2.5 or three dimensions essential for high-aspect ratio microsystems. Given the freedom to fabricate 3D systems, designers think in terms of the whole system, not a series of 2D reticulations of the system (i.e., masks). The mask-to-model approach is still somewhat suitable for surface micromachined devices but becomes less useful as the number of processes, materials, and mechanical degrees of freedom increases, as in the case of high-aspect ratio micromachining (especially for a process such as LIGA).[56] A number of current commercial CAD packages for MEMS are competing for market share, and the codes have been improving steadily. For the future, CAD programs addressing generic miniaturization problems rather than just micromachining for Si and poly-Si would be highly desirable. The architecture should have both lithographic and nonlithographic machining options, adhere to accepted format standards for data communication, and integrate available design, modeling, and simulation software from both traditional and nontraditional (i.e., IC based manufacturing) industries wherever possible.

Derived CAD Packages for MEMS

For some of the simplest micromachined structures, modest modification of existing IC software packages enabled designing of the micromachine as in regular IC processing. Marshall et al.,[57] for example, modified the standard Magic VLSI mask layout package (http://opencircuitdesign.com/magic/archive/papers/Magic_A_VLSI_Layout_System.pdf) to permit the design of simple micromachined structures using CMOS processes. This modification makes standard foundry work through the MOSIS service (http://www.mosis.org) possible.[58] Other traditional IC mask layout software packages are used by MEMS engineers from companies such as TMA and Cadence. In the public domain, one can turn to KIC from the University of California, Berkeley.[59] For a comparison of various layout design and verification software packages, visit

http://www.ee.rochester.edu/users/sde/cad/ LDV.html. Mechanical drafting tools with interfaces to mask making, such as AutoCAD, have full geometric flexibility. Other popular mechanical CAD tools for 3D solid model construction, meshing, application of loads and boundary conditions, and visualization of results include Pro/Engineer, PATRAN, and I-DEAS. Suppliers of CAD systems to the semiconductor industry also offer one- and two-dimensional process simulators. These simulators cover standard semiconductor processes such as oxidation, diffusion, thin film deposition, and plasma etching. An example is SAMPLE[60–62] for simulation of projection lithography, deposition, and etching. Simulation tools for basic physical properties include ABAQUS for structural and thermal finite-element simulation and FASTCAP (with its follow-on MEMCAP) (available for download from http://www.rle.mit.edu/cpg/research_codes.htm) for electrostatic boundary-element simulation.

COSMOS (http://www.cosmosm.com) has a MEMS analysis capability for mechanical, thermal, electrostatic, electromagnetic, and fluid flow modeling. COSMOS sells a version that is tightly integrated with the 3D modeling software SolidWorks™. SolidWorks is a player in the mechanical CAD tools arena for 3D solid model construction. Its tight integration with the COSMOS FEA package also enabled it to enter the MEMS simulation industry. AnSoft (http://www.ansoft.com) has software products for 2D and 3D electromagnetic field and thermal field finite-element simulation capabilities applicable to RF-MEMS analysis and design. AnSoft's products integrate electromagnetic, circuit, and system engineering modules. Field equation solvers such as QuickField (http://www.quickfield.com) are increasingly being used for MEMS modeling. Such software provides a quick analysis tool for 2D field problems such as electromagnetics, heat transfer, and fluid flow.

CAD Specifically Developed for MEMS

Some early examples of CAD programs developed specifically for MEMS include Oyster from IBM,[63] MEMCAD from Massachusetts Institute of Technology (MIT),[64] CAEMEMS from the University of Michigan,[65] and the SESES system from ETH (Zurich).[66] These programs mainly address bulk Si micromachining and poly-Si surface micromachining applications.

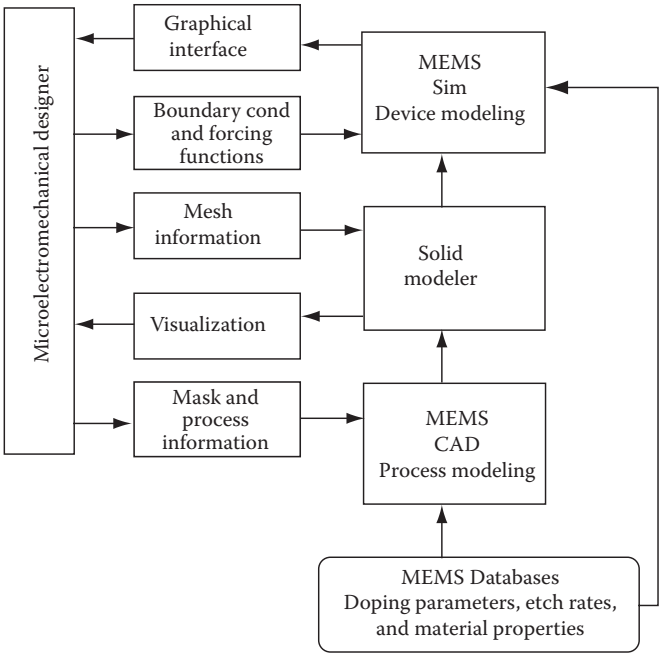

FIGURE 6.63 Block diagram of the CAEMEMS system. [Crary, S., and Y. Zhang. 1990. In *Proceedings: IEEE Micro Electro Mechanical Systems (MEMS '90)*, 113–14. Napa Valley, CA. With permission.[65]]

The CAEMEMS program provides a database of material properties and process model parameters, a process modeler that takes process information as input and produces a solid model of the device to be fabricated, a solid modeler that allows for visualization and design verification, and a device modeler that performs finite element simulations of components and systems. The database can be updated by the user as new information becomes available. A block diagram of the CAEMEMS software package is shown in Figure 6.63.[65] ANSYS Multiphysics is the version of ANSYS FEA software that has been used for MEMS modeling. ANSYS Multiphysics has a broad physics capability, such as structural modal, static, transient, electrostatic-structural, high-frequency and low-frequency electromagnetics, electrothermal-structural coupled physics, free surfaces and capillary action, capacitance extraction, Newtonian/non-Newtonian continuum flow, and fluidic structural capability to evaluate damping effects, among others.

The architecture of MEMCAD, illustrated in Figure 6.64a, integrates various simulators, databases, and a solid state modeler with a user interface.[54] As outlined by the dashed blocks in the figure, the CAD system consists of three sections: the microelectronic CAD section, the mechanical CAD section, and the material property simulator. The interactions among these three sections and the flow of information is denoted by the direction of the arrows. In MEMCAD V1.0, the primary interface for mechanical modeling was through PATRAN. MEMCAD V2.0 provides this function from I-DEAS. In the microelectronic section, the mask is created using KIC. SUPREM 3 and SAMPLE are integrated to provide depth and cross-sectional modeling capabilities. Microcosm licensed the MEMCAD technology from MIT and released the first redesigned commercial version in June 1996. Besides MEMCAD V4.0, Microcosm also developed FlumeCAD, geared toward modeling of microfluidic devices. In January 2001 Microcosm Technologies changed its name to Coventor (http://www.coventor.com).

IntelliSense Corp. sells IntelliSuite™ (http:// www.intellisense.com),[67] incorporating the MEMaterial® database and the anistropic etching module AnisE®. The material database contains electrical, mechanical, optical, and physical properties of semiconductor thin films collected from the literature. As in the case of CAEMEMS, the database can be updated by the user. The architecture of IntelliCAD, with a central graphical user interface, is shown in Figure 6.64b. Figure 6.65 shows a typical output of MEMaterial. The selected 3D plot shows the density variation of a plasma-enhanced chemical vapor-deposited Si nitride film as a function of deposition temperature and pressure. AnisE simulates single-crystal silicon anistropic etching. It predicts the effects of etchant's temperature, concentration, and etch time on the final 3D geometry. Users can study etch stops, corner compensation, higher-order etch planes, and process tolerances for single- or double-sided masks. The program added RF-MEMS design tool (2002) and a bio-MEMS design tool (2003).

Other simulators for anistropic etching of Si are available. For example, the Anisotropic Crystalline Etch Simulation (ACES™) is a first personal computer-based 3D etch simulator from the University of Illinois at Urbana-Champaign. The program can simulate silicon etching with different front-surface orientations in different etchants. 2D and 3D simulation programs for anisotropic etching profiles have also been developed by Sequin at the University of California, Berkeley,[68] Koide et al. at Hitachi,[69] and Li et al. at Caltech.[70] These programs enable the prediction of a change in cross-sectional shape of a feature in a Si wafer with arbitrary crystallographic orientation and with a mask including concave and convex edges.

Coventor now markets CoventorWare,™ which consists of a system-level modeling environment, a 2D layout editor, materials property editor and database, a 3D model generator, and a multiphysics numerical analysis framework. It has also added a new module that interfaces with IC design environment by exporting models to IC simulators from Synopsys and Cadence.

CFD Research Corporation (CFDRC) is another provider of advanced software tools for modeling, simulation, and design of MEMS. Their software has been used for the analysis of a wide variety of physical phenomena such as fluid flow, heat transfer, combustion, and fluid-structure interaction. Industrial applications include MEMS, electronics packaging, semiconductor turbomachinery, and automotive engineering (http://www.cfdrc.com/).

MEMS Pro, originally from MEMSCAP, provides a unified MEMS and IC design environment. It includes certain software elements licensed from Tanner Research. MEMS Pro was sold in 2004 to SoftMEMS (http://www.softmems.com/) and is still marketed under the same name. It provides an integrated MEMS and IC- design environment with system-level tools, layout editing, 3D Solid Modeler (3D view generator from layout and fabrication process description), FEA modeling tools, and MEMS verification tool for design rule checks.

SUGAR V3.1 from University of California, Berkeley, is a free simulation program for MEMS devices composed of beams, electrostatic gaps, anchors, circuits elements etc. The approach is based on a modified nodal analysis to solve coupled nonlinear differential equations. The simulation algorithms are implemented in MATLAB®

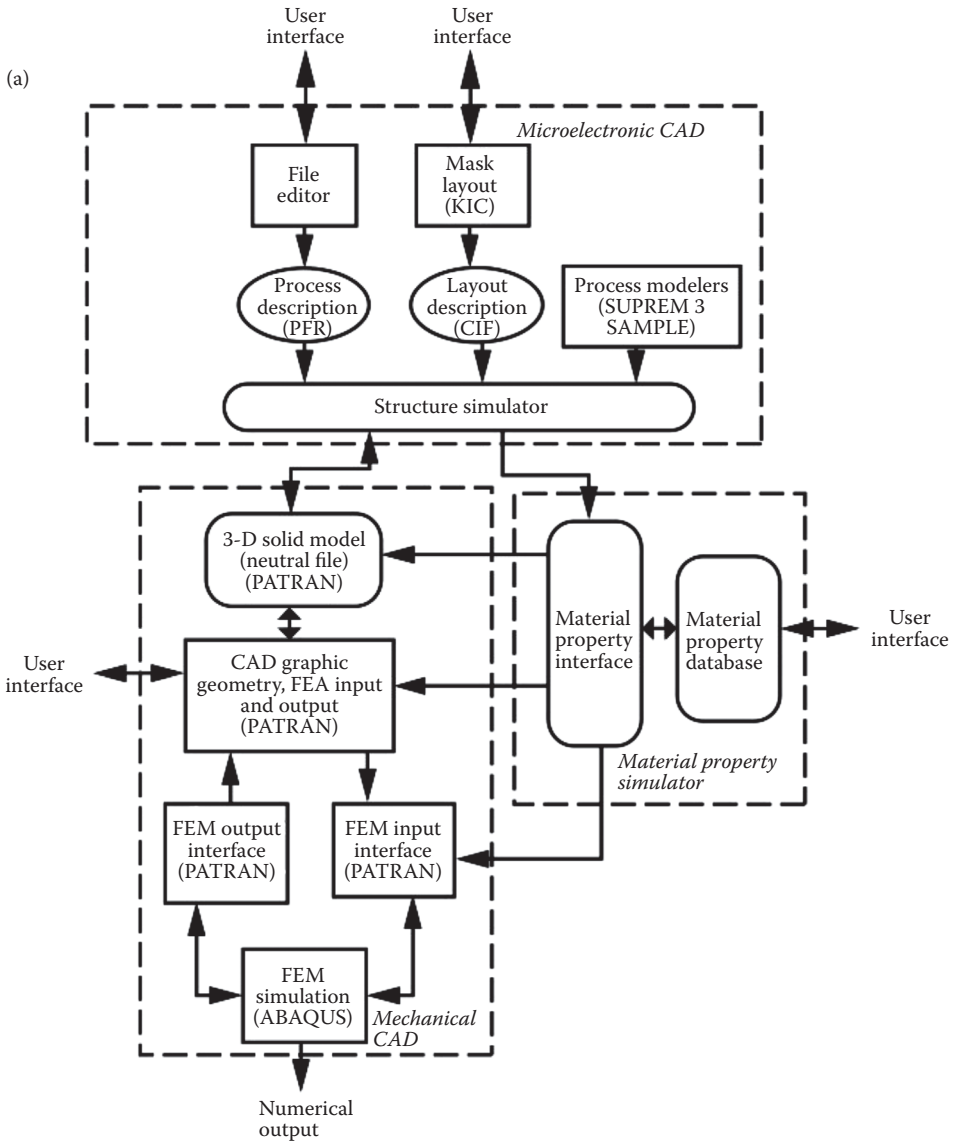

FIGURE 6.64 (a) Outline of the Massachusetts Institute of Technology MEMCAD. (b) Schematic of IntelliCAD architecture. (Courtesy of Dr. F. Maseeh, IntelliSense.)

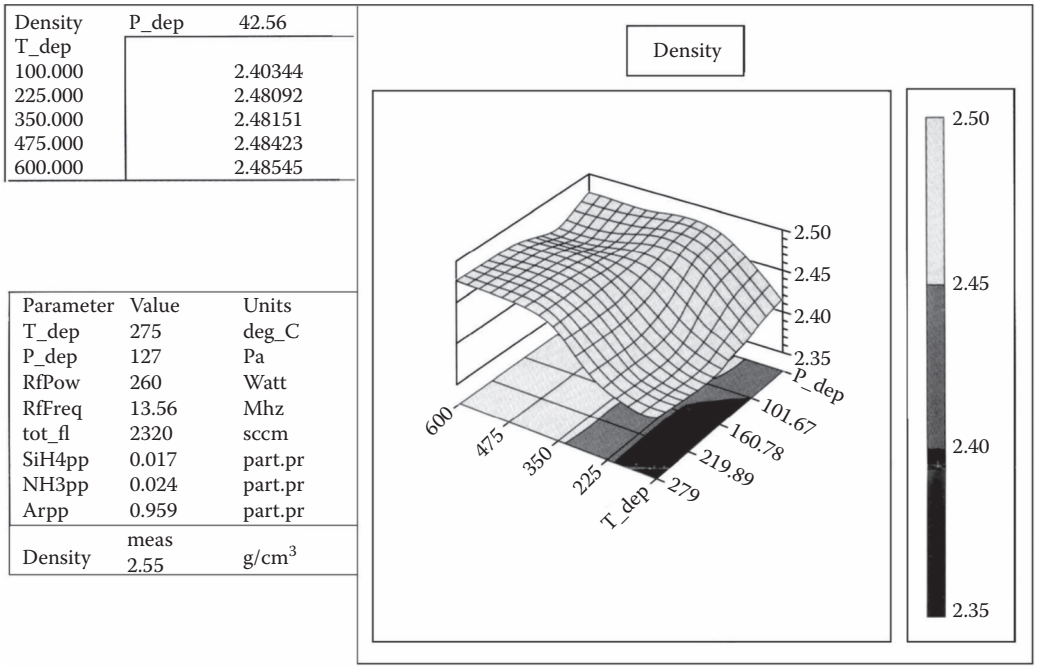

FIGURE 6.65 The MEMaterial design window from IntelliSense Corp. The three-dimensional graph shows the variation of Si nitride density deposited by plasma-enhanced chemical vapor-deposition. The table at the bottom left shows the process parameters, their numerical values, and units. The resulting density is shown at the bottom of the table. The user can alter any of the parameters. (Courtesy of Dr. F. Maseeh, IntelliSense.)

and are portable across all Unix and personal computer platforms.

FEMLAB, marketed by COMSOL (http://www.comsol.com), has entered the MEMS market with its MEMS Module. FEMLAB is a partial differential equation-based FEA modeling tool. It has modules for mechanical, thermal, DC and AC electrical, and fluidic modeling of devices among others. The FEMLAB MEMS Module includes ready-made applications that cover microfluidics plus electromagnetic-structural, thermal-structural, and fluid-structural interactions. Its MEMS-specific application modes are electrostatics, stress and strain, piezoelectric, and electrokinetics.

ALGOR (http://www.algor.com) has a MEMS module for mechanical, thermal, and fluid flow modeling. It also has electrostatic analysis and piezoelectric material model capabilities.

The major improvements in the leading MEMS software have been in a tighter integration with solid modeling as well as IC design environments, system-level modeling for quick analysis, capabilities of modeling microfluidics for the bio-MEMS industry, and capabilities for modeling RF-MEMS. Some FEA software packages have also added MEMS modules.

Future of CAD for MEMS and NEMS

Future MEMS CAD packages should seamlessly integrate 2D IC processes with 3D MEMS and traditional machining in a wide variety of materials. A conspicuous example for the need of such a 3D microdesign tool is in micromolding of LIGA shapes, in which nontraditional (lithography) and traditional (plastic molding) technologies are combined (see Volume II, Chapter 10). As an example of work in this direction, Hill et al.[71] explored the use of the computer software I-DEAS Master Series™ Thermoplastic Molding to model the micromolding aspect of such LIGA parts and have found that it accurately describes the filling characteristics of the microparts. What is needed now is to extend this package to include lithography steps.

A good introduction to the available CAD programs for IC processes comes from Fichtner.[72] A most detailed account of simulation and design issues of microsystems and microstructures is by Adey et al.[73] For access to continuously updated information on MEMS modeling, visit the MEMS Interchange on the Web (http://www-mtl.mit.edu/semisubway/semi subway.html); equally useful is http://www.memsnet.org.

With the advent of NEMS and bio-MEMS, molecular modeling has come to the forefront. Molecular modeling is a collective term that refers to theoretical methods and computational techniques to model or mimic the behavior of molecules. For molecular modeling (say on protein or DNA sensors), software can now successfully model the dynamics of most molecular interactions under numerous static and dynamic conditions. Molecular dynamics (MD) is a specialized discipline of molecular modeling and computes the behavior of a system as a function of time. The main justification of the MD method is that statistical ensemble averages are equal to time averages of the system. Because molecular systems generally consist of a vast number of particles, it is impossible to find the properties of such complex systems analytically; MD simulation circumvents this problem by using numerical methods. Molecular dynamics simulations are playing an increasingly important role in many areas of science and engineering, from biology and pharmacy to nanoelectronics and structural materials. We review only some available software packages for molecular modeling.

A lot of the modeling work is geared toward DNA and proteins; software is available to graphically manipulate 3D images of proteins and nucleic acids. The modules perform complex molecular and quantum mechanical calculation and protein structure homology analysis. Files in standard formats such as that of the Protein Data Bank can be imported.

Some other programs to check out are the following:

- CPMD (Car-Parrinello Molecular Dynamics)—This code can be used to perform *ab initio* molecular dynamics calculations. It allows for time-dependent density functional calculations, wave function optimization, and path-integral molecular dynamics.
- Siesta (Spanish Initiative for Electronic Simulations with Thousands of Atoms)—This code uses numerically truncated orbitals (single- and double-zeta approach) to build an order-N density functional code. This code is ideal for modeling large scale nanostructures (i.e., nanotubes, nanowires, and molecules).
- NWChem—This code is a highly parallel quantum chemistry package capable of self-consistent field, Hartree-Fock (RHF, UHF), and Gaussian density functional calculations, as well as several other techniques.
- Atomistix (ATK and VNL)—This commercial package provides the ability to calculate I-V curves in nanostructures and molecular junctions. The code is based on a nonequilibrium Green's function approach, and it also takes advantage of numerically truncated orbitals to allow for calculations of large systems.
- LAMMPS—This is a general purpose molecular dynamics simulator that has the option to use Leonard Jones potentials, embedded atom potentials, and potentials for biomolecules and proteins. This parallel code can easily handle systems with thousands of atoms. The ability to incorporate the effect of temperature provides an important complement to density functional techniques.
- MPB (MIT Photonic Bands package)—This code can calculate the band structure and electromagnetic modes of periodic dielectric structures.
- UTQUANT—This is a quasi-static CV simulator for one-dimensional silicon MOS structures.
- SEMC-2D (Schrödinger Equation Monte Carlo 2D)—This is a simulator for quantum transport and inelastic scattering effects in nanoscale semiconductor devices, such as nanoscale double-gate MOSFETs and tunnel injection lasers.

Questions

Questions by Chuan Zhang, UC Irvine

6.1: Compare the similarities and differences of scanning near-field optical microscopy (NSOM) and traditional optical microscopy. Explain how NSOM exceeds the resolution limit of traditional optical microscopes.

6.2: Classical far-field microscopy was introduced by Anton van Leeuwenhoek in the 16th century. It was a major breakthrough that played an important role in the advancement of science, engineering, and medicine. Briefly explain what is the underlying physical

limitation regarding the magnification/resolution of classical far-field optical microscopy.

6.3: What does the NSOM acronym stand for? What are the principles of NSOM? What is the difference between apertureless NSOM and aperture-based NSOM and what dictates their resolution?

6.4: Scanning tunneling microscopes (STMs) and atomic force microscopes (AFMs) are two so-called *proximal probe techniques* with the power to reveal the atomic world to us.
(a) What is the difference between these two?
(b) A crucial component in an STM is the integrated sharp tip, which has a curvature radius of about 50 Å, an angle of aperture of 5°, and a height of 10 µm. Sketch a process to fabricate this integrated tip on a Si wafer.

6.5: What is the effect of the following changes on quantum yield of fluorescence? Explain the reason for your answer.
(a) Raising the temperature.
(b) Adding a heavy atom to the solvent.
(c) Lowering solvent viscosity.
(d) What is the physical process that makes phosphorescence rare?

6.6: What does AFM stand for and what is the principle of operation of AFM? What kind of information can you obtain by using AFM? Briefly describe an application where AFM is employed.

6.7: Briefly state the difference between fluorescence and phosphorescence.

6.8: Please define the following analytical terms. Use equations when appropriate.
(a) Beer's law
(b) Transmittance
(c) Quantum yield
(d) Sensitivity
(e) Precision
(f) Accuracy

6.9: Suggest the type of system that you would employ for the separation of the following compounds. Justify your choice.
(a) DNA with a size of 500 bases in length and DNA with a size of 2,000 bases in length
(b) A protein of a MW = 15,000 Daltons and another protein of a MW = 100,000 Daltons
(c) A protein with a MW = 50,000 Daltons and a fluorophore with a MW = 300
(d) A mixture of long-chain unsaturated aliphatic compounds

6.10: Compare the merits of an AFM with transmission electron microscopy (TEM) and a scanning electron microscopy (SEM).

6.11: Why do the samples for TEM need to be extremely thin, while those for SEM don't need to be?

6.12: Both energy dispersive spectroscopy (EDS) and Auger electron spectroscopy (AES) can be utilized to conduct the composition analysis of a sample. Which one of them can be used to analyze light elements such as Li, Be, and C?

6.13: How does two-photon confocal microscopy enhance the resolution of fluorescence microscopy?

6.14: List the signals generated when electrons interact with a solid. What information about a material can be obtained from each of those signals?

6.15: Explain the Auger process.

6.16: Review the various steps in a typical finite element analysis (FEA), e.g., a stress-strain problem.

6.17: The identity of a semiconductor can be determined by measuring its intrinsic carrier concentrations at various temperatures. An unknown semiconductor is submerged in ice water (273K) and boiling water (373K). Its intrinsic carrier concentrations, n_i, were found to be 4.6×10^{18} m^{-3} and 3.1×10^{20} m^{-3} at 273K and 373K, respectively. What is the bandgap and identify of the semiconductor?

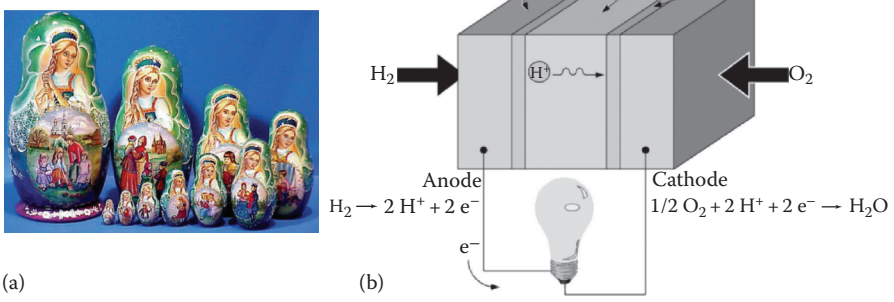
Part II

Scaling Laws, Actuators, and Power and Brains in Miniature Devices



(a) Nested Russian dolls as an example of isometric scaling. (b) Proton exchange membrane fuel cell.

> The civilization of abundance is also that of famines in African and other places. The collapse of totalitarian regimes has left intact all the evils of the democratic liberal societies, ruled by the demon of money. Marx's famous phrase about religion as the opiate of the masses can now be applied, and more accurately; to television, which will end up anaesthetizing the human race, sunk in an idiotic beatitude.
>
> **Octavio Paz in a passage on the science and technology of the West in *In Light of India***

> Napoleon asked: "Monsieur Laplace, why wasn't the Creator mentioned in your book on Celestial Mechanics?"
> Laplace replied: "Sir, I have no need for that hypothesis."

Introduction to Part II

Chapter 7 Scaling Laws
Chapter 8 Actuators
Chapter 9 Power and Brains in Miniature Devices

Introduction to Part II

Of the three chapters in Part II, the first deals with scaling laws, the second deals with actuators, and the third discusses surrounding power generation and the implementation of brains in miniaturized devices.

In Chapter 7, on scaling laws, we look at scaling from both intuitive and mathematical points of view. We are especially interested in deviations from linear scaling, where downscaling reveals new unexpected physical and chemical phenomena. The scaling chapter also constitutes an introduction to the subsequent treatises on actuators in Chapter 8 and on power and brains in Chapter 9. An actuator—like a sensor—is a device that converts energy from one form to another. In the case of an actuator, one is interested in the ensuing action; in the case of a sensor, one is interested in the information garnered. Scaling enables one to compare various actuator mechanisms, such as those proposed to propel a rotor blade, bend a thin Si membrane, or move fluids in fluidic channels. Power generation poses quite a challenge for miniaturization science; the smaller the power source, the less its total capacity. We will consider the powering of miniaturized equipment, as well as the miniaturization of power sources themselves, in Chapter 9. In the same chapter, we also discuss the different strategies for making micromachines smarter.

Part II should help the reader to choose a preferred actuator mechanism and/or power source through a better understanding of scaling and give some idea on how to incorporate intelligence in MEMS.
